## OIL EXPANSION FOR DIFFERENT TYPES OF LOAD VARIATIONS

During the last fifty years a great many papers dealing with temperature variations in cables subjected to load variations have been published. For the purpose of calculating the oil expansion in cables subjected to ordinary load variations the methods suggested by Shanklin and Buller[10] and Miller and Wollaston[11] seem to be very useful. Using either of these methods the oil expansion is obtained as a sum of exponential terms $S_0e^{-t/T}\cdot 1$. From what has previously been mentioned, pressure, current, and amount of oil which flows through a cross section of the cable are calculated by summing the quantities corresponding to the individual exponential terms. In a later part of this paper, therefore, the pressure, current, and amount of oil for an oil expansion $S_0e^{-t/T}\cdot 1$ will be calculated.

The above mentioned methods for calculating the variations of temperature and oil expansion in oil-filled cables at load variations are rather inconvenient when the load variation in question is a short circuit. The temperature function in the case of short circuit is better computed on the basis of other simplifying assumptions, as the interesting part of the temperature variation in the case of a short circuit occurs in a relatively thin layer of the insulation near the conductor, in which the short-circuit current is flowing. Herlitz[12] has worked out a theory for temperature during and after a short circuit in conductors in contact with paper-oil insulation, whereby consideration has been given to the heat capacitance of the conductors and to the temperature coefficient of the conductor resistance. The oil-expansion computed on the basis of this theory is expressed by a function involving exponential functions and error integrals.

For use in the present paper we shall develop a very approximate and very simple expression for the oil expansion in an oil-filled cable in the case of short circuit in conductors in contact with paper-oil insulation. We hereby make the simplifying assumptions (1) that the conductors, in which the short-circuit current flows, have a plane surface, (2) that the insulation can be regarded as semi-infinite, (3) that the short circuit is instantaneous, and (4) that the temperature in the conductors remains constant after the short circuit has occurred. The surface of the conductors per unit length of the cable is called $f$, the specific heat-conduction resistance of the insulation, $p$, the specific heat of the insulation with respect to a unit volume, $q$, and the temperature, which the conductors attain at the short circuit, $\vartheta_0$. If $x$ denotes the distance from the surface of a conductor to a point of the insulation, the temperature field $\vartheta$ in the insulation is expressed by

$$\vartheta(x,t)=\vartheta_0\left[1-\phi\left(\frac{x(pq)^{1/2}}{2(t)^{1/2}}\right)\right]\cdot 1. \qquad (32)$$ [13]

The heat effect per unit length of the cable, $P$, transferred from the conductors to the insulation is then

$$P(t)=-\frac{f}{p}\left(\frac{\partial\vartheta}{\partial t}\right)_{x=0}=\frac{1}{(\pi)^{1/2}}f\vartheta_0\left(\frac{q}{p}\right)^{1/2}\frac{1}{(t)^{1/2}}\cdot 1. \qquad (33)$$

If we denote the effective volumetric expansion coefficient of the insulation by $\beta'$, the oil expansion per unit time per unit length of the cable, $S$, is

$$S(t)=\frac{\beta' P(t)}{q}=\frac{K_0}{(t)^{1/2}}\cdot 1 \qquad (34)$$

where

$$K_0=\frac{1}{(\pi)^{1/2}}\frac{\beta' f\vartheta_0}{(pq)^{1/2}}. \qquad (35)$$

Pressure, current, and amount of oil which flows through a cross section of the cable for an oil expansion according to the very approximate method of computation set forth here will be calculated in a following paragraph. The pressure so obtained will be larger than the actual pressure, especially in cables with small conductor areas, since the temperature of the conductor actually decreases after the short circuit instead of being constant as here supposed.

In a future paper, the pressure, current and amount of oil for the case of a short-circuit current flowing in conductors in contact with paper-oil insulation will be worked out for an oil expansion calculated by a more exact method of computation resembling that given by Herlitz.

The expansion of oil in canals, if any, in the conductors is difficult to calculate, since the heat transfer from the conductors to the oil in the canals takes place both by conduction and by convection. One is safe in assuming that the oil in a canal of any conductor has at any moment the same temperature as the conductor. In the case of an instantaneous short circuit the oil in a conductor canal will then be subjected to a sudden temperature rise resulting in a sudden expansion of the oil. If, as above, $\vartheta_0$ denotes the temperature rise of the conductors because of an instantaneous short circuit, and if $a$ denotes the volume of the conductor canal per unit length, and $\beta$ the volumetric expansion coefficient of the oil, the oil expansion per unit length per unit time, $S$, for the oil in the conductor canal in question is, using the terminology of the operational calculus, expressed as follows

$$S(t)=\frac{d}{dt}(N_0\cdot 1), \tag{36}$$

where

$$N_0=a\vartheta_0\beta. \tag{37}$$

Pressure, current, and amount of oil will be computed for an expansion of oil of this kind in the following paragraph. The quantities so obtained turn out to be more convenient for calculating pressure, current, and amount of oil for an arbitrary expansion of oil than the expressions obtained above for an oil expansion $S_0\cdot 1$.

## PRESSURE AND FLOW FOR AN INSTANTANEOUS OIL EXPANSION $(d/dt)(N_0\cdot 1)$

Pressure, current, and amount of oil are calculated by the expressions earlier obtained for an oil expansion $S_0\cdot 1$ by differentiating these with respect to time, and writing $N_0$ instead of $S_0$. In this way one obtains

$$V(x,t)=\frac{N_0}{c}\frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1}\cos\frac{x}{L}(2n+1)\pi\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]. \tag{38}$$

For $x=0$ this leads to

$$V(0,t)=\frac{N_0}{c}\frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1}\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]. \tag{39}$$

$[cV(0,t)/N_0]=V_2'$ has been plotted as a function of $t/RC$ in Fig. 3.

$$I(x,t)=\frac{N_0}{rcL}4\sum_{n=0}^{\infty}(-1)^n\sin\frac{x}{L}(2n+1)\pi\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]. \tag{40}$$

For $x=\pm L/2$ this leads to

$$I\left(\pm\frac{L}{2},t\right)=\pm\frac{N_0}{rcL}4\sum_{n=0}^{\infty}\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]. \tag{41}$$

$[rcLI(\pm(L/2), t)/\pm N_0] = I_2'$ has been plotted as a function of $t/RC$ in Fig. 4.

$$M(x, t) = N_0 L\left\{\frac{x}{L} - \frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}\sin\frac{x}{L}(2n+1)\pi\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right\}$$

$$= N_0 L\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}\sin\frac{x}{L}(2n+1)\pi\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right\}. \tag{42}$$

For $x = \pm L/2$ this leads to

$$M\left(\pm\frac{L}{2}, t\right) = \pm N_0 L\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}\left\{1-\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right\}. \tag{43}$$

$[M(\pm(L/2), t)/\pm N_0 L] = M_2'$ has been plotted as a function of $t/RC$ in Fig. 5.

### PRESSURE AND FLOW FOR AN ARBITRARY OIL EXPANSION $S(t)\cdot 1$

If any action (pressure, current, or amount of oil) of an oil expansion $(d/dt)(1\cdot 1)$ is $A(t)$, then because of the linearity of the partial differential equations, valid for the oil flow, the action $G(t)$ of an oil expansion $S(t)$ is expressed by Duhamel's integral

$$G(t) = \int_0^t S(\lambda)A(t-\lambda)d\lambda. \tag{44}$$

Using this equation in connection with the above obtained expressions for pressure, current, and amount of oil for an oil expansion $(d/dt)(N\cdot 1)$, (38), (40), and (42), one obtains

$$V(x, t) = \frac{1}{c}\frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1}\cos\frac{x}{L}(2n+1)\pi\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\int_0^t S(\lambda)\exp\left[\frac{(2n+1)^2\pi^2\lambda}{RC}\right]d\lambda, \tag{45}$$

$$I(x, t) = \frac{1}{rcL}4\sum_{n=0}^{\infty}(-1)^n\sin\frac{x}{L}(2n+1)\pi\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\int_0^t S(\lambda)\exp\left[\frac{(2n+1)^2\pi^2\lambda}{RC}\right]d\lambda, \tag{46}$$

$$M(x, t) = L\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}\sin\frac{x}{L}(2n+1)\pi$$

$$\times\left\{\int_0^t S(\lambda)d\lambda - \exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\int_0^t S(\lambda)\exp\left[\frac{(2n+1)^2\pi^2\lambda}{RC}\right]d\lambda\right\}. \tag{47}$$

### PRESSURE AND FLOW FOR AN EXPONENTIALLY DECREASING OIL EXPANSION $S_0e^{-t/T}\cdot 1$

Pressure, current, and amount of oil for the oil expansion $S_0e^{-t/T}\cdot 1$ is calculated by substituting $S(t) = S_0e^{-t/T}$ in Eqs. (45), (46), and (47).

$$V(x, t) = S_0 rL^2\frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)((2n+1)^2\pi^2-(RC/T))}\cos\frac{x}{L}(2n+1)\pi$$

$$\times\left\{\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right\}. \tag{48}$$

For $x = 0$ this leads to

$$V(0, t) = S_0 rL^2\frac{4}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)((2n+1)^2\pi^2-(RC/T))}\left\{\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2 t}{RC}\right]\right\}. \tag{49}$$

$[V(0,t)/S_0rL^2]=V_3'$ has been plotted in Fig. 3 as a function of $t/RC$ for $\alpha=RC/T=0.02$, 0.05, 0.1, 0.2, 0.5, 1, 2, 5, 10, 20, 50, and 100.

$$I(x,t)=S_0L4\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2\pi^2-(RC/T)}\sin\frac{x}{L}(2n+1)\pi\left\{\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \quad (50)$$

For $x=\pm L/2$ this leads to

$$I\left(\pm\frac{L}{2},t\right)=\pm S_0L4\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2\pi^2-(RC/T)}\left\{\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right\}. \quad (51)$$

$[I(\pm(L/2),t)/\pm S_0L]=I_3'$ has been plotted in Fig. 4 as a function of $t/RC$ for the same values of $\alpha=RC/T$ as given above.

$$M(x,t)=S_0rcL^3\left\{\frac{x}{L}\frac{T}{RC}\left[1-\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)\right]-\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2((2n+1)^2\pi^2-(RC/T))}\right.$$
$$\left.\times\sin\frac{x}{L}(2n+1)\pi\left[\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right]\right\}. \quad (52)$$

For $x=\pm L/2$ this leads to

$$M\left(\pm\frac{L}{2},t\right)=\pm S_0rcL^3\left\{\frac{T}{2RC}\left[1-\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)\right]-\frac{4}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2((2n+1)^2\pi^2-(RC/T))}\right.$$
$$\left.\times\left[\exp\left(-\frac{RC}{T}\frac{t}{RC}\right)-\exp\left[-\frac{(2n+1)^2\pi^2t}{RC}\right]\right]\right\}. \quad (53)$$

$[M(\pm(L/2),t)/\pm S_0rcL^3]=M_3'$ has been plotted in Fig. 5 as a function of $t/RC$ for the same values of $\alpha=RC/T$ as given earlier.

A practical example will demonstrate the use of the curves.

### Example 2

For a certain cable the oil expansion per unit length per unit time for a sudden switching on the load is

$$S(t)=S_1[e^{-(t/4000)}-0.6e^{-(t/400)}-0.2e^{-(t/100)}]$$

where $S_1$ is a constant. It is desired to calculate the variation of pressure at the midpoint of the cable, partly for switching on the load at the time $t=0$, after which the load remains switched on an infinite time, partly for switching on the load at the time $t=0$ and switching off the load at the time $t=200$ sec. The computation of the pressure will be carried out for a time constant of the cable $RC=0$, 1000, and 4000 sec.

For $RC=0$ the pressure $V$ in switching on the load is

$$(V(t))_{RC=0}=\tfrac{1}{8}S_1rL^2[e^{-(t/4000)}-0.6e^{-(t/400)}-0.2e^{-(t/100)}].$$

$[(V(t))_{RC=0}/\tfrac{1}{8}S_1rL^2]$ has been plotted in Fig. 6.

For the case where the load is switched off after 200 sec., the pressure $W$ is

$$(W(t))_{RC=0}=\begin{cases}(V(t))_{RC=0} & \text{for } t<200 \text{ sec.}\\ (V(t))_{RC=0}-(V(t-200))_{RC=0} & \\ & \text{for } t>200 \text{ sec.}\end{cases}$$

$[(W(t))_{RC=0}/\tfrac{1}{8}S_1rL^2]$ has been plotted in Fig. 7.

For $RC=1000$ sec. one obtains for the exponential terms in the expression for $S$

$$\frac{RC}{T_1}=\frac{1000}{4000}=0.25,$$

$$\frac{RC}{T_2}=\frac{1000}{400}=2.5,$$

$$\frac{RC}{T_3}=\frac{1000}{100}=10.$$

The pressure $V$ in switching on the load is, accordingly,

$$(V(t))_{RC=1000\ \text{sec.}}=S_1rL^2\left[\left(V_3'\left(\frac{t}{1000}\right)\right)_{\alpha=0.25}-0.6\left(V_3'\left(\frac{t}{1000}\right)\right)_{\alpha=2.5}-0.2\left(V_3'\left(\frac{t}{1000}\right)\right)_{\alpha=10}\right].$$

The functions $V_3'$ are taken from Fig. 3. $[(V(t))_{RC=1000\ \text{sec.}}/\frac{1}{8}S_1rL^2]$ has been plotted in Fig. 6.

The pressure $W$ for the load remaining switched on 200 sec. is calculated in the same way as in the case $RC=0$ treated above.

$[(W(t))_{RC=1000\ \text{sec.}}/\frac{1}{8}S_1rL^2]$ has been plotted in Fig. 7.

For $RC=4000$ sec. one obtains in a similar way

$$(V(t))_{RC=4000\ \text{sec.}}=S_1rL^2\left[\left(V_3'\left(\frac{t}{4000}\right)\right)_{\alpha=1}-0.6\left(V_3'\left(\frac{t}{4000}\right)\right)_{\alpha=10}-0.2\left(V_3'\left(\frac{t}{4000}\right)\right)_{\alpha=40}\right].$$

$[(V(t))_{RC=4000\ \text{sec.}}/\frac{1}{8}S_1rL^2]$ has been plotted in Fig. 6 and $[(W(t))_{RC=4000\ \text{sec.}}/\frac{1}{8}S_1rL^2]$ in Fig. 7.

Figure 6 shows that in the present case the variation in the computed pressure, resulting from taking into account the elasticity and the compressibility of the cable, is but little even with a time constant for the oil flow so large as 4000 sec. If all the terms in the expression for $S$ had the same sign, the variation in the calculated maximum pressure, however, would have been considerable, with the time constants for the oil flow occurring in the present case. Mostly, however, $S$ is composed of exponential terms with different signs in such a way that $S$ at the time $t=0$ assumes a small value, thereafter increases to a maximum, and then decreases to zero in resemblance to the case occurring in the example. With the values of the time constant for the oil flow, and the time constant in the first exponential term in the expression for the oil expansion occurring in practical cases, the maximum pressure in switching on a constant load calculated for $RC=0$ seldom diverges any

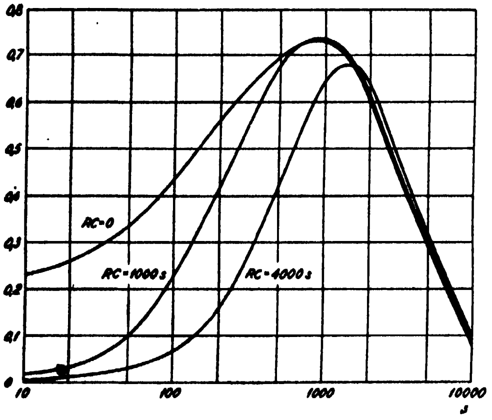

FIG. 6. Relative pressure at the midpoint of a cable in switching on a load giving an oil expansion $S(t)=S_1[e^{-t/4000}-0.6e^{-t/400}-0.2e^{-t/100}]$ for different time constants of the oil flow.

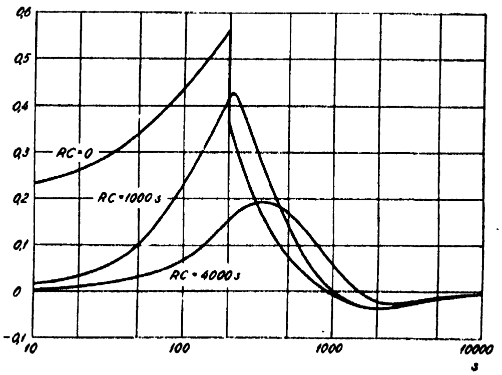

FIG. 7. Relative pressure at the midpoint of a cable in switching on for 200 sec. the same load as occurring in Fig. 6 for different time constants of the oil flow.

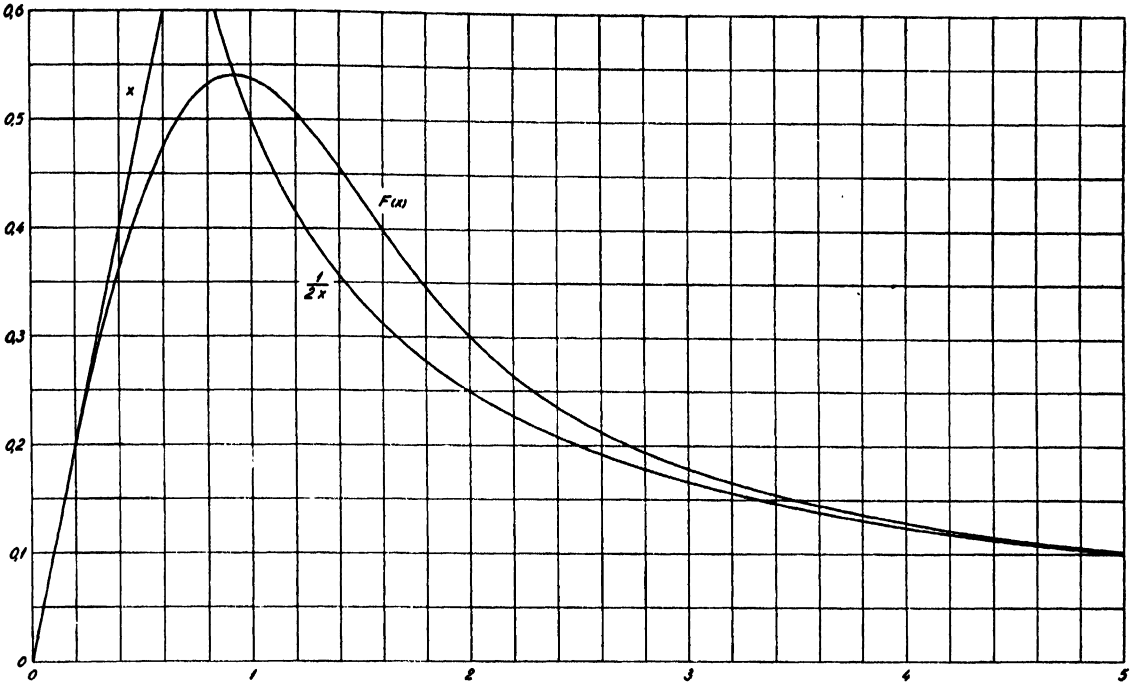

FIG. 8. $F(x)=e^{-x^2}\int_0^x e^{\xi^2}d\xi$ together with the approximations $F(x)\doteq x$ and $F(x)\doteq 1/2x$ valid for small, respectively for large values of $x$.

considerable amount from the pressure calculated for the actual value of $RC$.

This is not the case in the calculation of the maximum increase of pressure and the following maximum decrease of pressure occurring in switching on a constant load for a time interval that is small relative to the time constant for the oil flow in the cable. Figure 7 shows thus that the maximum pressure for the load in question with $RC=1000$ sec. comes to 76 percent, and with $RC=4000$ sec. only 34 percent of the maximum pressure with $RC=0$.

The following decrease of pressure is reduced too by the elasticity and the compressibility of the cable.

### PRESSURE AND FLOW FOR THE OIL EXPANSION $K_0/(t)^{\frac{1}{2}}\cdot 1$

Pressure, current, and amount of oil for the oil expansion $K_0/(t)^{\frac{1}{2}}\cdot 1$ is calculated by substituting $S(t)=K_0/(t)^{\frac{1}{2}}$ in Eqs. (45), (46), and (47).

The results in the present paragraph are most simply expressed by the function $F(x)$, defined in the following way:

$$F(x)=e^{-x^2}\int_0^x e^{\xi^2}d\xi. \tag{54}$$

This function has been tabulated by Miller and Gordon.[14] $F(x)$ has been plotted in Fig. 8 for $0<x<5$ together with the functions $y=2x$ and $y=1/2x$, which approximate the function $F(x)$ for small respectively large values of the argument $x$. The advantage in using the function $F(x)$ instead of the function

$$f(x)=\int_0^x e^{\xi^2}d\xi,$$

as used e.g., by Dawson,[15] is that $F(x)$ is limited and more convenient for interpolation than $f(x)$.[14]

Pressure, current, and amount of oil can now

---

[15] H. G. Dawson; Proc. Lond. Math. Soc. **29**, 519 (1897–98).

be expressed in the following way:

$$V(x,t)=K_0\left(\frac{r}{c}\right)^{\frac{1}{2}}L\frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^2}$$

$$\times\cos\frac{x}{L}(2n+1)\pi F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right). \quad (55)$$

For $x=0$ this leads to

$$V(0,t)=K_0\left(\frac{r}{c}\right)^{\frac{1}{2}}L\frac{8}{\pi^2}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^2}$$

$$\times F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right). \quad (56)$$

$[V(0,t)/K_0(r/c)^{\frac{1}{2}}L]=V_4'$ has been plotted as a function of $t/RC$ in Fig. 3.

$$I(x,t)=\frac{K_0}{(rc)^{\frac{1}{2}}}\frac{8}{\pi}\sum_{n=0}^{\infty}\frac{(-1)^n}{2n+1}$$

$$\times\sin\frac{x}{L}(2n+1)\pi F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right). \quad (57)$$

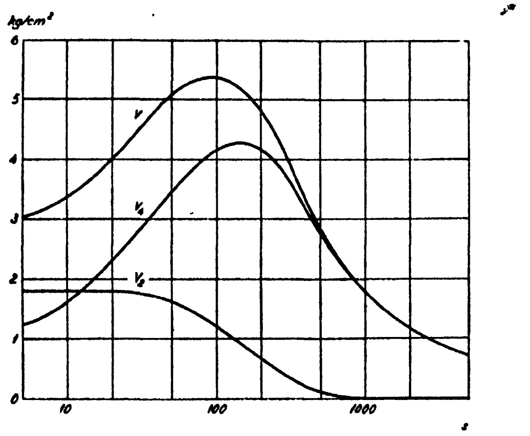

FIG. 9. Pressure $V$ at the midpoint of a cable, occurring at a short circuit in the cable as specified in the text, for 20°C temperature of the oil in the oil canal. $V=V_2+V_4$, where $V_2$ corresponds to the expansion of the oil in the canal, $V_4$ to the expansion of the oil in the insulation.

For $x=\pm L/2$ this leads to

$$I\left(\pm\frac{L}{2},t\right)=\pm\frac{K_0}{(rc)^{\frac{1}{2}}}\frac{8}{\pi}\sum_{n=0}^{\infty}\frac{1}{2n+1}$$

$$\times F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right). \quad (58)$$

$[I(\pm(L/2),t)/\pm(K_0/(rc)^{\frac{1}{2}})]=I_4'$ has been plotted as a function of $t/RC$ in Fig. 4.

$$M(x,t)=K_0(rc)^{\frac{1}{2}}L^2\left[2\frac{x}{L}\left(\frac{t}{RC}\right)^{\frac{1}{2}}-\frac{8}{\pi^3}\sum_{n=0}^{\infty}\frac{(-1)^n}{(2n+1)^3}\right.$$

$$\left.\times\sin\frac{x}{L}(2n+1)\pi F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right)\right]. \quad (59)$$

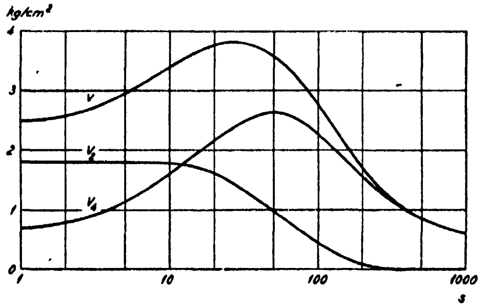

FIG. 10. Pressure $V$ at the midpoint of the same cable and for the same short circuit current in this cable as in Fig. 9 for 40°C temperature of the oil in the oil canal. $V=V_2+V_4$, where $V_2$ corresponds to the expansion of the oil in the canal, $V_4$ to the expansion of the oil in the insulation.

For $x=\pm L/2$ this leads to

$$M\left(\pm\frac{L}{2},t\right)=\pm K_0(rc)^{\frac{1}{2}}L^2\left[\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right.$$

$$\left.-\frac{8}{\pi^3}\sum_{n=0}^{\infty}\frac{1}{(2n+1)^3}F\left((2n+1)\pi\left(\frac{t}{RC}\right)^{\frac{1}{2}}\right)\right]. \quad (60)$$

$[M(\pm(L/2),t)/\pm K_0(rc)^{\frac{1}{2}}L]=M_4'$ has been plotted as a function of $t/RC$ in Fig. 5.

The use of the formulas worked out in this paragraph is explained by the following example.

### Example 3

It is desired to calculate the maximal pressure rise in the single-core cable described in Ex. 1 for a cable length of 1 km in the case of a short circuit of 1 sec. duration, during which the conductor and the oil in the conductor canal are heated 10°C. It is supposed that the heat effect of the secondary current in the sheath is negligible. The pressure will be calculated for the temperature of the oil in the canal 20°C and 40°C.

Besides the data for the cable given in Ex. 1

the following data are needed:

$$p=550°\text{C cm } W^{-1},\quad q=2°\text{C}^{-1}\text{ cm}^{-3}\ W\text{ sec.},$$
$$\beta=0.0007°\text{C}^{-1},\quad \beta'=0.0004°\text{C}^{-1}.$$

From the data given in Ex. 1 are further calculated

$$f=\pi\cdot 1.3=4.1\text{ cm},$$
$$a=(\pi/4)\cdot 0.6^2=0.28\text{ cm}^2.$$

The increase in pressure at the midpoint of the cable $V_2(0, t)$ caused by the expansion of the oil in the canal is according to (37) and (39)

$$V_2(0, t)=a\vartheta_0\beta\frac{1}{c}V_2'\left(\frac{t}{RC}\right)$$
$$=0.28\cdot 10\cdot 0.0007\cdot\frac{1}{1.09\cdot 10^{-3}}V_2'\left(\frac{t}{RC}\right)$$
$$=1.8V_2'\left(\frac{t}{RC}\right)\text{ kg cm}^{-2}$$

where $V_2'(t/RC)$ is taken from Fig. 3.

The increase in pressure at the midpoint of the cable $V_4(0, t)$ caused by the heat transferred from the conductor to the insulation is according to (35) and (56)

$$V_4(0, t)=\frac{\beta' f\vartheta_0 L(r)^{\frac{1}{2}}}{(\pi pqc)^{\frac{1}{2}}}V_4'\left(\frac{t}{RC}\right)$$
$$=\frac{0.0004\cdot 4.1\cdot 10\cdot 10^5 V_4'(t/RC)}{(\pi\cdot 550\cdot 2\cdot 1.09\cdot 10^{-3})^{\frac{1}{2}}}\begin{cases}(1.43\cdot 10^{-4})^{\frac{1}{2}}\\(5.3\cdot 10^{-4})^{\frac{1}{2}}\end{cases}$$
$$=10.1V_4'\left(\frac{t}{RC}\right)\text{ at } 20°\text{C}$$
$$=6.2V_4'\left(\frac{t}{RC}\right)\text{ at } 40°\text{C}$$

where $V_4'(t/RC)$ is taken from Fig. 3.

$V_2$, $V_4$, and $V=V_2+V_4$ for 20°C temperature of the oil in the oil canal have been plotted in Fig. 9, and $V_2$, $V_4$, and $V=V_2+V_4$ for 40°C oil temperature in Fig. 10.

From Fig. 9 and Fig. 10 is read the maximum pressure

$$V_{\max}=\begin{cases}5.4\text{ kg cm}^{-2}\text{ for } t=95\text{ sec. with } 20°\text{C}\\3.8\text{ kg cm}^{-2}\text{ for } t=30\text{ sec. with } 40°\text{C},\end{cases}$$

In working out the theory for the oil expansion after a short circuit we made the simplifying assumption that the temperature of the conductors remained constant after the short circuit. It is interesting to make an estimate in the present case of how much the conductor temperature has decreased from the moment of short circuit to the moment of occurrence of maximum pressure.

With the idealizing assumption mentioned above, namely, that the conductor temperature remains constant, the effect per unit length of the cable, $P$, transferred to the insulation was given in (33). The amount of heat per unit length, $Q$, transferred to the insulation from the moment of short circuit to the time $t$ is then

$$Q(t)=\int_0^t P(\lambda)d\lambda=\frac{2}{(\pi)^{\frac{1}{2}}}f\vartheta_0\left(\frac{q}{p}\right)^{\frac{1}{2}}(t)^{\frac{1}{2}}.$$

Hereby we calculate the amount of heat per unit length in the present case transferred to the insulation from the moment of short circuit to the moment $t_1$, when the maximum pressure occurs

$$Q(t_1)=\frac{2}{(\pi)^{\frac{1}{2}}}\cdot 4.1\cdot 10\cdot\left(\frac{2}{550}\right)^{\frac{1}{2}}\cdot\begin{cases}(95)^{\frac{1}{2}}=26\text{ W sec. cm}^{-1}\text{ for } 20°\text{C}.\\(30)^{\frac{1}{2}}=15\text{ W sec. cm}^{-1}\text{ for } 40°\text{C}.\end{cases}$$

These transferred amounts of heat have to be compared with the amount of heat per unit length, $Q_1$, accumulated in the conductor and in the oil canal. The specific heat for copper in respect to a unit volume is 3.4°C$^{-1}$ cm$^{-3}$ W sec. Neglecting the amount of heat accumulated in the oil canal we get

$$Q_1=0.95\cdot 3.4\cdot 10=32\text{ W sec. cm}^{-1}.$$

The amount of heat transferred from the conductor to the insulation from the moment of short circuit to the moment, when the maximal pressure, calculated according to the simplifying assumption mentioned above, occurs, is consequently not negligible compared with the total amount of heat accumulated in the conductor. The preparation of a more exact theory, as mentioned above, seems to be justified.

The work here presented has been carried out at Sieverts Kabelverk, Sundbyberg, Sweden. I thank Sieverts Kabelverk and especially Mr. H. Spanne, chief engineer at Sieverts Kabelverk, for permission to publish this paper.

# The Electrostatic Field of a Point Charge Inside a Cylinder, in Connection with Wave Guide Theory

C. J. Bouwkamp and N. G. de Bruijn
*Natuurkundig Laboratorium der N. V. Philips' Gloeilampenfabrieken, Eindhoven, Netherlands*

(Received February 21, 1947)

In this paper the field of a point charge inside a hollow, infinitely long circular cylinder is studied. The case of an axial point charge is treated in detail. Three different methods are developed. The first method shows how to calculate the induced charges at the surface of the cylinder without explicit knowledge of the potential itself. The surface charge-density function is obtained as the solution of a Fourier-type integral equation. Then the potential caused by these charges is calculated. The second method works in the opposite direction. Here the potential is obtained as solution of a boundary value problem, followed by the calculation of the corresponding charges at the surface of the cylinder.

The integral, obtained for the surface charge density, is transformed by contour integration. Although the resulting series is very useful for numerical purposes, a stronger method is necessary, in order to calculate the charge density just opposite the point source. Figure 1 shows the calculated values of the induced surface charge density. Several approximations for the charge-density function are considered, in connection with recent work of Weber (cf. Table I).

The same is done for the field inside the cylinder. Various formulas are given which allow of numerical calculations. In Table II some calculated values of the potential are shown.

The third method is based on the theory of Fourier-Bessel-Dini series. The potential is developed in terms of discrete normal solutions of the potential equation in cylindrical coordinates. The coefficients in this development can be derived from the behavior of the potential in the immediate neighborhood of the primary source.

Furthermore, it is emphasized that the study of the above potential problem can serve as a guide in questions of wave propagation in hollow circular cylinders. In this connection the third method is shown to be extremely useful, as it enables us to calculate directly the fields in the far zone from that in the immediate neighborhood of the exciting source. This new method is demonstrated in case of acoustic waves inside a cylinder, caused by a harmonically vibrating point source.

## 1. INTRODUCTION

PREVIOUS works of Schelkunoff,[1] Weyrich,[2] Buchholz,[3] and Oberhettinger,[4] among others, already contain complete information with regard to fields in circular pipes, as produced by Hertzian dipoles. Therefore, the generation of special types of wave patterns, caused by given current and charge distributions on the exiting antennas, can be dealt with quantitatively. The calculations in this domain of electromagnetics, however, are far from elementary, such that a non-mathematically minded engineer might hardly recognize the usefulness of those theoretical treatments. Hence, every attempt to diminish the necessary amount of mathematics, may be worth while to consider. Until now a considerable amount of complex function theory is required. We believe, however, that this can be greatly avoided if one bases oneself on the theory of Fourier-Bessel-Dini series. This method is undoubtedly within reach of every engineer,

because the analogous conventional theory of the ordinary Fourier series is common knowledge nowadays.

In this paper we will not consider the vector wave propagation as occurring in electromagnetic theory. Those topics will be treated elsewhere. The new method will be demonstrated in the case of scalar wave propagation only.

The major part of the present article, however, will be devoted to the study of the electrostatic field of a point charge inside the cylinder. Consequently, only a minor part of the mathematics developed here is claimed to be useful in wave guide theory.

Beginning with the simplest problem, we confine ourselves to the case of a point charge situated on the axis of the cylinder. Later on we will briefly indicate how to extend the theory to excentric point charges.

## 2. STATEMENT OF THE SIMPLEST PROBLEM. CALCULATION OF THE CHARGES INDUCED ON THE SURFACE OF THE CYLINDER

Let $a$ be the radius of the cylinder, and let the point charge have a value $+1$. Furthermore, let $z$, $\rho$, $\varphi$ denote the right-handed cylindrical coordinates of a field point $P$. Henceforth the origin may coincide with the given point charge, and the $z$-axis be taken along the axis of the cylinder.

The electric force $\mathbf{E}$ can be derived from a potential $V$ according to $\mathbf{E}=-\operatorname{grad} V$. It is evident that the $z$-axis is an axis of symmetry, so that $V$ depends only on $z$ and $\rho$. In addition, $V$ is even in $z$.

To calculate $\mathbf{E}$ and $V$, we first follow a rather unconventional method, by calculation of the *charges*, induced on the wall of the cylinder, without explicit knowledge of the potential itself. Afterwards the field is readily found from the original point charge and these induced charges. The surface density of the induced charges will be denoted by $\eta(z)$.

We may remark that $V$ is the so-called Green function of the first kind. It is a regular solution of the potential equation, except for a singularity in the origin, so that the function $V(P)-1/r$ remains finite for $r\rightarrow 0$; furthermore, $V=0$ on the boundary, and both $V$ and $\operatorname{grad} V$ tend to zero, if $P$ tends to infinity inside the cylinder.

As is well known, there is one, and only one, function $V(z, \rho)$ fulfilling all these conditions simultaneously. Once this function is obtained, the charges on the boundary of the cylinder can be computed from

$$\eta(z)=\frac{1}{4\pi}\frac{\partial V}{\partial \rho}, \quad (\rho=a). \tag{1}$$

Let us now show how $\eta(z)$ can be found without explicit knowledge of the potential $V$. Be $g(z, \rho)$ a given regular solution of the potential equation inside the cylinder, and suppose $g$ and $\partial g/\partial z$ to be bounded in that domain. By Green's theorem, we at once express the value of $g$ in the origin as a surface integral over its boundary values, namely

$$g(0, 0)=-\frac{1}{4\pi}\int g\frac{\partial V}{\partial \rho}d\sigma=-\int g(z, a)\eta(z)d\sigma. \tag{2}$$

In this $d\sigma$ means the surface element of the boundary of the cylinder; the integration in (2) extends over this boundary.

Omitting the left-hand integral in (2), the remaining equality can be interpreted as an integral equation for $\eta(z)$, which may be readily solved, if a convenient choice is made for the rather arbitrary function $g$. We take

$$g(z, \rho)=e^{-i\lambda z}I_0(\lambda\rho) \tag{3}$$

where $I_0$ is the Bessel function of purely imaginary argument and zeroth order. The function (3) is a regular potential, with $g$ and $\partial g/\partial z$ bounded inside the cylinder, if the constant $\lambda$ is restricted to *real* values.

Substitution of (3) in (2) leads to

$$1=-\int_0^{2\pi} a d\varphi\int_{-\infty}^{\infty} e^{-i\lambda z}I_0(\lambda a)\eta(z)dz,$$

whence it follows

$$\int_{-\infty}^{\infty} z^{-i\lambda z}\eta(z)dz=-\frac{1}{2\pi a I_0(\lambda a)}, \quad (-\infty<\lambda<\infty). \tag{4}$$

Thus the integral equation (2) is reduced to one of the common Fourier type (4). Its solution can be written down immediately. By inversion of

(4), one obtains for the required charge density

$$\eta(z) = -\frac{1}{4\pi^2 a}\int_{-\infty}^{\infty} e^{i\lambda z}\frac{d\lambda}{I_0(\lambda a)}$$

$$= -\frac{1}{2\pi^2 a^2}\int_0^{\infty}\frac{\cos(z/a)t}{I_0(t)}dt. \qquad (5)$$

Starting from this integral expression, we can develop solutions more useful for numerical purposes. For non-vanishing $z$ we may transform the above integral into a series by means of the conventional contour integration. In the cut plane $z=0$, however, stronger methods must be used, as will be seen below.

Consider the following integral in the complex $t$-plane:

$$\frac{1}{2\pi i}\int_W \frac{e^{izt/a}}{I_0(t)}dt,$$

the path of integration $W$ leading from $-R$ to $R$ along the real axis, and back from $R$ to $-R$ along a semi-circle of radius $R$ and center 0. Avoiding values of $R$ for which the semi-circle passes through a zero of $I_0(t)$, we can prove that for positive values of $z$, the contribution of the semi-circle tends to zero, when $R$ tends to infinity. Let $k_1$, $k_2$, $\cdots$ denote, in ascending order, the positive zeros of the Bessel function $J_0(k)$. Then $ik_n$ are the simple poles of the integrand in the upper half of the $t$-plane. The residue theorem now gives

$$\frac{1}{2\pi i}\int_{-\infty}^{\infty}\frac{e^{izt/a}}{I_0(t)}dt = \sum_{n=1}^{\infty}\frac{e^{-k_n z/a}}{I_0'(ik_n)}.$$

We have $I_0'(ik_n) = iJ_1(k_n)$, and so for the charge density

$$\eta(z) = -\frac{1}{2\pi a^2}\sum_{n=1}^{\infty}\frac{e^{-k_n z/a}}{J_1(k_n)}, \quad (z \geqslant 0). \qquad (6)$$

Only for $z=0$ does this series not converge in the ordinary sense. Unless $z$ is very small, it is very useful for numerical computation. A small number of terms are already sufficient in the range $z \geqslant a$.

The total charge, induced on the cylinder between $z \geqslant 0$ and $\infty$, can be found by integration:

$$2\pi a\int_z^{\infty}\eta(\zeta)d\zeta = -\sum_{n=1}^{\infty}\frac{e^{-k_n z/a}}{k_n J_1(k_n)}, \quad (z \geqslant 0).$$

The latter series does converge at $z=0$. The total amount of induced charge on the upper half of the cylinder should be $-\frac{1}{2}$; we have thus an opportunity to verify a well-known formula in Bessel-function theory, originally credited to Nielsen:

$$\sum_{n=1}^{\infty}\frac{1}{k_n J_1(k_n)} = \tfrac{1}{2}.$$

For small values of $z$ the convergence of the series (6) is too slow for practical evaluation. Hence we have to develop other expressions for $\eta(z)$, which do allow of numerical computation near the "cut plane" $z=0$. This can be accomplished by Watson's method for an analogous problem.[5]

Therefore we consider the following integral

$$\frac{1}{2\pi i}\int\frac{\cos\lambda w}{(w-t)I_0(w)\cos(\pi w/\beta)}dw$$

wherein $\lambda$, $\beta$, $t$ are real parameters; $\beta>0$, $\cos(\pi t/\beta)\neq 0$. The path of integration is a circle of radius $R>t$, and center 0, not passing through any zero of the denominator of the integrand. When one adds the condition $\beta|\lambda|<\pi$, the integral tends to zero, if $R$ increases to infinite values. Thus the sum of the residues of the integrand is zero also. The poles of the integrand are all simple; they lie at

$$w=t, \qquad \text{(a)}$$

$$w=\pm ik_n, \quad (n=1, 2, \cdots), \qquad \text{(b)}$$

$$w=\pm(\nu+\tfrac{1}{2})\beta, \quad (\nu=0, 1, 2, \cdots). \qquad \text{(c)}$$

The corresponding residues are easily found to be

$$\frac{\cos\lambda t}{I_0(t)\cos(\pi t/\beta)}, \qquad \text{(a}')$$

$$-\frac{\cosh\lambda k_n}{J_1(k_n)\cosh(\pi k_n/\beta)[k_n \pm it]}, \qquad \text{(b}')$$

$$-\frac{\beta}{\pi}\frac{(-1)^\nu\cos(\lambda\beta\nu+\lambda\beta/2)}{I_0(\beta\nu+\beta/2)[(\nu+\frac{1}{2})\beta\mp t]}. \qquad \text{(c}')$$

---

[5] G. N. Watson, "The use of series of Bessel functions in problems connected with cylindrical wind-tunnels," Proc. Roy. Soc. **130**, 29 (1930/31).

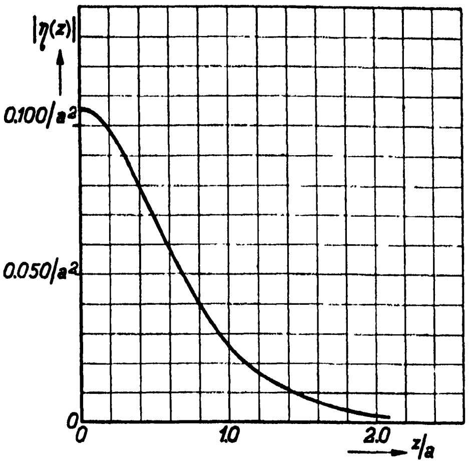

FIG. 1. Curve showing the surface charge density $|\eta|$ on the wall of the grounded cylinder, induced by a unit-point charge situated in the axis at $z=0$; $z$ denotes the distance along the cylinder, measured from the source containing plane; $a$ is the radius of the cylinder.

The sum of all residues together being zero, one has

$$\frac{\cos\lambda t}{I_0(t)\cos(\pi t/\beta)}=\sum_{n=1}^{\infty}\frac{2k_n\cosh\lambda k_n}{J_1(k_n)\cosh(\pi k_n/\beta)}\frac{1}{k_n{}^2+t^2}+\frac{\beta}{\pi}\sum_{\nu=0}^{\infty}\frac{(-1)^\nu\cos(\lambda\beta\nu+\lambda\beta/2)}{I_0(\beta\nu+\beta/2)}\frac{(2\nu+1)\beta}{(\beta\nu+\beta/2)^2-t^2}. \quad (7)$$

Evidently, the right-hand side of (7) is nothing else but the expansion in rational fractions of the left-hand side.

We now multiply both sides of (7) by $\cos(\pi t/\beta)$, thus neutralizing the poles in (c), and integrating from $t=-\infty$ to $t=\infty$. Using the following formulas[5]

$$\int_{-\infty}^{\infty}\frac{\cos(\pi t/\beta)}{k_n{}^2+t^2}dt=\frac{\pi}{k_n}e^{-\pi k_n/\beta},$$
$$\int_{-\infty}^{\infty}\frac{\cos(\pi t/\beta)}{(\beta\nu+\beta/2)^2-t^2}dt=\frac{(-1)^\nu 2\pi}{(2\nu+1)\beta}, \quad (8)$$

we easily obtain

$$\int_0^{\infty}\frac{\cos\lambda t}{I_0(t)}dt=\beta\sum_{\nu=0}^{\infty}\frac{\cos\lambda\beta(\nu+\frac{1}{2})}{I_0(\beta\nu+\beta/2)}+2\pi\sum_{n=1}^{\infty}\frac{\cosh\lambda k_n}{J_1(k_n)[1+e^{2\pi k_n/\beta}]}. \quad (9)$$

Hence, for the induced charge density

$$-a^2\eta(z)=\frac{\beta}{2\pi^2}\sum_{\nu=0}^{\infty}\frac{\cos(\beta\nu+\beta/2)z/a}{I_0(\beta\nu+\beta/2)}+\frac{1}{\pi}\sum_{n=1}^{\infty}\frac{\cosh k_n z/a}{J_1(k_n)[1+e^{2\pi k_n/\beta}]}. \quad (10)$$

It may be emphasized that our proof of (10) holds for $\beta>0$ and $-\pi a/\beta<z<\pi a/\beta$. The first series on the right of (10) is convergent for all real values of $z$. It may be considered as an approximation of the integral in (5), obtained when the integration interval is divided into equal parts of length $\beta$, and the integrand in each separate interval is replaced by its central value. The second series should then be interpreted as a correction term. The latter, however, only converges for $-2\pi a/\beta<z<2\pi a/\beta$. By analytic continuation, it can be shown that (10) holds for this extended range, twice as large as might be expected from the proof of (10), as given above. Moreover, for the special value $\beta=a\pi/|z|$, the first series vanishes identically, whilst the "correction term" reduces to the series (6). Consequently, Eq. (10) is more basic than (6).

Equation (10) is very suitable for numerical calculations. The constant $\beta$ is still arbitrary, except for $-2\pi a/\beta<z<2\pi a/\beta$. Let us consider the extreme case $z=0$ in detail. We already saw that in this case (6) cannot be used on behalf of its divergence. Equation (10) can be used with any positive $\beta$. We calculated $-2\pi^2a^2\eta(0)$ in seven decimals with $\beta=1$, $\beta=3$, respectively. In the first case we had to take eighteen terms of the first series and only one of the second. The result was found to be

$$2.0832296+0.0000033=2.0832329.$$

With $\beta=3$ we had to consider six terms of the first, and three terms of the second series, obtaining in this case

$$2.0053020+0.0779307=2.0832327,$$

in close agreement with the earlier value. Thus we can state

$$\int_0^{\infty}\frac{dt}{I_0(t)}=2.083232\cdots,\quad \eta(0)=-\frac{0.10554}{a^2}. \quad (11)$$

Numerical computation of the surface charge density is now easily established. When $z \geqslant a$, already the first four terms of (6) are sufficient to guarantee the correctness of the fourth decimal. Inserting known data from existing Bessel-function tables, (6) becomes

$$\begin{aligned}-a^2\eta(z) = 0.30657 \exp(-2.40z/a)\\ -0.46774 \exp(-5.52z/a)\\ +0.58636 \exp(-8.65z/a)\\ -0.68466 \exp(-11.79z/a). \quad (12)\end{aligned}$$

In the remaining range $0 \leqslant z \leqslant a$, Eq. (10) may be used with $\beta = 2$. Then one obtains

$$\begin{aligned}-a^2\eta(z) = 0.08003 \cos(z/a) + 0.02076 \cos(3z/a)\\ +0.00372 \cos(5z/a) + 0.00060 \cos(7z/a)\\ +0.00009 \cos(9z/a) + 0.00001_4 \cos(11z/a)\\ +0.00032 \cosh(2.4z/a). \quad (13)\end{aligned}$$

The data of Fig. 1 were computed by means of Eqs. (12) and (13). The curve shows a rapid decrement of the surface charges with increasing distance from the cut plane.

By expanding both sides of (9) into a power series of $\lambda$, and identifying the corresponding coefficients, we obviously obtain

$$\int_0^\infty \frac{t^{2r}}{I_0(t)}dt = \beta \sum_{\nu=0}^{\infty} \frac{(\beta\nu+\beta/2)^{2r}}{I_0(\beta\nu+\beta/2)} + (-1)^r 2\pi \sum_{n=1}^{\infty} \frac{k_n^{2r}}{J_1(k_n)[1+e^{2\pi k_n/\beta}]}.$$

The numerical values of these integrals can be found in the same way as shown above for $r = 0$. Then for $\eta(z)$ a power series in $z^2/a^2$ can be derived, convergent for $|z| < a$. The expression (13), however, is much more useful for numerical purposes in the corresponding range of $z$-values.

## 3. FORMULAS FOR THE POTENTIAL AND THE ELECTRIC FIELD

The potential $V(P)$ can be considered as the sum of the potential $1/r$, due to the unit charge in the origin, and the potential $V_0(P)$, due to the induced charges on the surface of the cylinder:

$$V(P) = \frac{1}{r} + V_0(P) = \frac{1}{} + \int \frac{\eta(\zeta)}{} d\sigma.$$

In this $r$, $r_1$, denote the distances from $P$ to the origin, and the surface element, respectively. Again, $V_0(P)$ depends only upon $z$ and $\rho$.

At first we restrict ourselves to points on the axis of the cylinder. Then we have

$$V_0(z, 0) = 2\pi a \int_{-\infty}^{\infty} \frac{\eta(x+u)}{(u^2+a^2)^{\frac{1}{2}}} du.$$

Using (5), we obtain

$$V_0(z, 0) = -\frac{2}{\pi} \int_0^\infty \frac{\cos\lambda z}{I_0(\lambda a)} d\lambda \int_0^\infty \frac{\cos\lambda u}{(u^2+a^2)^{\frac{1}{2}}} du.$$

On account of a well-known integral for the $K$-function, namely

$$K_0(\lambda a) = \int_0^\infty \frac{\cos\lambda u}{(u^2+a^2)^{\frac{1}{2}}} du, \quad (14)$$

we obtain for the potential of the induced charges, at points on the axis of the cylinder

$$V_0(z, 0) = -\frac{2}{\pi} \int_0^\infty \frac{K_0(\lambda a)}{I_0(\lambda a)} \cos\lambda z d\lambda. \quad (15)$$

In the rotationally symmetrical problem under consideration, the potential outside the axis is easily obtained, once the potential on the axis of symmetry has been found. We simply have to take the mean value of $V_0(z+i\rho\cos\varphi, 0)$ over a full period of the angle $\varphi$. Thus

$$V_0(z, \rho) = \frac{1}{2\pi} \int_0^{2\pi} V_0(z+i\rho\cos\varphi, 0) d\varphi. \quad (16)$$

The integration over $\varphi$ can be performed, leading to

$$V_0(z, \rho) = -\frac{2}{\pi} \int_0^\infty \frac{K_0(\lambda a)}{I_0(\lambda a)} I_0(\lambda\rho) \cos\lambda z d\lambda, \quad (17)$$

and for the total potential we get

$$V(z, \rho) = \frac{1}{(z^2+\rho^2)^{\frac{1}{2}}} - \frac{2}{\pi a} \int_0^\infty \frac{K_0(t)}{I_0(t)} \times I_0(t\rho/a) \cos(tz/a) dt. \quad (18)$$

The corresponding axial and radial components of the electric force are readily derived from

(18) by differentiation

$$E_z=-\frac{z}{(z^2+\rho^2)^{3/2}}-\frac{2}{\pi a^2}\int_0^\infty \frac{K_0(t)}{I_0(t)}\times tI_0(t\rho/a)\sin(tz/a)dt,$$

$$E_\rho=\frac{\rho}{(z^2+\rho^2)^{3/2}}+\frac{2}{\pi a^2}\int_0^\infty \frac{K_0(t)}{I_0(t)}tI_1(t\rho/a)\cos(tz/a)dt. \qquad (19)$$

It does not seem possible to transform these integrals explicitly into known functions.

Having thus found expressions for the electric field inside the cylinder, we can easily verify them afterwards. For any real value of $\lambda$, the function

$$\cos(\lambda z)\cdot I_0(\lambda\rho)$$

is a regular solution of the potential equation inside the cylinder. Furthermore, the right-hand side of (17), being an absolutely convergent linear combination of those functions, is here a regular potential as well. Therefore, the function $V$ of (18) is also a regular potential, with exception of the origin, where it has just the required singularity. It only remains to be checked that $V$ vanishes on the boundary at $\rho=a$. This, however, is evident from the Fourier inversion of (14):

$$\frac{2}{\pi}\int_0^\infty K_0(\lambda a)\cos\lambda z d\lambda=\frac{1}{(z^2+a^2)^{1/2}}.$$

## 4. A SECOND METHOD TO SOLVE THE POTENTIAL PROBLEM[6]

The *first* method to obtain expressions for the field inside the cylinder, as given above, started from a certain pre-calculated surface charge distribution on the boundary. This method is a little unconventional. Usually one works in the opposite direction: first the potential is obtained as the solution of a boundary value problem, and then the surface charges are calculated. The results above immediately indicate how this *second* method runs. One should try to find a function $f(\lambda)$ such that the potential of the yet unknown charges be expressible as follows

$$V_0(z,\rho)=\int_0^\infty f(\lambda)I_0(\lambda\rho)\cos\lambda z d\lambda,$$

this being a continuous sum of elementary potential functions. Fortunately, the primary potential of the unit point charge can already be expressed in that way:

$$\frac{1}{r}=\frac{2}{\pi}\int_0^\infty K_0(\lambda\rho)\cos\lambda z d\lambda. \qquad (20)$$

and, hence, for the total potential

$$V(z,\rho)=\int_0^\infty\left\{f(\lambda)I_0(\lambda\rho)+\frac{2}{\pi}K_0(\lambda\rho)\right\}\cos\lambda z d\lambda.$$

A sufficient condition that $V(z,\rho)$ be zero on the boundary of the cylinder is that the integrand vanish there; consequently the function $f(\lambda)$ can be determined from

$$f(\lambda)I_0(\lambda a)+\frac{2}{\pi}K_0(\lambda a)=0,$$

and then one obtains (17).

Moreover, in combining Eqs. (17) and (20), we can derive the following expression

$$V(z,\rho)=\frac{2}{\pi}\int_0^\infty\frac{I_0(\lambda a)K_0(\lambda\rho)-K_0(\lambda a)I_0(\lambda\rho)}{I_0(\lambda a)}\times\cos\lambda z d\lambda, \qquad (21)$$

which more directly shows the vanishing at $\rho=a$. Equation (21) enables us to come to the integral expression (5) for the charge density. Theretofore, we use (1) and the Wronskian of $I_0$, $K_0$:

$$I_0(t)K_0'(t)-I_0'(t)K_0(t)=-\frac{1}{t}, \qquad (22)$$

and so we are back at our former starting point.

## 5. APPROXIMATE EXPRESSIONS FOR THE SURFACE CHARGES

Weber,[6] in his theory of a point charge inside a cylinder, follows the second method apart from slight modifications of minor importance. His Eqs. (13), (17), and (18) are equivalent to ours as shown in Eqs. (18) and (19). Equation (5) for

---

[6] E. Weber, "The electrostatic field produced by a point charge in the axis of a cylinder," J. App. Phys. 10, 663 (1939).

the surface charge density, however, was not given by Weber.

As for numerical calculations, Weber writes "the actual evaluation of the field distribution is rather difficult on account of the Fourier integrals which necessitate a point for point numerical integration in infinite limits," and further "the numerical evaluation of the integrals is very laborious." Weber, therefore, does not integrate point for point, but approximates the integrands by more tractable elementary functions, such that the remaining integrals can be computed explicitly.

As a fair approximation, suggested by existing tables of Bessel functions, Weber uses, for instance

$$\frac{K_0(t)}{I_0(t)}tI_1(t)\approx\frac{t}{2}e^{-t},\quad (t>0). \tag{23}$$

From the lower integral in (19), $E_\rho$ can then be evaluated at the surface of the cylinder. Weber's result for the corresponding density of charge, according to $\eta(z)=-E_\rho/4\pi$, may be written

$$-a^2\eta(z)\approx\frac{1}{4\pi}\left\{\frac{1}{(1+\zeta^2)^{3/2}}+\frac{1}{\pi}\frac{1-\zeta^2}{(1+\zeta^2)^2}\right\},$$
$$(\zeta=z/a). \tag{23'}$$

Furthermore, Weber derives expressions for the field in the cut plane as well for points at the surface of the cylinder, by another approximation, different from (23). His approximation (21) reads

$$\frac{K_0(t)}{I_0(t)}\approx(2\pi)^{1/2}te^{-2t},\quad (t>0). \tag{24}$$

We need not, however, confine ourselves to the special values $z=0$ or $\rho=a$, as did Weber. When (24) is applied, we obtain

$$\frac{1}{(2\pi)^{1/2}}\int_0^\infty\frac{K_0(t)}{I_0(t)}I_0(t\rho/a)\cos(tz/a)dt$$
$$=Re\int_0^\infty e^{-t(2+i\zeta)}J_0(it\rho/a)tdt$$
$$\approx Re\frac{2+i\zeta}{[(2+i\zeta)^2-\rho^2/a^2]^{3/2}};$$

TABLE I. Values of surface charge density $|\eta|$ in units $1/a^2$. First column: rigorous values; second: Weber's approximation (23'). Third and fourth columns: approximations (25'), (24'), respectively.

| $z/a$ | $-a^2\eta(z)$ | | | |
|---|---|---|---|---|
| 0 | 0.1055 | 0.1049 | 0.1040 | 0.1285 |
| 0.2 | 0.0980 | 0.0975 | 0.0969 | 0.1144 |
| 0.4 | 0.0795 | 0.0795 | 0.0792 | 0.0827 |
| 0.6 | 0.0581 | 0.0589 | 0.0586 | 0.0510 |
| 0.8 | 0.0396 | 0.0413 | 0.0406 | 0.0280 |
| 1.0 | 0.0259 | 0.0281 | 0.0269 | 0.0147 |
| 1.2 | 0.0165 | 0.0190 | 0.0174 | 0.0076 |
| 1.4 | 0.0104 | 0.0129 | 0.0111 | 0.0041 |

| 1.8 | 0.0040 | 0.0060 | 0.0042 | 0.0018 |
| 2.0 | 0.0025 | 0.0041 | 0.0025 | 0.0016 |

and then, from (18)

$$V(z,\rho)\approx\frac{1}{(z^2+\rho^2)^{1/2}}-\frac{1}{a}\left(\frac{8}{\pi}\right)^{1/2}Re\frac{2+i\zeta}{[(2+i\zeta)^2-\rho^2/a^2]^{3/2}}.$$

Especially on the cut plane, when differentiated to $(-\rho)$, this formula yields

$$E_\rho\approx\frac{1}{\rho^2}\left\{1+\left(\frac{8}{\pi}\right)^{1/2}\frac{6\rho^3/a^3}{[4-\rho^2/a^2]^{5/2}}\right\},\quad (z=0).$$

This result is apparently in disagreement with that of Weber. His relation reads

$$E_{\rho,\text{ Weber}}\approx\frac{1}{\rho^2}\left\{1+\left(\frac{8}{\pi}\right)^{1/2}\frac{\rho^3/a^3}{[4-\rho^2/a^2]^{3/2}}\right\},\quad (z=0).$$

The reason for this discrepancy is that Weber dropped one factor $\gamma$ in the integrand of his integral (22), so that actually he has used the following approximation

$$\frac{K_0(t)}{I_0(t)}\approx(2\pi)^{1/2}e^{-2t} \tag{25}$$

instead of (24).

In the latter case we find for general values of $z$ and $\rho$

$$V(z,\rho)\approx\frac{1}{(z^2+\rho^2)^{1/2}}-\frac{1}{a}\left(\frac{8}{\pi}\right)^{1/2}Re\{(2+i\zeta)^2-\rho^2/a^2\}^{-1/2}$$

leading exactly to Weber's formula for $E_\rho$.

In either of the cases Eqs. (24) and (25), the corresponding surface charges, can be calculated. We obtained, respectively,

$$-a^2\eta(z)\approx\frac{1}{4\pi}\left\{\frac{1}{(1+\zeta^2)^{3/2}}+\left(\frac{8}{\pi}\right)^{1/2}Re\frac{3(2+i\zeta)}{(1+i\zeta)^{5/2}(3+i\zeta)^{5/2}}\right\},\qquad(24')$$

$$-a^2\eta(z)\approx\frac{1}{4\pi}\left\{\frac{1}{(1+\zeta^2)^{3/2}}+\left(\frac{8}{\pi}\right)^{1/2}Re\frac{1}{(1+i\zeta)^{1/2}(3+i\zeta)^{3/2}}\right\}.\qquad(25')$$

Table I shows the three different approximations (23′), (24′), (25′), in presence of the correct values, as computed from (12), (13). The approximation (24′) is obviously very poor, leading to values which are too large at $z\approx 0$ and too small at $z\approx 2a$. Either of the approximations (23′) and (25′) is excellent. That of Weber (23′) is a better approximation at small values of $z$ than is (25′). On the other hand, for values of $z$ exceeding $a$, the latter is much better than the former. Moreover, Weber's formula yields negative values for $-a^2\eta(z)$, when $\zeta>3.6$. This is physically impossible, however. The surface charge density must always have the same sign. The right-hand side of (25′), on the contrary, is positive for large values of $\zeta$. Therefore, as a whole, the approximation (25) may be considered as the most useful one, at least as far as we confine ourselves to the surface charges.

The radial field at the surface of the cylinder, just opposite the point charge, is 1.3262 times as large as it would be under influence of the free-point charge, when the cylinder was removed. The corresponding factors in the three approximations (23), (25), and (24), are 1.3071, 1.3183, and 1.6142, respectively.

## 6. FORMULAS WHICH ADMIT OF NUMERICAL CALCULATIONS INSIDE THE CYLINDER

For exact numerical calculations the integral representation (18) is almost without any value. In Section 2 we derived expressions for the charge density which served its useful purpose. The field can be dealt with in a similar manner. The integral (15), however, is no suitable starting point, because its integrand shows a logarithmic singularity in the lower limit. The difficulties owing to the many-valuedness of the $K$-function may be conveniently avoided in the following way. By partially integrating (15) and using (22), one readily obtains

$$V_0(z,0)=-\frac{2}{\pi z}\int_0^\infty\frac{\sin(tz/a)}{tI_0^2(t)}dt.\qquad(26)$$

We now proceed in the same manner as we did before with (5). In this case the path of integration in the complex plane has to avoid the origin by a small indentation in the upper-half plane. We then obtain for $z>0$

$$\frac{1}{\pi}\int_0^\infty\frac{\sin(tz/a)}{tI_0^2(t)}dt=\tfrac{1}{2}+\sum_{n=1}^{\infty}\underset{(t=ik_n)}{\text{residue}}\frac{e^{itz/a}}{tI_0^2(t)}.$$

We calculate the residue in $t=ik_n$ by putting $t=x+ik_n$, developing the function into ascending powers of $x$, and taking the coefficient of $1/x$ in that expansion. The function is of the type $f(x)/g^2(x)$, where $g(x)$ has a simple zero in $x=0$, and $f(0)\neq 0$. The coefficient of $1/x$ turns out to be

$$\frac{f}{g'^2}\left\{\frac{f'}{f}-\frac{g''}{g'}\right\}\qquad\frac{z}{ak_n}\frac{e^{-k_nz/a}}{J_1^2(k_n)}$$

Consequently, for $z>0$

$$V_0(z,0)=-\frac{1}{z}+\frac{2}{a}\sum_{n=1}^{\infty}\frac{e^{-k_nz/a}}{k_nJ_1^2(k_n)}.$$

To obtain the total potential on the axis of the cylinder we must add the potential of the unit charge in the origin. For positive values of $z$ the latter is $1/z$. Hence

$$V(z,0)=\frac{2}{a}\sum_{n=1}^{\infty}\frac{e^{-k_nz/a}}{k_nJ_1^2(k_n)}.$$

Applying (16), we finally obtain for $z>0$

$$V(z,\rho)=\frac{2}{a}\sum_{n=1}^{\infty}\frac{J_0(k_n\rho/a)}{k_nJ_1^2(k_n)}e^{-k_nz/a}.\qquad(27)$$

The series (27) converges also for $x=0$ with the only exception of the origin, where it diverges to infinity. In actual numerical work (27) appears to be useful for $z/a\geqslant 0.2$; in the remaining range $0\leqslant z/a\leqslant 0.2$ other methods should be applied.

One naturally asks whether or not it is possible to establish developments for the potential, analogous to that of formula (10) for the surface charge density. Actually, the required transformation is readily performed for points in the axis of the cylinder. We only write down the final result:

$$V_0(z,0)=-\frac{2}{\pi z}\sum_{\nu=0}^{\infty}\frac{\sin(\beta\nu+\beta/2)z/a}{(\nu+\frac{1}{2})I_0{}^2(\beta\nu+\beta/2)}$$

$$+\frac{1}{a}\sum_{n=1}^{\infty}\frac{\{1+e^{-2\pi k_n/\beta}\}\cosh(k_nz/a)-(2\pi a/\beta z)\sinh(k_nz/a)}{k_nJ_1{}^2(k_n)\cosh^2(\pi k_n/\beta)}. \quad (28)$$

The first series converges for all real $z$, the second for $|z|\leqslant 2\pi a/\beta$; $\beta$ is an arbitrary positive number. If especially $\beta=2\pi a/z$, the first series vanishes identically, whereas the second one reduces to (27) for $\rho=0$.

For actual numerical evaluation we have chosen $\beta=2$. Then the series (28) becomes

$$-aV_0(z,0)=\frac{a}{z}\{0.79432\sin(z/a)$$
$$+0.01782\sin(3z/a)+0.00034\sin(5z/a)$$
$$+0.00000_6\sin(7z/a)+0.01014\sinh(2.4z/a)\}$$
$$-0.00323\cosh(2.4z/a). \quad (29)$$

Although convergent for $z/a<\pi$, (29) may be useful for $z/a\leqslant 1$.

Unfortunately, there do not seem to exist simple developments for general non-zero values of $\rho$, because (16) yields for the continuation of $(\sin z/a)/(z/a)$ outside the axis

$$\frac{a}{\rho}\int_0^{\rho/a}\cos(tz/\rho)I_0(t)dt,$$

which integral cannot be solved explicitly.

For small values of $z$ we can expand the initial integral (26) into powers of $z/a$. We then obtain

$$V_0(z,0)=--\sum^{\infty}\frac{(-1)^\nu\lambda_{2\nu}}{(2\nu)!}\left(\frac{z}{a}\right)^{2\nu}, \quad (30)$$

where

$$\lambda_{2\nu}=\frac{1}{(2\nu+1)\pi}\int_0^{\infty}\frac{t^{2\nu}}{I_0{}^2(t)}dt, \quad (31)$$

$$\lambda_0=0.4353382,$$
$$\lambda_2=0.2059112,$$
$$\lambda_4=0.6588568.$$

TABLE II. Values of the potential (measured in units $1/a$) inside a grounded cylinder under induction of an axial positive unit-point charge; $a$ = radius of the cylinder, $z$ and $\rho$ the usual cylindrical coordinates. Point charge in the origin.

| $z/a$ \ $\rho/a$ | 0 | 0.2 | 0.4 | 0.6 | 0.8 |

| 0.7 | 0.648 | 0.591 | 0.410 | 0.287 | 0.133 |
| 0.8 | 0.493 | 0.454 | 0.355 | 0.231 | 0.109 |
| 0.9 | 0.379 | 0.353 | 0.281 | 0.189 | 0.091 |
| 1.0 | 0.292 | 0.272 | 0.219 | 0.147 | 0.071 |
| 1.2 | 0.176 | 0.164 | 0.135 | 0.092 | 0.045 |
| 1.4 | 0.107 | 0.101 | 0.083 | 0.057 | 0.028 |
| 1.6 | 0.066 | 0.062 | 0.051 | 0.036 | 0.017 |
| 1.8 | 0.041 | 0.039 | 0.032 | 0.022 | 0.011 |
| 2.0 | 0.025 | 0.024 | 0.019 | 0.014 | 0.007 |

Except $\lambda_0$, these numerical values were given by Watson.[5]

We can now apply (16) with greater success than before. In performing the transformation (16) upon (30) we obtain

$$V_0(z,\rho)=-\frac{2}{a}\sum_{\nu=0}^{\infty}\frac{(-1)^\nu\lambda_{2\nu}}{(2\nu)!}F_\nu\left(\frac{z}{a},\frac{\rho}{a}\right), \quad (32)$$

where

$$F_\nu(u,v)=\frac{1}{2\pi}\int_0^{2\pi}(u+iv\cos\varphi)^{2\nu}d\varphi$$
$$=(u^2+v^2)^\nu P_{2\nu}\left\{\frac{u}{(u^2+v^2)^{\frac{1}{2}}}\right\}, \quad (33)$$

and $P_{2\nu}$ is the usual symbol for the Legendre polynomial. For instance

$$F_0=1,$$
$$F_1=u^2-\tfrac{1}{2}v^2,$$
$$F_2=u^4-3u^2v^2+\tfrac{3}{8}v^4.$$

It may be remarked that (32) converges for $z^2+\rho^2<4a^2$.

The development (32) becomes much more familiar when spherical coordinates $r$, $\vartheta$, are introduced, connected to the cylindrical ones by means of

$$r^2=z^2+\rho^2;\quad \tan\vartheta=\rho/z.$$

Then (32) is transformed into

$$V_0(z,\rho)=-\frac{2}{a}\sum_{\nu=0}^{\infty}\frac{(-1)^{\nu}\lambda_{2\nu}}{(2\nu)!}\left(\frac{r}{a}\right)^{2\nu}P_{2\nu}(\cos\vartheta). \quad (34)$$

This series is convergent for $r/a<2$; it is nothing else but the development of $V_0(P)$ into spherical potential functions.

Especially in the cut plane $z=0$ we found

$$-aV_0(0,\rho)=0.8707+0.1030(\rho/a)^2+0.0206(\rho/a)^4+0.0057(\rho/a)^6.$$

The first three coefficients are calculated from the values $\lambda_0$, $\lambda_2$, and $\lambda_4$, as specified above; the last coefficient is taken so that the total is 1.0000, on account of $V_0(0,a)$ being $-1/a$, thus neglecting terms of higher order than $(\rho/a)^6$.

Numerical evaluation of the potential inside the cylinder may be readily accomplished now. The different expressions (27), (28), and (34) have reasonable overlapping regions of useful convergence. Numerical data for the total potential are to be found in Table II.

The electric field itself can also be calculated numerically. From (27) we deduce for $z>0$

$$\begin{aligned}E^z&=\frac{2}{a^2}\sum_{n=1}^{\infty}\frac{J_0(k_n\rho/a)}{J_1^2(k_n)}e^{-k_nz/a},\\E_\rho&=\frac{2}{a^2}\sum_{n=1}^{\infty}\frac{J_1(k_n\rho/a)}{J_1^2(k_n)}e^{-k_nz/a}.\end{aligned} \quad (35)$$

It may be noted that in Watson's paper[5] two series $S_1$, $S_2$ occur which are related to the series (35) by

$$E_z=\frac{2}{a^2}S_1;\quad E_\rho=-\frac{2}{a}\frac{\partial S_2}{\partial z}.$$

Therefore, Watson's series can be obtained from that shown in (27). Whereas Watson has given explicitly only the first four terms of the development corresponding to (32), we found the general term here expressible in spherical potential functions; cf. (34). With exclusion of the immediate neighborhood of the cut plane $z=0$, Eqs. (35) are very useful for numerical purposes. Around the cut plane we better use (34) and compute $E_r$, $E_\vartheta$ instead of the cylindrical components; further details may be omitted, however.

## 7. A THIRD METHOD OF SOLUTION

Either of the two distinct methods developed previously yields complete information concerning the field of the axial point charge in the cylinder. The mathematics there involved are quite instructive, and can serve successfully as a guide in problems of wave propagation inside the same cylinder.

The reader is aware that even in the simplest potential problem, as was treated above, a considerable amount of analysis was used. In this respect wave guide theory is still less tractable. The question whether this is really necessary, from an engineer's point of view, will be answered in due course.

In practical wave guide applications, one is mainly interested in the fields far from the exciting antenna, where many of the higher modes have already been damped out. With this restriction in mind, and thus ignoring the field in the nearby zone, we have investigated whether it is possible to calculate the field in the far zone more directly, without the usual extensive amount of complex function theory. This new method was found by inspection and generalization of the expansion (27), obtained for the potential in the preceding section. Each separate term of that series, for non-vanishing $z$, is a solution of the potential equation, fulfilling the required boundary condition at the surface of the cylinder, and showing the suitable behavior at infinity. So we might have expected in advance the possibility of solving our potential problem by means of such a development, in terms of discrete normal solutions of the potential equation:

$$V(z,\rho)=\sum_{n=1}^{\infty}c_nJ_0(k_n\rho/a)e^{-k_n|z|/a}. \quad (36)$$

When the proposed method actually works, it must be possible, somehow, to calculate the unknown coefficients $c_n$ in this development from the behavior of $V(z,\rho)$ in the immediate neighborhood of the prescribed singularity at the origin, although just in the point charge, (36) is known to diverge. In the following we will show how this problem can be solved. We consider a more general problem, however, so that the new method is equally well applicable to solutions of the wave equation. Moreover, we need not restrict ourselves to rotationally symmetrical fields. In many cases the prescribed singularity is of the type

$$\frac{1}{R}=\{z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0{}^2\}^{-\frac{1}{2}},$$

where $R$ denotes the distance between the field point $(z, \rho, \varphi)$ and the source at $(0, \rho_0, 0)$. Singularities of this character are commonly used, both in electrostatics and in wave guide theory. We may, however, admit still more general types of sources.

Suppose $G(z, \rho)$ is a *given function* with one or more singularities for $z=0$, $0\leqslant\rho\leqslant a$. Let $G$ be even in $z$, and let it have continuous derivatives of the second order, outside the singularities. In the previous case of an axial point charge, $G=(z^2+\rho^2)^{-\frac{1}{2}}$.

Furthermore, we suppose that $f_n(z)$ is a *given system* $(n=1, 2, \cdots)$ of continuously differentiable functions with the property $f_n'(0)\neq 0$. For instance, $f_n(z)=\exp(-k_nz/a)$.

The problem under consideration can now be stated in the following general form: How to find the coefficients $c_n$ in (37), when the following properties of the function $F(z, \rho)$ are ***known***:

(i) $F$ is an even function of $z$.

(ii) $F-G$ has continuous derivatives of the second order, both outside and inside the singularities of $G$.

(iii) For $z\neq 0$, $F$ can be expanded into a uniformly (in $\rho$) convergent series of the form

$$F(z,\rho)=\sum_{n=1}^{\infty}c_nJ_m(k_{n,m}\rho/a)f_n(|z|), \tag{37}$$

where $k_{n,m}$ denotes the $n$th positive zero of the Bessel function $J_m(k)$, and $m$ is a given integer.

The answer to this question is readily given if appropriate use is made of the well-known Fourier-Bessel-Dini series theory, for details of which the reader may be referred to Watson's standard work on Bessel functions.[7]

On account of the conditions stated under (ii) we infer that $(\partial/\partial z)(F-G)$ can be developed into a Fourier-Bessel series. This series is uniformly convergent in any closed interval, contained in $0<\rho<a$, for any value of $z$, whether outside or on the cut plane $z=0$. Thus we have

$$\frac{\partial}{\partial z}(F-G)=\sum_{n=1}^{\infty}b_n(z)J_m(k_{n,m}\rho/a).$$

The coefficients $b_n(z)$ can be determined in the conventional manner, using the orthogonality of the set of functions $\rho^{\frac{1}{2}}\cdot J_m(k_{n,m}\rho/a)$ upon $0\leqslant\rho\leqslant a$. One finds[7]

$$b_n(z)=\frac{2}{a^2J_{m+1}{}^2(k_{n,m})}\int_0^a\rho\frac{\partial}{\partial z}(F-G)J_m(k_{n,m}\rho/a)d\rho.$$

As either of the two functions $F$, $G$ is even in $z$, with continuous derivatives, we have $b_n(0)=0$. For points *above* the cut plane $(z>0)$ the integral may be broken up into two other integrals, namely

$$b_n(z)=\frac{2}{a^2J_{m+1}{}^2(k_{n,m})}\frac{\partial}{\partial z}\int_0^a\rho F(z,\rho)J_m(k_{n,m}\rho/a)d\rho$$
$$-\frac{2}{a^2J_{m+1}{}^2(k_{n,m})}\int_0^a\rho\frac{\partial G}{\partial z}J_m(k_{n,m}\rho/a)d\rho.$$

From (37), which, for fixed $z\neq 0$ is nothing else but the Fourier-Bessel series of the function $F(z, \rho)$, we obtain

$$\int_0^a\rho F(z,\rho)J_m(k_{n,m}\rho/a)d\rho=c_nf_n(|z|)\frac{a^2}{2}J_{m+1}{}^2(k_{n,m})$$

Therefore, if $z>0$

$$b_n(z)=c_nf_n'(z)-\frac{2}{a^2J_{m+1}{}^2(k_{n,m})}\int_0^a\rho\frac{\partial G}{\partial z}J_m(k_{n,m}\rho/a)d\rho.$$

Now let $z$ tend to zero through positive values; then $b_n(z)\rightarrow 0$, and $f_n'(z)\rightarrow f_n'(0)\neq 0$. Consequently, the above integral must tend to a limit value also, and the coefficient $c_n$ is equal to

$$c_n=\frac{2}{a^2f_n'(0)J_{m+1}{}^2(k_{n,m})}\lim_{z\rightarrow 0^+}\int_0^a\rho\frac{\partial G}{\partial z}\times J_m(k_{n,m}\rho/a)d\rho. \tag{38}$$

The actual evaluation of the limit in (38) usually does not lead to difficulties. Let us take

---

[7] G. N. Watson, *A Treatise on the Theory of Bessel Functions* (Cambridge, 1944), Chapter XVIII.

as an example the potential problem in its simplest form, whereby the point charge is situated on the axis. Then (38) may be applied for $m=0$, $G=(z^2+\rho^2)^{-\frac{1}{2}}$. In the limit, the main contribution to the integral (38) is attributed to the values of the integrand in the neighborhood of $\rho=0$. Therefore we may substitute unit value for the Bessel function $J_0$. Consequently for the limit value

$$\lim\int_0^a \rho\frac{\partial}{\partial z}(z^2+\rho^2)^{-\frac{1}{2}}d\rho=\lim\frac{\partial}{\partial z}\int_0^a \frac{\rho d\rho}{(z^2+\rho^2)^{\frac{1}{2}}}$$

$$=\lim\frac{\partial}{\partial z}\{(z^2+a^2)^{\frac{1}{2}}-z\}=-1.$$

Furthermore, $f_n'(0)=-k_{n,0}/a=-k_n/a$; thus,

$$c_n=\frac{2}{a^2k_nJ_1^2(k_n)},$$

in agreement with (27).

Until now we were only interested in boundary-value problems of the *first* kind, with vanishing $V$ at the surface of the cylinder. In boundary-value problems of the *second* kind, the normal component of grad $V$ vanishes there; this means $\partial V/\partial\rho=0$ in case of the cylinder. In this second problem the potential can also be developed in terms of Bessel functions. The difference is that the argument $k_{n,m}\rho/a$ is changed into $\kappa_{n,m}\rho/a$, where $\kappa_{n,m}$ means the $n$th positive zero of $J_m'(\kappa)$. Completely analogous to (37), (38), under similar conditions, we now have the following device:

Given

$$\Phi(z,\rho)=\sum_{n=1}^{\infty}\gamma_nJ_m(\kappa_{n,m}\rho/a)f_n(|z|), \qquad (37')$$

"behaves like" $G(z,\rho)$ for $z\rightarrow 0$, then the coefficients $\gamma_n$ can be determined from

$$\gamma_n= a^2f_n'(0)\{1-m^2/\kappa_{n,m}^2\}J_m^2(\kappa_{n,m})$$

$$\times\lim_{z\rightarrow 0^+}\int_0^a \rho\frac{\partial G}{\partial z}J_m(\kappa_{n,m}\rho/a)d\rho. \qquad (38')$$

We would like to emphasize that in practical applications we may forget all the precise mathematical conditions and restrictions. Then there only remains the very simple procedure to obtain the coefficients in the postulated expansions (37) and (37′) from the Eqs. (38) and (38′), respectively. In this connection the actual evaluation of those limits is of secondary importance.

This *third* powerful method is incomplete, in so far that it does not very well provide numerical calculations in the nearby zone, because the convergence of the series (37) and (37′) is usually too slow there. This, however, might always be overcome by suitable extrapolation of the data outside the cut plane. On the other hand, it has many advantages. For instance, unlike the other two methods, it is equally well applicable to either the potential or the wave equation; the only difference occurs in the system of functions $f_n(z)$. Nor does it matter whether or not there is symmetry around the axis of the cylinder.

## 8. FIELD OF AN ECCENTRIC POINT CHARGE

In case of an eccentric point charge, situated at $(0, \rho_0, 0)$, the potential $V(z,\rho,\varphi)$ will be expressible as a Fourier series with respect to $\varphi$, containing only cosine terms. Thus*

$$V(z,\rho,\varphi)=\sum_{m=0}^{\infty}\epsilon_m\cos m\varphi\sum_{n=1}^{\infty}c_{n,m}$$

$$\times J_m(k_{n,m}\rho/a)e^{-k_{n,m}|z|/a}. \qquad (39)$$

The coefficients $c_{n,m}$ have to be determined from the knowledge that $V$ behaves like $(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{-\frac{1}{2}}$ in the neighborhood of the source at $(0,\rho_0,0)$. Obviously the method of Section 7 is applicable, if the functions $G$, $F$, are defined as follows:

$$G(z,\rho)\equiv\frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{\cos m\varphi d\varphi}{(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{\frac{1}{2}}}, \qquad (40)$$

$$F(z,\rho)\equiv\frac{1}{2\pi}\int_{-\pi}^{\pi}V(z,\rho,\varphi)\cos m\varphi d\varphi$$

$$=\sum_{n=1}^{\infty}c_{n,m}J_m(k_{n,m}\rho/a)e^{-k_{n,m}|z|/a}. \qquad (40')$$

It remains to show how the limit in (38) can be actually evaluated in case of the special $G$-function (40). This can be accomplished by

---

* $\epsilon_0=1$; $\epsilon_m=2$ if $m>0$.

means of a useful *symbolic* formula, namely

$$\lim_{z\to 0^+}(\partial G/\partial z) = -(1/\rho_0)\delta(\rho-\rho_0), \qquad (41)$$

where $\delta$ denotes a delta-function, "vanishing everywhere, except for $\rho=\rho_0$, such that its integral over $\rho$ from $-\infty$ to $+\infty$ has unit value." As $G$ is even in $z$, one has, outside the singularity, $\partial G/\partial z\to 0$ if $z\to 0$; for $\rho=\rho_0$, this derivative tends to infinity. Therefore, the existence of something like (41) seems reasonable. Our final result is completely rigorous, although (41) has only a symbolic meaning. For further details the reader may be referred to the appendix.

When (41) is applied to (38), we easily obtain

$$c_{n,m} = \frac{2}{a}\frac{J_m(k_{n,m}\rho_0/a)}{k_{n,m}J_{m+1}^2(k_{n,m})},$$

and thus for the potential of the eccentric charge

$$V(z,\rho,\varphi) = \frac{2}{a}\sum_{m=0}^{\infty}\epsilon_m\cos m\varphi$$
$$\times\sum_{n=1}^{\infty}\frac{J_m(k_{n,m}\rho_0/a)J_m(k_{n,m}\rho/a)}{k_{n,m}Y_{m+1}^2(k_{n,m})}e^{-k_{n,m}|z|/a}. \qquad (42)$$

As it should be, this Green function of the first kind for the potential equation inside the cylinder, is symmetrical in $\rho$ and $\rho_0$. For $\rho_0=0$, (42) obviously reduces to (27).

The method of the discrete normal solutions has thus proved its value. We could write the proper solution almost at once. Of course, this is not the only way; it is certainly possible to generalize the first or second method, treated in the preceding sections. For instance, one will find for the analog of (5)

$$\eta(z,\varphi) = -\frac{1}{2\pi^2a^2}\sum_{m=0}^{\infty}\epsilon_m\cos m\varphi$$
$$\times\int_0^{\infty}\frac{I_m(t\rho_0/a)}{I_m(t)}\cos(tz/a)dt,$$

and by contour integration, analogous to (6),

$$\eta(z,\varphi) = -\frac{1}{2\pi a^2}\sum_{m=0}^{\infty}\epsilon_m\cos m\varphi$$
$$\times\sum_{n=1}^{\infty}\frac{J_m(k_{n,m}\rho_0/a)}{J_{m+1}(k_{n,m})}e^{-k_{n,m}|z|/a}.$$

The same expression for the surface charge density is obtained from (42) if (1) is applied to it.

Similarly, other formulas for the axial point charge can be generalized to an eccentric charge. Further details may be omitted. We better demonstrate the usefulness of the third method by a problem of wave propagation.

## 9. THE GREEN FUNCTIONS FOR THE WAVE EQUATION INSIDE THE CYLINDER. RADIATION OF ENERGY BY ACOUSTIC POINT SOURCES

We restrict ourselves to harmonic vibrations of frequency $\omega/2\pi$, and time dependence $\exp(-i\omega t)$. The velocity potential of a free-point source is

$$U_0=e^{ikR}/R;\quad R^2=z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2. \qquad (43)$$

Outside the point source, the velocity potential $U$ is a solution of the wave equation

$$\Delta U+k^2U=0. \qquad (44)$$

There are two different types of wave functions, according to whether $U$ or $\partial U/\partial\rho$ vanishes at the wall of the cylinder. The Green function of the first kind $U$ is that solution of (44) which vanishes at the surface of the cylinder, which has at infinity the character of plane waves, coming from the direction of the origin of coordinates, and finally such that $U-U_0$ remains finite for $R\to 0$. The Green function of the second kind $U_2$ has a vanishing $\partial/\partial\rho$ at $\rho=a$, the other requirements being the same as those for $U_1$. Instead of the singularity (43) we may take merely $1/R$.

Discrete normal solutions of the wave equation (44) are

$$\cos m\varphi\cdot J_m(k_{n,m}\rho/a)$$
$$\times\exp[-(z/a)(k_{n,m}^2-k^2a^2)^{\frac{1}{2}}], \qquad (45)$$

$$\cos m\varphi\cdot J_m(\kappa_{n,m}\rho/a)$$
$$\times\exp[-(z/a)(\kappa_{n,m}^2-k^2a^2)^{\frac{1}{2}}]. \qquad (45')$$

The functions (45) vanish at $\rho=a$, those of (45′) have a vanishing derivative with respect to $\rho$. On account of symmetry around the plane $\varphi=0$, the potentials do not contain terms with $\sin(m\varphi)$.

Therefore we may expect for $z\neq 0$

$$u_1=\sum_{m=0}^{\infty}\epsilon_m \cos m\varphi \sum_{n=1}^{\infty} c_{n,m}J_m(k_{n,m}\rho/a)$$

$$\times\exp[-(|z|/a)(k_{n,m}^2-k^2a^2)^{\frac{1}{2}}], \quad (46)$$

$$u_2=\sum_{m=0}^{\infty}\epsilon_m \cos m\varphi \sum_{n=1}^{\infty} \gamma_{n,m}J_m(\kappa_{n,m}\rho/a)$$

$$\times\exp[-(|x|/a)(\kappa_{n,m}^2-k^2a^2)^{\frac{1}{2}}]. \quad (46')$$

In these cases the functions $f_n(z)$ are, respectively,

$$\exp[-(z/a)(k_{n,m}^2-k^2a^2)^{\frac{1}{2}}],$$

$$\exp[-(z/a)(\kappa_{n,m}^2-k^2a^2)^{\frac{1}{2}}].$$

It is seen that the only difference between (39) and (46) is in the occurrence of different functions $f_n(z)$. Consequently we can at once write down the result

$$c_{n,m}=\frac{2}{a}\frac{J_m(k_{n,m}\rho_0/a)}{(k_{n,m}^2-k^2a^2)^{\frac{1}{2}}J_{m+1}^2(k_{n,m})}. \quad (47)$$

Obviously the Green function $U_1$ for the wave equation reduces to that of the potential equation (cf. (42)) when $k$ tends to zero. Concerning the square root, we must define for $ka>k_{n,m}$

$$(k_{n,m}^2-k^2a^2)^{\frac{1}{2}}=-i(k^2a^2-k_{n,m}^2)^{\frac{1}{2}}$$

because of the time factor $\exp(-i\omega t)$.

For the second Green function we obtain by application of (38′)

$$\frac{J_m(\kappa_{n,m}\rho_0/a)}{a\,(1-m^2/\kappa_{n,m}^2)(\kappa_{n,m}^2-k^2a^2)^{\frac{1}{2}}J_m^2(\kappa_{n,m})}, \quad (47')$$

It is to be noticed that in case of *resonance* the method fails, because then some coefficient $c$ or $\gamma$ becomes infinitely large. This resonance phenomenon occurs for special values of the applied frequency, namely $ka=k_{n,m}$ or $ka=\kappa_{n,m}$, respectively, for some values of $n$, $m$. They correspond to the cut-off frequencies of the circular wave guide. In practice actual infinities do not occur, because of certain corrections which have been neglected in our treatment, and which only play an important part near the cut-off frequencies.

Once the amplitudes of the different modes of propagation are known, it is not difficult to compute the amount of energy, radiated by the point source into the cylinder. At large distances from the cut plane $z=0$, the potential is determined by the undamped waves only. So we have

$$u_1\approx\sum_{0<k_{n,m}<ka}\sum \epsilon_m c_{n,m}\cos m\varphi J_m(k_{n,m}\rho/a)$$

$$\times\exp[-i(\omega t-(|z|/a)(k^2a^2-k_{n,m}^2)^{\frac{1}{2}})].$$

Because of the fact that the system of functions

$$\cos m\varphi J_m(k_{n,m}\rho/a)$$

is orthogonal over the cross section of the cylinder, one evidently has

$$\frac{1}{2\pi}\iint|u_1|^2dS=\sum|c_{n,m}|^2\int_0^a J_m^2(k_{n,m}\rho/a)\rho d\rho,$$

where the surface integral is extended over the cross section of the cylinder, and the summation extends over $n$, $m$ such that $k_{n,m}<ka$. The integration over $\rho$ can be performed, and after inserting the values of $c_{n,m}$ from (47), one obtains

$$\frac{1}{2\pi}\iint|u_1|^2dS$$

$$=2\sum_{0<k_{n,m}<ka}\frac{J_m^2(k_{n,m}\rho_0/a)}{(k^2a^2-k_{n,m}^2)J_{m+1}^2(k_{n,m})}. \quad (48)$$

Similarly, for the other problem

$$\frac{1}{2\pi}\iint|U_2|^2dS=2\sum_{0<\kappa_{n,m}<ka}$$

$$\times\frac{J_m^2(\kappa_{n,m}\rho_0/a)}{(k^2a^2-\kappa_{n,m}^2)[1-(m^2/\kappa_{n,m}^2)]J_m^2(\kappa_{n,m})}. \quad (48')$$

The physical meaning of the right-hand side of (48′) is that it provides us with the numeric by which the output energy of a *freely* radiating source should be multiplied in order to obtain the energy output, when the same source is placed inside the cylinder, at a distance $\rho_0$ from the axis.

By the method of images we can also treat the case of a point source inside a cylinder with one end closed. Let $d$ denote the distance from the source to the closed end. Then, by introducing an unclosed cylinder with two sources, a distance $2d$ apart, and vibrating out or in phase, we obtain for the potentials

$$u_1 = U_1(z+d,\ \rho,\ \varphi) - U_1(z-d,\ \rho,\ \varphi),$$

$$u_2 = U_2(z+d,\ \rho,\ \varphi) + U_2(z-d,\ \rho,\ \varphi).$$

The far field is a result of two interfering systems of plane waves. It is not difficult to obtain the correspondingly changed energy factors. Before in (48) and (48′) the summation is performed, each separate term must be multiplied by suitable interference factors; these factors are

$$2\sin^2\left[\frac{d}{a}(k^2a^2 - k_{n,m}^2)^{\frac{1}{2}}\right], \tag{49}$$

$$2\cos^2\left[\frac{d}{a}(k^2a^2 - \kappa_{n,m}^2)^{\frac{1}{2}}\right], \tag{49'}$$

respectively. The resulting expressions, which we need not write down in detail, will then provide us with the numerical factors, by which the output of the free source should be multiplied to obtain its output, when placed at distances $d$ and $\rho_0$ from the closed end and the axis, respectively, inside a one-sided cylinder.

Questions of wave propagation in electromagnetic theory can be dealt with in quite the same way, further details of which will not be given at present.

## APPENDIX

The validity of the symbolic formula (41) remains to be proved. That means, in rigorous mathematical terms, we have to prove

$$\lim_{z\to 0^+}\int_0^a \rho f(\rho)\frac{\partial G_m}{\partial z}d\rho = -f(\rho_0), \tag{A}$$

where $G_m$ is defined by

$$G_m = \frac{1}{2\pi}\int_{-\pi}^{\pi}\frac{\cos m\varphi d\varphi}{(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{\frac{1}{2}}}. \tag{B}$$

Equation (A) holds true for $0<\rho_0<a$, if $f(\rho)$ is continuous upon the closed interval $(0, a)$, but otherwise arbitrary.

For a complete proof of (A) it is sufficient to know that (A) is valid in the following two special cases:

(1) $f(\rho)=\rho^m$, where $m$ is the same as in $G_m$;

(2) $f(\rho)$ vanishes at $\rho=\rho_0$.

The most general case is obviously a linear combination of these special cases, because one can always write

$$f(\rho) = \frac{f(\rho_0)}{\rho_0^m}\cdot\rho^m + g(\rho),$$

where $g(\rho)$ vanishes at $\rho=\rho_0$.

### Case 1

For $z>0$, from well-known formulas in Bessel-function theory, we have

$$\begin{aligned}(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{-\frac{1}{2}} &= \int_0^\infty e^{-zt}J_0[t(\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{\frac{1}{2}}]dt \\ &= \sum_0^\infty \epsilon_\nu \cos\nu\varphi\int_0^\infty e^{-zt}J_\nu(\rho_0t)J_\nu(\rho t)dt.\end{aligned}$$

Upon multiplication by $\cos(m\varphi)$, and integration over a full period of $\varphi$, we obtain

$$G_m = \int_0^\infty e^{-zt}J_m(\rho_0t)J_m(\rho t)dt. \tag{C}$$

Consequently

$$\begin{aligned}\int_0^a \rho\cdot\rho^m(\partial G_m/\partial z)d\rho &= \int_0^a \rho^{m+1}d\rho\int_0^\infty -te^{-zt}J_m(\rho_0t)J_m(\rho t)dt \\ &= -\int_0^\infty t^{-m-1}e^{-zt}J_m(\rho_0t)dt\int_0^{at}\kappa^{m+1}J_m(x)dx \\ &= -a^{m+1}\int_0^\infty e^{-zt}J_m(\rho_0t)J_{m+1}(at)dt.\end{aligned}$$

Let $z$ tend to zero; then the integral above tends to

$$\int_0^\infty J_m(\rho_0t)J_{m+1}(at)dt = (\rho_0^m/a^{m+1}) \quad (0<\rho_0<a).$$

Hence

$$\lim_{z\to 0^+}\int_0^a \rho\cdot\rho^m(\partial G_m/\partial z)d\rho = -\rho_0^m \tag{D}$$

which is (A) for the special function $f(\rho)=\rho^m$.

### Case 2

It is easy to demonstrate that the contribution of the intervals outside the immediate vicinity of $\rho_0$ is zero; that means

$$\lim_{z\to 0^+}\left\{\int_0^{\rho_0-\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho + \int_{\rho_0+\epsilon}^a \rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right\} = 0, \tag{E}$$

where $\epsilon$ is any positive constant, such that $0\leqslant\rho_0-\epsilon<\rho_0+\epsilon\leqslant a$. For the proof of (E) we introduce $M$, the upper bound of $|f(\rho)|$ upon $(0, a)$. Then

$$\left|\int_0^{\rho_0-\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right| \leqslant M\int_0^{\rho_0-\epsilon}\left|\frac{\partial G_m}{\partial z}\right|d\rho.$$

Furthermore,

$$\frac{\partial G_m}{\partial z} = -\frac{z}{2\pi}\int_{-\pi}^{\pi}\frac{\cos m\varphi d\varphi}{(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{\frac{3}{2}}};$$

thus

$$\frac{\partial G_m}{\partial z} \leqslant \frac{z}{2\pi}\int_{-\pi}^{\pi}\frac{d\varphi}{(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{\frac{3}{2}}} \leqslant \frac{}{[z^2+(\rho-\rho_0)^2]^{\frac{3}{2}}}.$$

Therefore,

$$\left|\frac{\partial G_m}{\partial z}\right| \leqslant \frac{z}{(z^2+\epsilon^2)^{\frac{3}{2}}} \quad \text{if} \quad |\rho-\rho_0|\geqslant\epsilon.$$

Consequently

$$\left|\int_0^{\rho_0-\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right| \leqslant \frac{Mz}{(z^2+\epsilon^2)^{\frac{3}{2}}}\int_0^{\rho_0}\rho d\rho.$$

A similar bound is found for the contribution of the interval $(\rho_0+\epsilon, a)$. Upon combining them we obtain

$$\left|\int_0^{\rho_0-\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho+\int_{\rho_0+\epsilon}^{a}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right| \leqslant \frac{Mza^2}{2(z^2+\epsilon^2)^{3/2}}.$$

Let now $z$ tend to zero, $\epsilon$ being kept constant. Then (E) follows at once. (It should be noted that (E) holds for general functions $f(\rho)$, not necessarily vanishing at $\rho_0$.)

For the special function $f(\rho)$, with $f(\rho_0)=0$, the contribution of the remaining interval $\rho_0-\epsilon\leqslant\rho\leqslant\rho_0+\epsilon$ is very small, because $f(\rho)$ is very small there. Let us introduce the upper bound of $|f(\rho)|$ in this interval, thus

$$M(\epsilon)=\max_{|\rho-\rho_0|\leqslant\epsilon}|f(\rho)|,$$

then obviously $M(\epsilon)\rightarrow 0$ if $\epsilon\rightarrow 0$. Furthermore,

$$\left|\frac{\partial G_m}{\partial z}\right| \leqslant \frac{z}{2\pi}\int_{-\pi}^{+\pi}\frac{d\varphi}{(z^2+\rho^2-2\rho\rho_0\cos\varphi+\rho_0^2)^{3/2}}=-\frac{\partial G_0}{\partial z}.$$

Therefore,

$$\left|\int_{\rho_0-\epsilon}^{\rho_0+\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right| \leqslant -M(\epsilon)\int_{\rho_0-\epsilon}^{\rho_0+\epsilon}\rho\frac{\partial G_0}{\partial z}d\rho$$

$$\leqslant -M(\epsilon)\int_0^a\rho\frac{\partial G_0}{\partial z}d\rho.$$

Let now $z$ tend to zero; then the right-hand integral tends to $-1$, as follows from (D) when the latter formula is applied with $m=0$.

Thus we have

$$\left|\lim_{z\rightarrow 0+}\int_{\rho_0-\epsilon}^{\rho_0+\epsilon}\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\right| \leqslant M(\epsilon);$$

that means, on account of (E)

$$-M(\epsilon)\leqslant\lim_{z\rightarrow 0+}\int_0^a\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho\leqslant M(\epsilon).$$

This is true for any $\epsilon>0$; as $M(\epsilon)\rightarrow 0$ for $\epsilon\rightarrow 0$, consequently

$$\lim_{z\rightarrow 0+}\int_0^a\rho f(\rho)\frac{\partial G_m}{\partial z}d\rho=0=-f(\rho_0)$$

and this is the required expression in case 2. So we have rigorously proved the validity of the symbolic formula (41). It may be noticed here that according to Watson[8] we can deduce from (C) the following interesting formula

$$G_m=\frac{1}{\pi(\rho\rho_0)^{1/2}}Q_{m-1/2}\left(\frac{z^2+\rho^2+\rho_0^2}{2\rho\rho_0}\right), \tag{F}$$

where $Q$ denotes the Legendre function of the second kind. The $Q$-function has a singularity at the point where the argument is equal to 1; this corresponds with $z=0$, $\rho=\rho_0$.

Eindhoven, March, 1946.

# The Elastic Constants of Materials Loaded with Non-Rigid Fillers

JANE M. DEWEY
*General Laboratories, United States Rubber Company, Passaic, New Jersey*

(Received November 14, 1946)

General expressions are given for the modulus of rigidity, $\bar{\lambda}_2$, and compressibility, $\bar{k}$, of a medium of Lame's constants, $\lambda_1$ and $\lambda_2$, loaded with a volume fraction, $\phi$, of a filler of constants $\lambda_1'$ and $\lambda_2'$. To terms in the first power of $\phi$

$$\bar{\lambda}_2=\lambda_2\left(1+\frac{15(\lambda_2'-\lambda_2)(\lambda_1+2\lambda_2)}{2\lambda_2'(3\lambda_1+8\lambda_2)+\lambda_2(9\lambda_1+14\lambda_2)}\phi\right)$$

$$\bar{k}=k+\frac{3+4\lambda_2k'}{3+4\lambda_2k}(k'-k)\phi.$$

If the "filler" is a gas at a pressure, $p$, in a nearly incompressible medium, these give

Young's modulus $\quad \bar{E}=E\left(1-\frac{E}{9p+4E}\phi\right).$

Modulus of rigidity $\quad \bar{\lambda}_2=\lambda_2(1-\frac{5}{3}\phi).$

Compressibility $\quad \bar{k}=k+\frac{3}{3p+4\lambda_2}\phi.$

Poisson's ratio $\quad \bar{\sigma}=\sigma\left(1-\frac{3E}{9p+4E}\phi\right),$

where $\phi$ is the volume loading, $p$ is the pressure within the spherical cavities in the deformed state. Barred symbols refer to the properties of the loaded material; unbarred, to the medium alone. Expressions for the displacements and stresses within the medium and the particles, neglecting interactions between particles, are also given.

---

IN a letter to the Editor of this Journal,[1] the writer gave a solution of the linear equations describing small elastic deformations of a medium containing a single spherical inclusion of any elastic constants. This problem had previously been solved for simple tension by J. N. Goodier.[2] The solution can be extended to the determination of the elastic constants of a medium loaded with small spheres by the method applied by A. Einstein[3] to the calculation of the viscosity of a suspension and by H. M. Smallwood[4] to the problem of rigid fillers. This method gives the terms in the first power of the volume loading only, and is valid, with neglect of surface effects, for very dilute suspensions.[*, 5]

Consider a single sphere of radius $R$ at the origin of coordinates in an isotropic medium in which the displacement, $\mathbf{s}$, at a large distance from the sphere is given by

$$\mathbf{s}\underset{r\to\infty}{\longrightarrow}Axi+Byj+Czk. \tag{1}$$

Lame's constants of the sphere will be denoted by $\lambda_1'$ and $\lambda_2'$, of the medium by $\lambda_1$ and $\lambda_2$. $\lambda_2$ is the modulus of rigidity, $\lambda_1$ may be defined by $\lambda_1+\frac{2}{3}\lambda_2=k^{-1}$, where $k$ is the compressibility.

The dilatation, strain, and radial components of the stress tensor, $\mathbf{T}$, in the medium are

$$\nabla\cdot\mathbf{s}=A+B+C\\ -6\lambda_2(3\lambda_1+5\lambda_2)^{-1}c_{-2}r^{-3}M_1(\theta,\phi), \tag{2}$$

$$s_r=\tfrac{1}{3}(r+b_{-2}r^{-2})(A+B+C)\\ +(r+c_{-2}r^{-2}+c_{-4}r^{-4})M_1(\theta,\phi), \tag{3}$$

$$s_\theta=[r+2\lambda_2(3\lambda_1+5\lambda_2)^{-1}c_{-2}r^{-2}\\ -\tfrac{2}{3}c_{-4}r^{-4}]M_2(\theta,\phi), \tag{4}$$

$$s_\phi=s_\theta M_2^{-1}(\theta,\phi)M_3(\theta,\phi), \tag{5}$$

$$\times\{[b_{-2}-\tfrac{2}{5}\lambda_2(3\lambda_1+5\lambda_2)^{-1}c_{-2}]$$
$$\times(A+B+C)^2-2\lambda_2c_{-2}(3\lambda_1+5\lambda_2)^{-1}$$
$$\times(A^2+B^2+C^2)\}, \quad (16)$$

for an infinite volume, where $V$ is the total volume of the loaded medium.

Assuming that to the first power of the volume loading the added energy due to $N$ spheres is $N$ times the added energy due to a single sphere

$$W/V=\tfrac{1}{2}\{\lambda_1+(\lambda_1-\tfrac{2}{3}\lambda_2)$$
$$\times[b_{-2}-\tfrac{2}{5}\lambda_2(3\lambda_1+5\lambda_2)^{-1}c_{-2}]R^{-3}\phi\}$$
$$\times(A+B+C)^2+\lambda_2[1-(\lambda_1-\tfrac{2}{3}\lambda_2)$$
$$\times(3\lambda_1+5\lambda_2)^{-1}c_{-2}R^{-3}\phi]$$
$$\times(A^2+B^2+C^2), \quad (17)$$

where $\phi=\tfrac{4}{3}\pi NR^3/V$, the partial volume of the filler particles.

The strain constants, $A$, $B$, and $C$ of this expression are those for the medium, as appears from the derivation. The observed mean strain constants, $A_0$, $B_0$, and $C_0$, can be calculated to the first approximation by the method outlined by Einstein. The displacement in the $x$ direction can be written

$$s_x=Ax+\textstyle\sum_i \Delta s_{xi}=A_0x, \quad (18)$$

where $\Delta s_{xi}$ is the added displacement due to the $i$th particle.

If $X_i$ is the $x$ coordinate of the center of the $i$th particle and $x_i$ is the $x$ coordinate measured from $X_i$

$$x=x_i+X_i. \quad (19)$$

Differentiating (18)

$$A_0=A+\frac{\partial}{\partial x}\textstyle\sum_i \Delta s_{xi}=A+\sum_i\frac{\partial}{\partial x_i}\Delta s_{xi}. \quad (20)$$

Assume that the added displacement is given by Eqs. (3) to (5) less the displacement in the medium at a distance from a particle

$$\Delta s_{xi}=s_{xi}-Ax=s_{xi}-Ax_i-AX_i. \qquad (21)$$

Two assumptions are made here: the first, that at any point the added displacement due to each particle is the same as if the other particles were not present, and second, that the displacement at a distance from a particle is described by the boundary condition of Eq. (1). The first assumption should be correct to the first approximation in the volume loading. The second is approximately correct if each particle is surrounded by a region free of particles of dimensions much greater than the particle radius. This is true of most of the particles if they are randomly distributed and the volume loading is much less than one.

For randomly distributed particles $\sum\Delta X_i=0$ and

$$\sum \Delta s_{xi}=\sum s_{xi}-Ax_i. \qquad (22)$$

We replace the summation by $N$ times the mean value of $\Delta s_{xi}$

$$\sum_i \frac{\partial}{\partial x_i}\Delta s_{xi}=N/V\int_V \frac{\partial \Delta s_{xi}}{\partial x_i}dV=N/V\int_S \Delta s_{xi}\frac{x_i}{r_i}da, \qquad (23)$$

where the first integral is over the volume and the second over the surface. To terms in $R^3r^{-2}$ the integral is independent of $r_i$ and since the limits of angle are independent of $i$,

$$A_0=A+N/V\int_S \Delta s_x \sin\theta\cos\phi da, \qquad (24)$$

where $\Delta s_x$ may be taken for a particle at the origin. $B_0$ and $C_0$ are obtained by interchanging variables.

Carrying out the integration

$$\begin{aligned}A_0=&(1+\tfrac{2}{5}(3\lambda_1+8\lambda_2)(3\lambda_1+5\lambda_2)^{-1}R^{-3}\phi)A\\&+\tfrac{1}{3}[b_{-2}R^{-3}-\tfrac{2}{5}(3\lambda_1+8\lambda_2)\\&\times(3\lambda_1+5\lambda_2)^{-1}c_{-2}R^{-3}](A+B+C)\phi, \qquad (25)\end{aligned}$$

whence, by combining with corresponding expressions for $B_0$ and $C_0$,

$$A_0+B_0+C_0=(1+b_{-2}\phi)(A+B+C), \qquad (26)$$

$$\begin{aligned}A_0^2+B_0^2+C_0^2=&[1+\tfrac{4}{5}(3\lambda_1+8\lambda_2)\\&\times(3\lambda_1+5\lambda_2)^{-1}c_{-2}R^{-3}\phi]\\&\times(A^2+B^2+C^2)\\&+\tfrac{2}{3}(b_{-2}-\tfrac{2}{5}c_{-2})R^{-3}\\&\times(A+B+C)^2\phi. \qquad (27)\end{aligned}$$

The constants $\bar{\lambda}_1$ and $\bar{\lambda}_2$ of the suspension are obtained by equating the expression for the work per unit volume

$$\begin{aligned}W/V=&\tfrac{1}{2}\bar{\lambda}_1(A_0+B_0+C_0)^2\\&+\bar{\lambda}_2(A_0^2+B_0^2+C_0^2) \qquad (28)\end{aligned}$$

to the expression (17).

Substituting (26) and (27) in (17) and equating coefficients of $(A_0+B_0+C_0)^2$

$$\begin{aligned}\bar{\lambda}_1=&\lambda_1-(\lambda_1+2\lambda_2)\\&\times(b_{-2}-2\lambda_2(3\lambda_1+5\lambda_2)^{-1}c_{-2})R^{-3}\phi. \qquad (29)\end{aligned}$$

Equating coefficients of $(A_0^2+B_0^2+C_0^2)$,

$$\begin{aligned}\bar{\lambda}_2=&\lambda_2[1-3(\lambda_1+2\lambda_2)(3\lambda_1+5\lambda_2)^{-1}c_{-2}R^{-3}\phi]\\=&\lambda_2\{1+15(\lambda_2'-\lambda_2)(\lambda_1+2\lambda_2)\\&\times[2\lambda_2'(3\lambda_1+8\lambda_2)\\&+\lambda_2(9\lambda_1+14\lambda_2)]^{-1}\phi\}. \qquad (30)\end{aligned}$$

Whence

$$\frac{1}{\bar{k}}=\bar{\lambda}_1+\tfrac{2}{3}\bar{\lambda}_2=\frac{1}{k}[1-(\lambda_1+2\lambda_2)b_{-2}R^{-3}\phi], \qquad (31)$$

or

$$k=k+(3+4\lambda_2k)(3+4\lambda_2k')^{-1}(k'-k)\phi. \qquad (32)$$

Two special cases are of importance:

(a) The case of a rigid filler,

$$\lambda_2'\gg\lambda_2, \quad \text{and} \quad k'\ll k.$$

Then,

$$k=k[1-(1+\tfrac{4}{3}\lambda_2k)\phi]. \qquad (32a)$$

$$\bar{\lambda}_2=\lambda_2[1+\tfrac{5}{2}(\lambda_1+2\lambda_2)(\lambda_1+\tfrac{8}{3}\lambda_2)^{-1}\phi]. \qquad (30a)$$

(b) The case of included air or other gas

$$\lambda_2'=0, \quad \lambda_1'\simeq p,$$

where $p$ is the pressure of the included gas

(after the deformation)*

$$k = k + (3+4\lambda_2 k)(3p+4\lambda_2)^{-1}(1-kp)\phi. \quad \text{(32b)}$$

The application of this formula to data on elastomers containing small amounts of gas is difficult as $p$ is not known and $\lambda_2$ and $p$ are of the same order of magnitude. If aged samples of reasonably permeable elastomers are studied, $p$ can probably be taken as 1 atmosphere. In GR-I or other nearly impermeable materials, $p$, for very long times after molding, is probably approximately equal to the gas pressure at the time of molding. It may, therefore, differ considerably from 1 atmosphere. For any reasonably low gas pressure $kp \ll 1$ and

$$\bar{k} \simeq k + (3+4\lambda_2 k)(3p+4\lambda_2)^{-1}\phi, \quad \text{(32b')}$$

$$\bar{\lambda}_2 \simeq \lambda_2[1 - \tfrac{5}{3}(\lambda_1+2\lambda_2)(\lambda_1+\tfrac{14}{9}\lambda_2)^{-1}\phi]. \quad \text{(30b)}$$

The approximate formulae for Young's modulus, $E$, and Poisson's ratio, $\sigma$, valid for a medium of $\lambda_1 \gg \lambda_2$, containing gas at a low pressure are

$$\bar{E} \simeq E[1 - E(9p+4E)^{-1}\phi], \quad \text{(33)}$$

$$\bar{\sigma} \simeq \sigma[1 - 3E(9p+4E)^{-1}\phi]. \quad \text{(34)}$$

The percentage changes in the modulus of rigidity and Young's modulus are of the same order of magnitude as the volume percent of gas in the material. The change in compressibility of a gum rubber stock caused by 0.01 percent of gas at atmospheric pressure is of the order of the compressibility, however. At pressures above an atmosphere, the compressibility varies rapidly with the pressure of the included gas.

Within an embedded sphere and at its surface,

$$\nabla \cdot \mathbf{s} = 3a_1, \quad \text{(35)}$$

$$s_r = (c_1 M_1(\theta, \phi) + a_1)r, \quad \text{(36)}$$

$$s_\theta = c_1 r M_2(\theta, \phi), \quad \text{(37)}$$

$$s_\phi = c_1 r M_3(\theta, \phi), \quad \text{(38)}$$

$$T_{rr} = 2\lambda_2' c_1 M_1(\theta, \phi) + (3\lambda_1' + 2\lambda_2')a_1, \quad \text{(39)}$$

$$T_{r\theta} = 2\lambda_2' c_1 M_2(\theta, \phi), \quad \text{(40)}$$

$$T_{r\phi} = 2\lambda_2' c_1 M_3(\theta, \phi), \quad \text{(41)}$$

$$a_1 = (\lambda_1 + 2\lambda_2)(4\lambda_2 + 3\lambda_1' + 2\lambda_2')^{-1} \times (A+B+C), \quad \text{(42)}$$

$$c_1 = 15\lambda_2(\lambda_1+2\lambda_2)[2\lambda_2'(3\lambda_1+8\lambda_2) + \lambda_2(9\lambda_1+14\lambda_2)]^{-1}. \quad \text{(43)}$$

As would be expected, the radial components of stress on the surface of a particle have their maximum value when the filler is rigid, the case treated by Smallwood.[4]

Comparison of Eq. (30) for the modulus of rigidity with the calculation made by Taylor[6] of the viscosity of a suspension of fluid spheres of viscosity in a fluid of viscosity

$$\bar{\mu} = \mu\left[1 + \frac{5\mu' + 2\mu}{2(\mu' + \mu)}\phi\right],$$

shows that the two relations are of the same form only for $\lambda_1$, $\lambda_1'$, $\mu'$, and $\lambda_2'$ infinite. The difference between the two cases lies in the importance of surface tension in the suspension of fluid droplets. Suspension of droplets of any fluid in another increases the viscosity, while blowing, for instance, reduces the rigidity of a solid. Added work on the fluid suspension is done against surface tension, deforming the droplets. Mathematically, the difference appears in the omission of the condition that the normal component of stress on the droplet be single valued. This difference in stress on the two sides of the surface is balanced by surface tension.

---

* The equations and boundary conditions used in determining the displacements and stresses of Eqs. (2)-(8) are the conditions of equilibrium for a media obeying Hooke's law and a linear relation between volume and pressure. When differential values of the constants are used, these conditions are valid for media of any type, since a linear relation may always be assumed for an infinitesimal deformation. For an ideal fluid $\lambda_2 = 0$ and $dp = -\lambda_1(dV/V)$, which reduces approximately to $\lambda_1 = p$ for a gas.

# Heat Transfer between a Fluid and a Porous Solid Generating Heat[1]

Stuart R. Brinkley, Jr.[2]
*Central Experiment Station, U. S. Bureau of Mines, Pittsburgh, Pennsylvania*

(Received September 16, 1946)

The theory, due to Anzelius, of the transfer of heat between a fluid flowing with constant velocity through a porous solid is extended to include the case where the solid generates heat. Expressions are obtained for the temperatures of solid and fluid as functions of position and time, it being assumed that the heat source function is a linear function of the temperature of the solid with coefficients independent of position and time. The application of the theory to a description of the temperature in catalytic reactions is indicated.

## INTRODUCTION

A THEORY of the transfer of heat between a porous body and a warm fluid has been developed by Anzelius[3] and Schumann.[4] A fluid carrying heat is supposed to flow with constant velocity through a porous substance such as a solid body in a finely divided state which is initially at a different temperature than that of the fluid. The temperatures of solid and fluid are determined for different positions at later times, it being assumed that the volume specific heats of solid and fluid are constant, and that there is no conduction of heat in either the solid or the fluid. The problem is, of course, idealized by these simplifying assumptions. However, in his extensive series of measurements of heat transfer from a gas stream to a bed of broken solids, Furnas[5] obtained excellent experimental confirmation of the simple theory.

In the present communication, this theory is extended to the case where the solid is generating heat. In addition to the assumptions above, it is further assumed that the heat source function is a linear function of the temperature of the porous solid, the parameters of the linear function being independent of position or time.

The theory should be applicable to a calculation of solid and gas temperatures in catalytic reactions if the reaction vessel is so designed that all but a negligible amount of the heat of reaction is transported by the sensible heat of the gas and if either (a) the reaction is of the zeroth other without volume change, or (b) the flux of the gas through the reaction vessel is so large that reaction is limited to a few percent.

## THE BASIC EQUATIONS

Consider a semi-infinite ($x \geqslant 0$) porous solid through which a fluid is flowing in the positive $x$-direction with volume current $g$. Let the temperatures of solid and fluid at a distance $x$ from the origin and at time $t$ be $U(x, t)$ and $V(x, t)$, respectively. It is assumed that the solid in a particular element of volume loses heat by transfer to the fluid and gains heat by generation at a rate $F$ per unit volume of porous solid, where in general,

$$F = F(x, t; U), \tag{1}$$

and that the fluid in the element of volume gains heat by transfer from the solid and by the flux of heat into the volume which accompanies the flow of the fluid. By considering the rate of increase of heat in the solid and fluid contained between the transverse planes $x$ and $x+dx$, and assuming that the rate of heat transfer is governed by Newton's law of cooling, it is easy to show that the transfer of heat from solid to fluid is governed by the relations,

$$\begin{gathered} c_s\rho_s\frac{\partial U}{\partial t}+h(U-V)-F(x, t; U)=0, \\ c_f\rho_f\frac{\partial V}{\partial t}+h(V-U)+c_f\rho_f g\frac{\partial V}{\partial x}=0, \end{gathered} \tag{2}$$

where $c_s$ and $c_f$ are the heat capacities per unit

mass of solid and fluid, respectively, $\rho_s$ and $\rho_f$ are masses of solid and gas contained in unit volume of porous solid, respectively, $h$ is the coefficient of heat transfer between solid and gas per unit volume of porous solid, and where it has been assumed that the quantities $c_s\rho_s$, $c_f\rho_f$, and $g$ are constants.

In the present communication, the solution of Eqs. (2) is obtained for the case where the heat source function is a linear function of the temperature of the solid,

$$F(x, t;\, U)=h(\alpha+\beta U), \tag{3}$$

with $\alpha$ and $\beta$ constant. If the heat is generated by chemical reaction, one will usually have

$$F\sim e^{-\epsilon/RT}=e^{-\epsilon/RT_0}\left[1+\frac{\epsilon}{RT_0^2}(T-T_0)+\cdots\right],$$

from which the accuracy of the linear approximation, Eq. (3), may be estimated. Here, $\epsilon$ is the activation energy of the reaction, $R$ is the gas constant, and $T$ is the absolute temperature.

For convenience, the temperature of the inlet fluid is taken to be zero, and the temperature of the porous solid at the initial instant of time on the same temperature scale is denoted by $U_0$. The boundary conditions for Eqs. (2) are therefore

$$\begin{aligned} &U=U_0, \quad x\geqslant gt,\\ &V=0, \quad\;\; x=0. \end{aligned} \tag{4}$$

The first condition is a statement of the fact that the porous solid is at its initial temperature at points which have not yet been reached by the fluid.

With the notation $a=h/c_f\rho_f g$, $b=h/c_s\rho_s g$, and the change of independent variable

$$\xi=ax, \quad \tau=b(gt-x), \tag{5}$$

Eqs. (2) and (3) become

$$\begin{aligned} \partial U/\partial\tau&=V+(\beta-1)U+\alpha,\\ \partial V/\partial\xi&=U-V, \end{aligned} \tag{6}$$

with the boundary conditions, $U=U(\xi,\tau)$, $V=V(\xi,\tau)$,

$$U(\xi, 0)=U_0, \quad V(0, \tau)=0. \tag{7}$$

Equations (6) and (7) lead immediately to a pair of ordinary differential equations for $U(0,\tau)$ and $V(\xi, 0)$.

$$\begin{aligned} &\frac{d}{d\tau}U(0,\tau)+(1-\beta)U(0,\tau)=\alpha, \quad U(0,0)=U_0,\\ &\frac{d}{d\xi}V(\xi,0)+V(\xi,0)=U_0, \quad V(0,0)=0. \end{aligned} \tag{8}$$

The subsidiary boundary conditions are obtained by solution of Eq. (8).

$$\begin{aligned} &U(0,\tau)=U_0e^{(\beta-1)\tau}-\frac{\alpha}{1-\beta}\left[e^{(\beta-1)\tau}-1\right],\\ &V(\xi,0)=U_0(1-e^{-\xi}). \end{aligned} \tag{9}$$

Equation (6) may be simplified in a manner analogous to that employed by Schumann[4] by introducing new independent variables, $\Gamma$ and $\Delta$, where

$$\begin{aligned} \Gamma&=(U+V)e^{\xi+(1-\beta)\tau},\\ \Delta&=(U-V)e^{\xi+(1-\beta)\tau}. \end{aligned} \tag{10}$$

One obtains

$$\begin{aligned} &\partial\Gamma/\partial\tau+\partial\Delta/\partial\tau=\Gamma-\Delta+2\alpha e^{\xi+(1-\beta)\tau},\\ &\partial\Gamma/\partial\xi-\partial\Delta/\partial\xi=\Gamma+\Delta, \end{aligned} \tag{11}$$

and by further differentiation

$$\partial^2\Delta/\partial\xi\partial\tau=\Delta. \tag{12}$$

The boundary conditions for $\Gamma$ and $\Delta$ are evidently

$$\begin{aligned} &\Gamma(\xi,0)=U_0(2e^{\xi}-1), \quad \Delta(\xi,0)=U_0,\\ &\Gamma(0,\tau)=\Delta(\xi,0)=U_0+\frac{\alpha}{1-\beta}\left[e^{(1-\beta)\tau}-1\right]. \end{aligned} \tag{13}$$

The characteristics of Eq. (12) are the straight lines parallel to the axes through the point of interest $(\xi, \tau)$, and the boundary values of $\Delta$ are specified along a pair of characteristics (the axes). The solution of Eqs. (12) and (13) is thus a characteristic initial value problem and is straightforward by the method of Riemann.[6] The Reimann function is $I_0[2((\xi-\xi')(\tau-\tau'))^{\frac{1}{2}}]$, in which $\xi'$ and $\tau'$ are the variables of integration around the boundary of the region determined by the characteristics and the axes, and $I_0$ is the zeroth-order Bessel function of the first kind for

---

[6] R. Courant and D. Hilbert, *Methoden der Mathematischen Physik* (Julius Springer, Berlin 1924), Vol. II, pp. 311–317.

imaginary argument. The solution for $\Delta$ is

$$\Delta = U_0 I_0[2(\xi\tau)^{\frac{1}{2}}] + \alpha \int_0^{\tau} e^{(1-\beta)\tau'} I_0[2(\xi(\tau-\tau'))^{\frac{1}{2}}] d\tau'. \qquad (14)$$

This result may be rewritten in the convenient form,

$$\Delta = U_0 I_0[2(\xi\tau)^{\frac{1}{2}}] + \frac{\alpha}{1-\beta} \varphi[\tau(1-\beta), \xi/(1-\beta)], \qquad (15)$$

in which the function $\varphi(x, y)$, defined by

$$\varphi(x, y) = e^{x} \int_0^{x} e^{-x'} I_0[2(x'y)^{\frac{1}{2}}] dx', \qquad (16)$$

has been introduced. This function, originated by Laplace,[7] has been discussed by Thomas,[8] who has obtained the following useful properties:

$$\left.\begin{aligned} &\varphi(x, y) + \varphi(y, x) = e^{x+y} - I_0[2(xy)^{\frac{1}{2}}], \\ &(\partial/\partial x)\varphi(x, y) = \varphi(x, y) + I_0[2(xy)^{\frac{1}{2}}], \\ &(\partial/\partial y)\varphi(x, y) = \varphi(x, y) - (\partial/\partial y) I_0[2(xy)^{\frac{1}{2}}], \\ &\varphi(0, y) = 0, \quad \varphi(x, 0) = e^{x} - 1. \end{aligned}\right\} \qquad (17)$$

Tables of a related function,

$$g(x, y) = e^{-x^2-y^2} \varphi(x^2, y^2), \qquad (18)$$

have been constructed[9] and are to be published. By means of Eqs. (17), Eq. (15) is readily shown to satisfy Eqs. (12) and (13), and this solution is unique.[6]

An expression for the quantity Γ can be obtained by the integration of either of Eqs. (11), employing Eqs. (15) and (17). Expressions for the temperatures of solid and fluid can then be obtained by the combination of this result with the solution for the variable $\Delta$, Eq. (15). However, the temperature of the fluid is obtained more directly from the relation,

$$\partial V/\partial \xi = \Delta e^{-\xi-(1-\beta)\tau}, \qquad (19)$$

which results from the substitution of the definition of $\Delta$ in the second of Eqs. (6). The temperature of the solid is then obtained at once by the combination of this result with the expression for $\Delta$.

## THE TEMPERATURES OF SOLID AND FLUID

If the solution for $\Delta$ be combined with Eq. (19), there is obtained

$$\frac{\partial V}{\partial \xi} = \left\{ U_0 I_0[2(\xi\tau)^{\frac{1}{2}}] + \frac{\alpha}{1-\beta} \varphi[\tau(1-\beta), \xi/(1-\beta)] \right\} e^{-\xi-(1-\beta)\tau}. \qquad (20)$$

Integrating this expression between limits as an ordinary differential equation, and recalling that $V(0, \tau) = 0$, one obtains

$$V = U_0 \varphi(\xi, \tau) e^{-\xi-(1-\beta)\tau} + \frac{\alpha}{1-\beta} e^{(\beta-1)\tau} \int_0^{\xi} e^{\xi'} \varphi[\tau(1-\beta), \xi'/(1-\beta)] d\xi'. \qquad (21)$$

The integral of Eq. (21) can be evaluated by the method of integration by parts, employing the properties of $\varphi(x, y)$ which are summarized by Eqs. (17). The result of this process is

$$\int_0^{\xi} e^{-\xi'} \varphi[\tau(1-\beta), \xi'/(1-\beta)] d\xi' = \frac{1-\beta}{\beta} \{ \varphi(\xi, \tau) - \varphi[\xi/(1-\beta), \tau(1-\beta)] + [e^{\xi/(1-\beta)} - e^{\xi}] e^{\tau(1-\beta)} \} e^{-\xi}, \qquad (22)$$

if $\beta \neq 0$, and

$$\int_0^{\xi} e^{-\xi'} \varphi[\tau(1-\beta), \xi'/(1-\beta)] d\xi' = \{ \xi\varphi(\tau, \xi) + \tau\varphi(\xi, \tau) - (\xi\tau)^{\frac{1}{2}} I_1[2(\xi\tau)^{\frac{1}{2}}] \} e^{-\xi}, \qquad (23)$$

---

[7] H. Bateman, *Partial Differential Equations of Mathematical Physics* (The Cambridge University Press, New York 1932), p. 128.

[8] H. C. Thomas, J. Am. Chem. Soc. 66, 1664 (1944).

[9] S. R. Brinkley, Jr. and R. F. Brinkley, unpublished tables.

if $\beta=0$. $I_1$ is the first-order Bessel function of the first kind for purely imaginary argument. Therefore, the temperature of the fluid is given by

$$V(\xi,\tau)=\left(U_0+\frac{\alpha}{\beta}\right)\varphi(\xi,\tau)e^{-\xi-(1-\beta)\tau}+\frac{\alpha}{\beta}\{e^{\beta\xi/(1-\beta)}-\varphi[\xi/(1-\beta),\tau(1-\beta)]e^{-\xi-(1-\beta)\tau}-1\},\tag{24}$$

if $\beta\neq0$, and by

$$V(\xi,\tau)=\{(U_0+\alpha\tau)\varphi(\xi,\tau)+\alpha\xi\varphi(\tau,\xi)-\alpha(\xi\tau)^{\frac{1}{2}}I_1[2(\xi\tau)^{\frac{1}{2}}]\}e^{-\xi-\tau},\tag{25}$$

if $\beta=0$. The temperature of the solid is immediately obtained by combination of these results with the expression for $\Delta$. Then,

$$U(\xi,\tau)=\left(U_0+\frac{\alpha}{\beta}\right)\{e^{\beta\tau}-\varphi(\tau,\xi)e^{-\xi\ (1-\beta)\tau}\}-\frac{\alpha}{\beta}\left\{\frac{1}{1-\beta}\varphi[\tau(1-\beta),\xi/(1-\beta)]e^{-\xi-(1-\beta)\tau}+1\right\},\tag{26}$$

if $\beta\neq0$, and

$$U(\xi,\tau)-U_0=\{[\alpha(\xi+1)-U_0]\varphi(\tau,\xi)+2\tau\varphi(\xi,\tau)-\alpha(\xi\tau)^{\frac{1}{2}}I_1[2(\xi\tau)^{\frac{1}{2}}]\}e^{-\xi-\tau},\tag{27}$$

if $\beta=0$. The rate of heat transfer from solid to fluid per unit volume of porous solid is equal to $h\Delta(\xi,\tau)c^{-\xi-(1-\beta)\tau}$.

The application of these results to particular systems will be the subject of subsequent reports from this laboratory.

## THE STEADY STATE

The steady state values of the temperatures of fluid and solid are obtained from Eqs. (24) to (27) by proceeding to the limit of infinite $\tau$. The function $\varphi(\xi,\infty)$ is finite for finite $\xi$, and the function $\varphi(\tau,\xi)$ tends to $e^{\xi+\tau}$ as $\tau$ tends to infinity. Then, one obtains

$$V(\xi,\infty)=(\alpha/\beta)\{e^{\beta\xi/(1-\beta)}-1\},\quad U(\xi,\infty)=\frac{\alpha}{\beta}\left\{\frac{1}{1-\beta}e^{\beta\xi/(1-\beta)}-1\right.\tag{28}$$

if $\beta\neq0$, and

$$V(\xi,\infty)=\alpha\xi,\quad U(\xi,\infty)=\alpha(\xi+1),\tag{29}$$

if $\beta=0$. These steady state solutions have been previously obtained and employed for the calculation of catalyst and gas temperatures in a typical operation of the Michael process for the synthesis of hydrocarbons from carbon monoxide and hydrogen.[10]

## Concerning Estimates of the Minimum Sparking Potential Based upon the Cathode Work Function

DONALD H. HALE AND W. S. HUXFORD
*Department of Physics, Northwestern University, Evanston, Illinois*
April 4, 1947

JACOBS and LaRocque[1] have recently suggested a method for estimating the minimum sparking potential for cold cathode tubes. They measured the minimum sparking potentials for several cathodes in argon and calculated the corresponding value for $\gamma_m$. These values for $\gamma_m$ were then plotted against the corresponding values of the work functions and the minimum sparking potentials. By use of these two curves an attempt is made to estimate $\gamma_m$ and the minimum sparking potential in argon for any cathode, provided only the work function for the cathode material is known. Applying this method the authors obtain an approximate and reasonable value for the minimum sparking potential of a sodium cathode in argon.

This method of determining $\gamma_m$ from sparking data is not reliable. It has been pointed out that this procedure cannot be expected to yield good values for $\gamma$ in all cases.[2] This is shown by the results obtained by these authors since their values of $\gamma$ vary widely from those found by other workers. Schöfer[3] and Engstrom[4] found that the values of $\gamma$ for a barium cathode in argon increased with increasing values of $E/p$ starting with an $E/p$ of about 40. The authors found just the opposite. Their values of $\gamma$ decrease with increasing values of $E/p$. Further, their value of $\gamma$ at an $E/p$ of about 40 is three times greater than that measured by Schöfer. Since they worked at higher gas pressures than did earlier workers it may be that in their work the mechanism of electron emission by photons at the cathode was enhanced. However it is difficult to see how this could account entirely for their high values of $\gamma$.

The agreement between the calculated and experimental values of the minimum sparking potential for a sodium cathode in argon may be fortuitous. Bowls[5] measured $\gamma$ for a sodium cathode in nitrogen and Ehrenkrantz[6] measured the sparking potentials. Bowls found that the sodium cathode gave distinctly lower values of $\gamma$, for a wide range of values of $E/p$, than did a platinum cathode. Yet, Ehrenkrantz found that the sodium cathode showed a lower minimum sparking potential than did the platinum. Hale[7] and Ehrenkrantz found a similar situation with regard to sodium cathodes in hydrogen. The authors explain the lower $\gamma$ for sodium on the grounds that hydrogen or nitrogen combines with sodium to give a surface of high work function. Such an assumption would explain the low values for $\gamma$ but it cannot explain, on the basis of the author's argument, the observed low value of the minimum sparking potential. Actually it has been pointed out that sodium surfaces in hydrogen or nitrogen show low photoelectric thresholds.[8] Here then is a case of a cathode material which has a low work function, which shows low values of $\gamma$, in at least two gases, and yet has a low minimum sparking potential.

There are other interesting examples. The work functions for nickel and platinum are 5.01 and 6.30 volts, respectively.[9] Yet the minimum sparking potential for argon with cathodes of these materials is 195 volts in each case.[10] The work function for iron is 4.72 volts.[9] However, the minimum sparking potential for argon with an iron cathode is 265 volts. This is distinctly higher than the minimum sparking potential for platinum in argon. Yet platinum has the higher work function.

It is probably correct to say that, in a very general way, materials with low work functions will show high values of $\gamma$. However, exceptions are known and any prediction of the minimum sparking potential which is based upon the work function of the cathode may be badly in error. Much work remains to be done before this point is clear.

We wish to call attention to what appears to be a misstatement. The authors state that Bowls found a lower $\gamma$ for platinum in a large region of $E/p$ than he did for sodium. It appears that they intended to refer to a lower $\gamma$ for sodium which was what Bowls observed.

## Measurement of the Dynamic Stretch-Modulus and Hysteresis of Tire Cords

W. JAMES LYONS AND IRVEN B. PRETTYMAN
*The Firestone Tire and Rubber Company, Akron 17, Ohio*
April 17, 1947

THE modulus of elasticity (Young's) of synthetic filaments and films has been measured by Meyer and Lotmar[1] and Ballou and Silverman,[2] who employed sound-velocity methods which gave the dynamic value of the modulus at acoustical frequencies. These methods, however, are not applicable to the measurement of concomitant hysteretic losses. Wakeham and Honold[3] studied the elastic modulus and hysteresis effects in cotton, rayon, and Nylon tire cords under dynamic conditions, but at a relatively low frequency: 1 cycle/sec.

The exploratory studies reported herein were undertaken to develop a method for measuring not only the dynamic

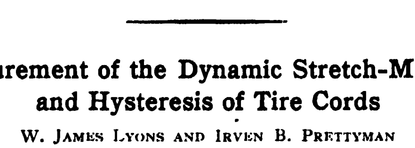

FIG. 1. Schematic diagram of cord stretch-vibrometer.

TABLE I. Representative measurements of dynamic properties of conventional tire cords, obtained on cord vibromete at constant impressed force-amplitude.

| Cord sample | | Static properties (conditioned at 65% R.H., 70°F) | | | Dynamic properties (at approximately 14% R.H., 78°F) | | |
|---|---|---|---|---|---|---|---|
| Fiber | Construction | Breaking load (Kg) | Ultimate elongation (Percent) | Resonant frequency, $f_0$ (cycles/sec.) | Dynamic modulus, $E$ ($10^{10}$ dynes/cm$^2$) | Internal friction, $\eta$ ($10^6$ poises) | Hysteresis index, $2\pi f\eta$ ($10^{10}$ dynes/cm$^2$) |
| Cotton | 11/4/2 | 8.5 | 14.3 | 169 | 7.7 | 4.0 | 0.42 |
| Viscose rayon | 1100/2 | 6.8 | 15.9 | 148 | 11.2 | 5.3 | 0.49 |
| Nylon | 210/3/3 | 14.6 | 19.5 | 116 | 6.1 | 2.4 | 0.17 |

modulus of filaments, yarns, and cords in the sonic or near-sonic range, but also their internal frictional (hysteretic) properties. Measurements of the modulus and friction have been successfully made on cotton, rayon, and Nylon cords forcibly vibrated longitudinally at frequencies above 100 cycles/sec., by electromagnetic means.

The apparatus is shown schematically in Fig. 1. A small light-weight coil is placed coaxial with the core of a strong electromagnetic field coil, so that the former is in a powerful magnetic field when a direct current passes through the field coil. The small coil is rigidly mounted on a plastic rod which passes through a hole at the axis of the core. The rod is supported by pieces of the test cord attached coaxially at each end. Static loads at the outer ends of the two pieces of cord balance each other and allow the cords to be placed under tension without displacing the rod and small coil. When an oscillating current is sent through this coil, the rod vibrates longitudinally, causing small periodic extensions and contractions in the pieces of test cord. In the initial trials, a small mirror was rotatably connected to the rod at the end opposite the vibrating coil, so that by means of an optical-lever system, amplitude of vibration could be detected and measured on a ground-glass scale. It was subsequently found that a micrometer microscope could be advantageously substituted for the optical-lever system, with improved accuracy; and this method was used to obtain the results reported herein. In the present experiments the vibrating coil was energized by a 50-watt power amplifier which was controlled by a regular commerical calibrated audiofrequency oscillator unit.

The principle underlying the present method is expressed by the equation of motion of the vibrating element under impressed force:

$$m(d^2s/dt^2)+(\eta/q)(ds/dt)+(E/q)s=F\cos\omega t, \qquad (1)$$

where $m$ = vibrating mass, $s$ = displacement from the equilibrium position; $\eta$ = coefficient of internal friction (hysteresis); $E$ = dynamic stretch modulus; $q$ = shape factor of cord; and $F$ = amplitude of applied force having frequency $\omega/2\pi$. Equation (1) has been applied to forced compressive vibrations in flat cylinders of rubber by Gehman, Woodford, and Stambaugh,[4] and to shear vibrations in similar specimens by Dillon, Prettyman, and Hall.[5] The design of the driving mechanisms used by these groups provided the prototype for the corresponding elements of the present equipment.

It can be shown readily that at resonance, to good approximation:

$$E=mq\omega_0^2=m(L/2A)(2\pi f_0)^2, \qquad (2)$$

where $A$ = cross-sectional area of cord or yarn (exclusive of interstices between fibers); $L$ = free length of each matched piece of cord, and $f_0$ = resonant frequency.

Equation (2) has been applied to observations of resonant frequencies made with the cord stretch-vibrometer on three kinds of tire cord, with the results summarized in Table I. To identify the cords the conventional static properties have been included in the table. All cord samples were vibrated under a tensional load of 1.2 kg, with $L=25.4$ cm (10 in.). The effective mass of the vibrating system, $m$, was found to be 17.0 g. The cross-sectional area of each sample was determined from the weight of a 200-cm specimen of the cord and the bulk density of the component fiber.

Internal friction, $\eta$, may be readily derived from observations on the stretch-vibrometer by means of the equation:

$$\eta=Fq/s_m\omega_0, \qquad (3)$$

$s_m$ being the maximum (resonance) strain-amplitude. Values of this quantity, as well as of an index of hysteresis losses $2\pi f\eta$, are entered in Table I. The latter quantity has been shown, in the case of rubber,[5] to be substantially independent of frequency.

## On the Analysis of Internal Flow Machinery

SABINUS H. CHRISTENSEN
*Carrier Corporation, Syracuse, New York*

April 11, 1947

THIS is a brief report of a new method of applied research which has opened an area of analysis hitherto inaccessible to internal flow machinery having moving passages (centrifugal and axial-flow compressors, and turbines).

The new technique is based on the rejection of the idealization in the gas-dynamic analysis of internal flow machinery that the fluid may be considered to be a compressible ideal gas, i.e. frictionless. It has been found by exhaustive analytic study of test data that the use of the frictionless gas concept fails to explain performance within very wide limits.

It is well known that the inefficiency of internal flow machinery is caused by the dissipation of available energy which is reflected in increase of entropy through the machine. The basic domain for research on internal flow machinery is then recognized to be that of making a detailed explanation of entropy increase caused by friction, separation, and turbulence. Taking the detailed change of entropy into full account now explains such hitherto inaccessible phenomena as quantitative values of shock loss at the entrance to rotating grids, and the theory of the maximum flow in a centrifugal compressor (as have been done by the writer in unpublished company reports).

The new method is directed towards the local evaluation of entropy in rapidly moving or rotating passages. The method utilizes the device of speeding up the moving passage (or the equally effective method of using a very heavy gas with slower passage speeds) until somewhere, within the passage the relative velocity is locally sonic. The exact equations of state, energy, and continuity are then satisfied by a definite entropy value at the blocking point. If a study is made of the energy *vs.* area gradient along the passage it will be seen that the blocking point is fixed by the passage design, thus providing the fourth simultaneous equation which solves the problem of determining the exact thermodynamic state inside a rapidly moving passage. It is believed that this technique is far superior to the less reliable method of trying to measure the state of the fluid by instruments which are forced to transmit their data through commutator rings and packings.

Instead of working with entropy change, re-arrangement of the gas-dynamic equations shows that the isentropic relations apply if the passage area is modified by the factor $\exp(-J\Delta S/R)$, $J$ being Joule's mechanical equivalent of heat, $\Delta S$ the increase in entropy, and $R$ the gas constant.

## Objective Aperture System for the Electron Microscope

CECIL E. HALL
*Massachusetts Institute of Technology, Cambridge, Massachusetts*

April 17, 1947

THE conventional objective aperture used in magnetic electron microscopes consists of a circular diaphragm about 25 microns in diameter, fixed with respect to the lens and coaxial with it. It prevents electrons scattered through angles larger than about $10^{-2}$ radian from reaching the image plane, thereby reducing background intensity and enhancing contrast in the image. An objective aperture is necessary for the examination of thick objects producing a high scattered intensity, such as replicas, sections, and the like, but it is of lesser value in the examination of specimens of suitable thinness and contrast. Electron microscopists are familiar with the many practical difficulties associated with the use of apertures. They are difficult to make, install, and align, and must be replaced frequently, because they accumulate films of non-conducting material which become charged and produce distortions in the image. It is therefore desirable to have an objective aperture system that can be installed quickly and renewed as occasion demands.

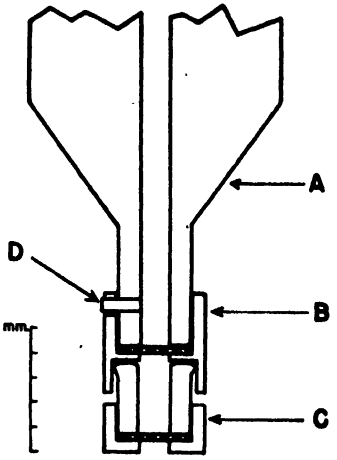

FIG. 1. Objective aperture system.

An objective aperture system having the advantage that it is attached to the specimen cartridge rather than to the lens, is shown in Fig. 1. It has been used successfully in this laboratory with an RCA type B electron microscope. The device consists essentially of a second screen mounted and aligned so that each opening of the specimen screen has below it a corresponding opening serving as an aperture stop. Aperture screens may be detached readily, if they are not required for the specimen under examination, and may be renewed frequently from standard material. *A* is the lower part of the specimen cartridge to which is fitted the cap, *B*, containing the specimen. The tip, *C*, containing the aperture screen is mounted in a friction cup so that it may be turned about the axis and rocked slightly to give small lateral displacements. Aperture screens, which must be non-magnetic since they are in the lens field, are punched from 200-per-inch copper Lektromesh.[1]

The procedure in using the device is as follows: Clip the cartridge to the stage of a 100-power optical microscope with cross-hairs in the eyepiece. Focus on the object screen and rotate the eyepiece until the cross-hairs are aligned with the screen wires. Focus on the aperture screen and rotate the tip *C* until the screen wires are square with the cross-hairs. Refocus on the object and center an open square on the cross-hairs with the mechanical stage. Focus on the aperture mesh and rock the tip, *C*, until an open square is centered on the cross-hair intersection. This procedure usually takes one or two minutes. Possibly a smaller object-to-aperture distance than the three milli-

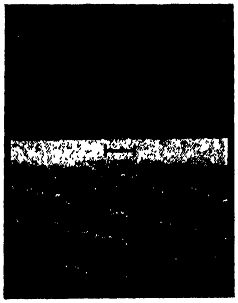

FIG. 2. Collodion-silicon replica of glass grating, shadowed with chromium; (a) without an aperture, (b) with mesh aperture. X3600.

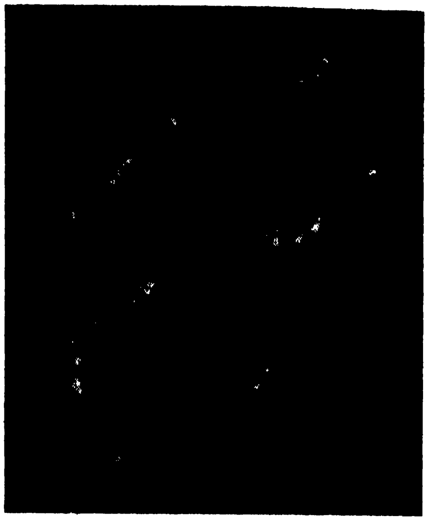

FIG. 3. Dark-field electron micrograph of carbon particles shadowed with uranium. ×11,666.

meters shown in the diagram would provide adequate contrast in the image and at the same time simplify the alignment of the two meshes.

Two micrographs of a collodion-silicon replica of a glass grating are shown in Fig. 2, to demonstrate the difference in contrast with and without the aperture screen; (a) was taken without an aperture, while (b) was taken with one. The replica was shadowed with chromium. Contacts were made from the original micrographs on the same Eastman Medium lantern slide plate and a contact print made from this on F-3 Kodabromide. Contrast, of course, depends on the photographic processing, but an effort was made to have the prints represent a reasonable comparison of the original plates. Although improved contrast in the image is most pronounced with thick specimens, improvement has also been noted in thin specimens containing small particles of low scattering power. Open areas in standard Lektromesh screens are square, but no distortions have been noted in the image which could be attributed to this unusual shape. Also, it is possible that electrons may be so widely scattered that they will reach the image plane through an opening other than the one directly below the point under observation. In the mesh normally employed the solid parts are three times as wide as the open squares, and since scattered intensity falls off rapidly with angle, the proportion of such widely scattered electrons appears to be inappreciable.

The multiple aperture was originally devised to enhance contrast in images of thick specimens, but it has proved to be very useful also for dark-field electron microscopy. If alignment of the two meshes is not perfect, and it very rarely is, a part of each object opening will be seen in dark field. An example of a dark-field micrograph made in this manner is reproduced in Fig. 3. The specimen consisted of carbon particles[2] on a collodion film, shadowed with uranium to a calculated thickness of about 13A. Shadow areas are dark because they contain no uranium, hence scatter least. The uranium film appears as a background of discrete spots ranging in diameter from 50 to 200A. The spots are quite well resolved for dark field, indicating that they are produced by electrons that have been scattered coherently and are therefore confined to a narrow angular aperture and velocity range. The dark-field micrograph thus reveals the presence of small ordered regions in the film that are not perceptible as such in bright field. Similar structure has also been observed with thin films of several other metals and compounds.

Images of the carbon particles shown in Fig. 3 are characterized by bright contours and dark centers, resulting from the fact that at small angles there is a relatively high intensity from electrons scattered close to the surface. Electrons scattered within the particles are spread over a much larger solid angle so that a smaller proportion enter the limiting aperture. An interesting feature, not visible in bright field, is the occurrence of numerous bright spots at the edges of the particles. This appearance is not associated with the uranium since the spots also appear in unshadowed specimens. In the micrograph shown, all such spots appear on edges *away* from the aperture, hence represent pencils that have been deflected *under* the particles. However, the occurrence on one edge only, is dependent on alignment of the electron microscope and on the objective current. They have been observed on edges toward or away from the aperture and on all sides simultaneously. The reason for enhanced scattered intensities is not evident at present. Possibly they are in the nature of crystalline reflections owing to regularities near the surface, although the images are considerably more diffuse than those produced by diffractions from common crystalline substances. Whether the enhanced scattering is to be accounted for on the basis of crystallinity or not, it must be noted that near the edges, electrons are incident and emergent at such small angles that refraction effects may be expected to be of significant magnitude. The observed deflection of electrons under the particles could be accounted for on the basis of refraction resulting from an inner potential of the order of 10 volts.

These observations demonstrate the utility of the multiple aperture which is, to be sure, a compromise for convenience rather than the equivalent of a clean, well-centered aperture of the conventional type. Probably a completely satisfactory solution of the aperture problem will require the redesign of present objectives to allow for insertion and alignment of apertures fixed to the lens, without the difficulties and hazards that presently attend this operation. As an alternative, the multiple aperture has some advantages, and furthermore, the ease with which it may be used for dark-field observations may stimulate this interesting and somewhat neglected aspect of electron microscopy.

# New Books

## A Shorter History of Science

By Sir William Cecil Dampier. The Macmillan Company, New York, 1944.

When Sir William Cecil Dampier's larger book, *A History of Science and Its Relations with Philosophy and Religion*, came from the press, we recognized that a great service had been rendered: science had been given its "setting in other modes of thought." Could Dampier streamline the larger book and produce *A Shorter History of Science* without devitalizing the story of the growth of science which made the larger book famous? In the condensation, the story has been more simply told, but even so its vitality has been preserved. The connections of science with other human activities have been reduced to the more direct impacts, but these fewer situations have been used expertly to show the relations of science to philosophy and religion. Undoubtedly the shorter history, like its monumental prototype, will become known, not simply for the facts and dates which it contains, but especially for the story it tells of the expanding mind and spirit of man.

"Science has two streams," we read in the first chapter, "corresponding to two sources, the first a gradual invention of tools and implements whereby men earn their living more safely and easily, and second the beliefs they form to explain the wonderful universe around them. The first may perhaps better be called technology, for its problems are too difficult for early theory, and only in later stages does it become applied science; the second, which in historic times grew into a pure search for knowledge, is the main subject of this book."

As one reads the book's eleven chapters—with titles such as: the origins, Greece and Rome, Galileo and Newton, the eighteenth century, recent biology, the new physics and chemistry, and the stellar universe—one turns back to the Preface for this summary: "The Greek Atomists, besides speculating on the structure of matter, developed therefrom a mechanical theory of life. Conversely, the philosophy of Plato, as modified by Aristotle, laid too much stress on innate ideas and logical deduction to make a favorable background for the beginnings of inductive experimental science. To Newton and his immediate followers the Heavens declared the Glory of God, but Newton's work produced a very different effect on the minds of Voltaire and other eighteenth-century sceptics. Darwin's revival of the old theory of evolution on the new basis of natural selection not only suggested an alternative origin for mankind, but spread evolutionary doctrine far beyond the limits of biology. The recent revolution in physics has shaken the evidence for philosophic determinism which the older synthesis seemed to require. Such broad effects must be noticed, but the more technical aspects of philosophy may be passed by."

Exponents of general education, who insist that all courses should be integrated into the whole life pattern of the learner, will like the spirit of *A Shorter History of Science*. Its author thinks that "early specialization is dangerous," and writes, "Those older schoolboys whose chief subjects are scientific should look at them also from a humanist standpoint, and realize their setting in other modes of thought, while those studying literature need some knowledge of science before they can be said to be well educated. For both groups, I believe that the history of science, the story of man's attempts to understand the mysterious world in which he finds himself, makes the best way of approach to common ground."

Carl F. Eyring
*Brigham Young University, Provo, Utah*

## Applied Atomic Power

By E. Smith, A. Fox, R. Sawyer, and H. Austin. Pp. 227, 6¼×9¼ in. Prentice-Hall, New York, 1946. Price $4.00.

This book with a rather ambitious title is easy and interesting reading uncomplicated by mathematics. Undergraduates will find everything simple except perhaps the descriptions of nuclear physics work at Los Alamos in Appendix I, which had best be read after reading Part III.

Part I contains a description of 32 uranium-bearing minerals and a history of radioactivity. Part II is introductory physics, mostly off-the-slide-rule stuff. Part III is an abstract of the Smyth Report with two noteworthy portraits of Fermi and Dunning, and a description of the three production piles at Hanford. The description of the Clinton Engineer Works is more sketchy because of security reasons.

Part IV, comprising the meat of the book, describes in considerable detail possible methods of using atomic power. The author, Sawyer, projects a 35,000 hp AK gas turbine using a closed cycle with a helium-carbon dioxide mixture. The inert helium makes possible a simple uranium heater. Many arrangements are discussed using fission heat in place of one fuel or another. It is emphasized that atomic energy will never replace other fuels but will supplement them. For some uses it is suggested that water be used as a moderator-coolant which is vaporized and then used to run a turbine. Atomic energy locomotives, ships, and rockets are considered.

Industrial benefits from gaseous-diffusion research are the subject of Part V.

Appendix III lists nuclear and atomic masses of isotopes from hydrogen to gold-197. A seven-page index is provided.

Duane Studley
*Colorado Springs, Colorado*

## Analytical Experimental Physics (Revised Edition)

By Harvey B. Lemon and Michael Ference, Jr., University of Chicago. Pp. 588+XVI, Figs. 584, Plates 66, 24×30 cm. University of Chicago Press, 1946. Price $8.00.

This college textbook first published in 1942 was hailed as the "Colossus of General Physics, one of the seven wonders of the textbook world." Now it has been revised, corrections have been made, rough spots have been smoothed out, figures, plates, and pages have been added. It is indeed a colossus in quantity and quality.

Little revision has been made in the chapters on mechanics, while in the section on heat qualitative discussions of the quantum theory of specific heats and of the properties of dilute solutions have been added. The chapter on alternating currents now includes a section on parallel circuits containing resistance, inductance, and capacitance. Much has been added to the chapter on conduction through gases so that it now includes a discussion of the motion of charged particles in electric and magnetic fields, of relativistic variation of mass with velocity, of the cyclotron, and of the betatron. As is to be expected the sections on nucleonics and electronics have been greatly expanded. A discussion is given of some nuclear reactions of tracers, nuclear fission, transuranic elements, nuclear chain reactions, and the atomic bomb. The electronic chapter now includes an analysis of the equivalent circuit of a triode, a discussion of gas-filled tubes, pentodes, photoelectric cells, electronic oscillators, radio transmitting and receiving apparatus, microelectric waves with radar transmitting and receiving systems, television, and the electron microscope. An interesting plate is added on radar, showing typical sending and receiving apparatus, a "P.P.I. scope" presentation of a convoy leaving New York harbor, and the trace in an oscilloscope of the reflection of radar waves from the moon. Some additions have been made to the chapter on wave motion and only minor changes in the chapters on sound and light. A useful set of trigonometric and logarithmic tables, together with a table of important physical constants, has been appended.

The book is what its title implies, both analytical and experimental in its approach to physics. Physical concepts are carefully interwoven with experimental data. The mathematics employed in the analysis is largely algebra and trigonometry with calculus used sparingly. The presentation is excellent and of the kind to appeal to the abler students. Though the book is more inclusive and more difficult than almost any other college one-year general text in physics, the authors have starred about one hundred sections which may be omitted so as to bring it within the scope of most college courses. There is, however, a section on the equivalent circuit of a triode which would appear to be beyond even the abler students with their present knowledge of physics. The topics are discussed in such a manner as to leave the student with a clear idea of the fundamental concepts and how these were developed.

Since the book is so large and heavy it might have been more practical to publish it in two smaller volumes. Whether this be good or bad advice the authors are to be congratulated on the challenge which they have given to students. Any student who masters this material can be sure of having a solid foundation in physics.

R. J. Stephenson
*The College of Wooster*

# New Booklets

Allied Radio Corporation, 833 West Jackson Boulevard, Chicago 7, Illinois, has announced the publication of a new 164-page catalog for 1947, covering radio and electronic products. Special emphasis is placed on equipment for industrial maintenance, research, and production requirements as well as for the needs of government agencies. 10,000 items. Free on request.

The Superpressure Division of the American Instrument Company, Silver Spring, Maryland, has issued its new 88-page catalog No. 406, entitled *Superpressure Catalytic Hydrogenation Apparatus.* Inquire on company letterhead.

United States Testing Company, Inc., 1415 Park Avenue, Hoboken, New Jersey, has revised its booklet *Testing Terms for Better Understanding.* The book describes some of the important tests of merchandise—tells how tests are made, what the results mean, what are standard and minimum specifications.

The Scientific Personnel Branch of the Navy Department, Washington 25, D. C., issues bi-monthly a *Scientific Personnel Bulletin*, listing employment opportunities in the Navy Department for scientists and technicians. 76 pages in the January-February, 1947, issue.

Eberbach and Son Company, Ann Arbor, Michigan, featured in its March issue of *The Announcer of Scientific Equipment* an article on the background and development of the modern analytical balance. 16 pages. Available on request.

Fischer and Porter Company, Hatboro, Pennsylvania, has released a new bulletin including dimensional and operational details of an improved continuous liquid specific gravity indicator. Address Department 6F-B of the company.

National Carbon Company, Inc., 30 East 42 Street, New York 17, New York, has published a new bulletin, *Catalogue Section M8808*, describing standard, seven-tube heat exchangers of "Karbate" impervious graphite for use under highly corrosive conditions.

The Winter 1946–47 number of *Interchemical Review*, published at 432 West 45th Street, New York 19, New York, has the following table of contents:

Maleic and Fumaric Resins....Charles S. Rowland.
Market Research in Industrial Fields....John P. Duane.
Oilcloth Pioneers in Maine....Charles R. Bragdon.

The Gaertner Scientific Corporation, 1201 Wrightwood Avenue, Chicago 14, Illinois, has recently published a new bulletin, 156-74, describing its optical benches and accessories. 26 pages.

# Here and There

### New Appointments

Eugene W. Boehne and Lan Jen Chu were recently appointed associate professors in the Department of Electrical Engineering at the Massachusetts Institute of Technology.

Two new appointments to the staff of the National Bureau of Standards were recently announced. Albert S. Cahn, Jr., will assist in the research involved in the design of two high speed electronic computing machines to be built for the Bureau of the Census and the Navy. P. J. Selgin will work on the development of electronic ordnance for the military services in the Ordnance Development Division.

The U. S. Weather Bureau has announced the appointment of Ross Gunn as the director of a newly organized Division of Physical Research, which will undertake studies of the atmosphere and basic physical processes that are related to the weather and the earth.

F. C. Henriques, Jr., has joined the staff of Tracerlab, Inc., at Boston, Massachusetts, as director of the Radiochemical Division

### Awards

Latest Franklin Institute awards for 1947 are as follows:

The Franklin Medal, highest honor of the Institute, to Enrico Fermi, physicist at the Nuclear Research Institute in Chicago, and to Sir Robert Robinson, professor of chemistry at Oxford University, England.

The Newcomen Medal to Everett G. Ackart, recently retired chief engineer of the E. I. du Pont de Nemours and Company.

The Clark Medal to Edward G. Boyer, manager of the Philadelphia Electric Company's gas department.

The Ballantine Medal to George C. Southworth of the Bell Telephone Laboratories.

### New Chairman for A. I. P.

George R. Harrison, dean of the School of Science, Massachusetts Institute of Technology, has been elected chairman of the American Institute of Physics, succeeding Paul E. Klopsteg, director of research, Northwestern University Technological Institute, who has served as chairman since 1940.

### Western Branch for Airborne Instruments Laboratory

A branch of the Airborne Instruments Laboratory, Inc., Mineola, New York, was recently established at Burbank, California. This will make possible a closer liaison between the main laboratory and west coast aircraft manufacturers in need of a consultation and development service. Airborne Instruments Laboratory is the peacetime outgrowth of the NDRC laboratory of the same name which operated under the direction of Columbia University during the war. Hector R. Skifter is president of the Laboratory and Robert D. Martin is supervising the west coast unit.

### Electrochemical Symposium at Pittsburgh

The annual spring symposium of the Pittsburgh section of the Electrochemical Society was held May 23 and 24 at the Mellon Institute. The subject was "High Temperature and Hetrogeneous Reactions."

### Electrochemical Congress at Louisville

A congress sponsored by the Electrochemical Society met in Louisville, Kentucky, April 9 to 12. A day's session was devoted to electronics, one to the corrosion of metals at elevated temperatures, and a third to the production of the best steels in the electric furnace. The Young Authors'. Prizes were awarded to N. A. Neilsen of Du Pont and to Burke Cartwright of the U. S. Bureau of Mines.

### Engineering Foundation Issues Report

The Engineering Foundation, 29 West 39th Street, New York 18, New York, made public in March its 32nd annual report to the board of trustees. The report stated, "It is clear that industry has, in general, become more research minded and large expansions of industrial research are to be expected. In some cases this will be by individual companies, in others, by associations of various types." Sixteen projects were sponsored by the Engineering Foundation during the past year, six of which were carried over from the preceding year. Among the projects were soil mechanics, fluid mechanics, materials of engineering comprising metal researches, welding, lubrication, and rolling friction. In addition to sponsoring engineering research, the Foundation also supports agencies or activities having as their objectives the advancement of the engineering profession.

### Changes in Electrical and Photometric Units

In pursuance of decisions of the International Committee on Weights and Measures, the National Bureau of Standards will introduce as of January 1, 1948, revised values of the units of electricity and of light. While the definitions of the units and the methods of fixing their magnitudes will be different from the present practical systems, the changes in magnitude will be so small as to affect appreciably only measurements of high precision. In certificates for standards and instruments issued by the Bureau during 1947, values will be given in both the old and the new units.

A complete description of the new units has appeared in the *Review of Scientific Instruments* for May, 1947.

# The Nucleation of Ice Formation by Silver Iodide

B. VONNEGUT
*General Electric Research Laboratory, Schenectady, New York*

(Received March 17, 1947)

Silver iodide particles have been found to serve as nuclei for the formation of ice crystals in super-cooled water and in water vapor super-saturated with respect to ice. It is believed that silver iodide serves as a very effective nucleus because it very closely resembles ice in crystal structure. Both dimensions of the unit cell of ice and silver iodide are the same to within approximately one percent. The maximum temperature at which the silver iodide particles serve as nuclei is approximately −4°C for particles one micron in diameter, and −8°C for particles 100 Angstrom units in diameter. A silver iodide smoke generator has been constructed which consumes 1 mg of silver iodide per second and produces $10^{15}$ effective nuclei per second.

V. J. SCHAEFER of this laboratory has recently reported that super-cooled liquid water clouds spontaneously transform from water to ice when the temperature is −35°C or lower. He observed that at temperatures as low as −20°C, the addition of fine particles of a wide variety of substances was without effect on the super-cooled cloud.[1]

B. M. Cwilong,[2] using a Wilson cloud chamber, found that moisture in clean air is precipitated as a cloud of ice crystals if the temperature during the expansion drops to −35.0°C or lower and the air is super-saturated with respect to ice at this temperature. He observed that the ice crystals were formed even though the expansion ratio was far less than that necessary to produce the formation of liquid water drops. Cwilong observed that if "ordinary atmospheric air" is used, ice crystals form at −27°C, and that if the air is "artificially contaminated with tobacco smoke," the limiting temperature is −23°C. He found "crystalline dust" to be no more active than "amorphous dust" in producing ice crystals.

Following Schaefer's work, experiments were made using Schaefer's apparatus and technique to see whether particles of substances very similar to ice in crystal structure might not serve as nuclei for ice formation at temperatures closer to the freezing point.

A search was made through x-ray crystallographic data for substances resembling ice as closely as possible in crystal system, space group,

TABLE I.

| Substance | System | Space group | Lattice constant | |
|---|---|---|---|---|
| Ice | hex. | $D_{6h}^4$ | 4.535 | 7.41* |
| AgI | hex. ZnO | $C_{6v}^4$ | $4.585_6$ | 7.490** |
| $PbI_2$ | hex. | $D_{3d}^3$ | 4.54 | 8.86 |

and dimensions of unit cell. Two substances were chosen which are listed in Table I along with ice for comparison.

These crystalline substances were tested to see if they would act as nuclei for the formation of ice when dusted as a powder into a super-cooled water cloud in Schaefer's apparatus at a temperature of −20°C.

Silver iodide was without apparent effect; however, the introduction of lead iodide powder caused the formation of a number of ice crystals in the super-cooled cloud. It appeared that far fewer ice crystals formed than would have been expected from the number of particles of lead iodide introduced.

The supposition that the lead iodide particles acted as nuclei because one of the dimensions of its unit cell was almost the same as that for ice was discarded when V. J. Schaefer discovered that iodiform crystals and iodine vapor behave in a similar way. The orthorhombic structure of iodine bears little relation to the structure of ice.

Later, investigations were made on the nucleating effect of smokes produced by electric sparks between electrodes of various metals. It was discovered that a single spark between silver electrodes in the presence of iodine vapor produced many thousands of times as many ice nuclei as lead iodide particles or iodine vapor alone. It was then found that silver iodide smoke, produced by heating silver iodide on a hot filament or by dispersing it in a flame, produced enormous numbers of nuclei. The failure of the initial experiment using silver iodide powder is attributed to the fact that the sample used was badly contaminated with soluble salts, a fact not known at the time. Powdered silver iodide without this impurity has since been found to serve as nuclei for ice formation.

It is believed that silver iodide acts as a very effective nucleus for the formation of ice crystals because it very closely resembles ice in crystal structure. It can be seen that both dimensions of the unit cell of ice and silver iodide are the same to within about one percent.

According to Dr. D. Harker of this laboratory, the arrangements of the atoms in the unit cells of ice and of silver iodide are almost identical despite their different space groups. The structure of ice is the same as that of silver iodide with the oxygen atoms occupying positions corresponding to the silver and iodine atoms. In silver iodide, each silver atom is bonded tetrahedrally to four iodine atoms. In ice each oxygen atom is bonded tetrahedrally, through hydrogen bridges, to four oxygen atoms.

Iodine vapor alone, or fine silver particles alone are without appreciable effect in forming ice crystals at a temperature of −20°C. If the experiment is carried out using iodine vapor alone in a system closed to the atmosphere of the laboratory, iodine vapor soon loses its property of nucleating a super-cooled cloud. It is believed that iodine compounds and iodine vapor act to produce nuclei by reacting to form silver iodide with minute traces of silver in the laboratory atmosphere. Such traces of silver might be caused by sparks from electrical equipment using contacts made of silver or copper that contains silver. Exceedingly small amounts of silver introduced into a super-cooled cloud in the presence of iodine vapor cause the formation of very large numbers of nuclei. One breath of air blown over a silver wire heated red will produce many millions of ice nuclei if it is introduced into a super-cooled cloud containing a small amount of iodine vapor.

Experiments are being made on methods for the production of silver iodide smokes consisting of very large numbers of very small particles. The most effective method found thus far for the production of such smokes is the following. A cotton string coated with silver iodide is fed at a fixed rate into an oxyhydrogen flame which vaporizes the silver iodide. A few inches away from the point at which the silver iodide is introduced, the flame is rapidly quenched by blowing a strong jet of compressed air through it. The blast of air quickly cools and dilutes the vaporized silver iodide in the flame so rapidly that it condenses to form an invisible smoke of very small silver iodide particles. Measurements have been made which show that a generator of this sort produces ice nuclei at the rate of approximately $10^{13}$ per second with the consumption of one milligram of silver iodide per second. Mr. E. F. Fullam has examined particles of this smoke with the electron microscope and found that they are of the order of 100 Angstrom units in diameter. One milligram, it can be computed, should yield about $3\times 10^{14}$ particles. The discrepancy between the two values may be caused by the fact that a portion of the silver iodide introduced into the flame may form a few very large particles or may form particles which for some reason are not effective nuclei.

It has been found that the effectiveness of the silver iodide particles as ice nuclei depends to a certain extent on the size of the particles. The smoke made by the oxyhydrogen flame technique has a particle size of the order of 100A diameter. This smoke does not cause large numbers of crystals to form until the temperature is −8°C or lower. Smokes made by vaporizing silver iodide from a hot wire have a particle size of the order of one micron and are effective at −4°C or below. A piece of silver iodide several millimeters in diameter placed in water in a test tube makes it difficult to super-cool the water to temperatures below about −3.5°C.

Recently the effect of silver iodide smoke was tried near Schenectady on a thin layer of supercooled fog at a temperature of −4°C. The smoke was produced by evaporating silver iodide on the surface of an electrically heated wire coil. The liquid water fog was transformed into small ice crystals for a distance of at least 150 feet from the point where the smoke was generated.

# Waves in Elastic Tubes: Velocity of the Pulse Wave in Large Arteries

ALLEN L. KING
*Dartmouth College, Hanover, New Hampshire*

(Received February 28, 1947)

An equation for waves in elastic tubes is developed and applied to cylindrical tubes with Hookian and with elastomeric walls. The former application yields the Moens-Korteweg formula, which has been found inadequate. The latter application leads to a rather complicated equation for the pulse-wave velocity.

Values of pulse-wave velocities are computed for the thoracic aorta by means of the foregoing equation, and the results are compared with measured mean velocities for the entire aorta. Graphs and tables are given, so that a graphical analysis of this velocity equation can be applied to any large artery; and the method is illustrated by computing the pulse-wave velocity in the left common carotid. The relation $l\div\int_0^l ds/v$, for the mean velocity over a tube of length $l$, is shown to be valid for the aorta and large arteries.

IN a series of papers Hamilton, Remington, and Dow have published an extensive and critical survey of previous work and of their own important contributions to the study of propagation velocities for the arterial pulse wave[1] and its relation to stroke volume[2] and the cardiac ejection curve.[3] They found their results to be in accord with those of previous investigators. At best, only qualitative agreement was found between measured velocities and those computed from the Moens-Korteweg formula[4]

$$v=F(Ee_0/2\rho r')^{\frac{1}{2}}. \qquad (1)$$

In this relation $E$ is Young's modulus of the wall material, $e_0$ is the thickness of the undistended wall, $r'$ is the internal equilibrium radius of the tube, and $\rho$ is the density of the fluid within the tube. Moens' factor $F$ is an empirical dimension-

Ralston of the College of Physicians and Surgeons of San Francisco has called my attention to a paper by Thomas Young [Trans. Roy. Soc. London **98**, 164 (1808)], wherein under the title, "Of the propagation of an impulse through an elastic tube," a formula for pulse-wave velocity is given, which can be transformed into that commonly ascribed to Korteweg.

less constant to which Moens assigned a value of 0.9, as a result of experiments with standing waves in elastic tubes. Hamilton and co-workers found the same value of Moens' factor for Gooch tubing; but for aortas they obtained better agreement with a value of 0.6–0.7 for the dog and 0.8 for the human; at diastolic pressure levels above 70 mm Hg. At lower pressure levels Moens' factor is not constant, and there is not even qualitative agreement.

In this paper a general wave equation is derived for the case of a homogeneous, non-viscous, and incompressible fluid in a thin-walled elastic tube. The Moens-Korteweg formula, with $F$ equal to unity, is readily obtained by introducing a simple version of the pressure-radius relation for a Hookian elastic tube with walls of negligible thickness. Aortas, however, have elastic properties similar to those of rubber tubes and, therefore, the pressure-radius relation for tubes with elastomeric walls should be used.[5] Pulse-wave velocities computed from the new equation are in good agreement with measured values. Even so, it should be realized that arterial pulsations are larger and vessel walls are thicker than assumed here. And, furthermore, blood is neither homogeneous nor non-viscous.

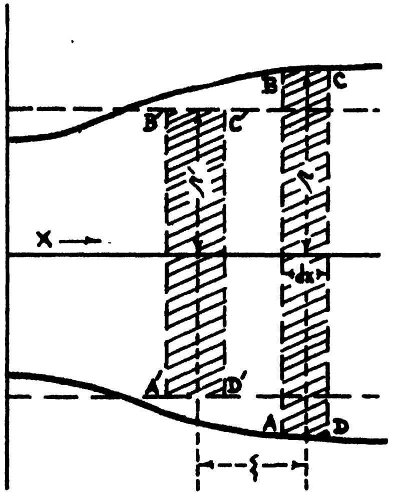

FIG. 1. Diagram of a portion of an elastic tube over which a wave is traveling.

## THE WAVE EQUATION

A homogeneous non-viscous incompressible fluid flows through a cylindrical tube with an elastic wall. The wall is sufficiently thin so that its inertia can be neglected in comparison with that of the fluid. The speed of a transverse wave down the tube is desired.

Let a thin element of fluid $ABCD$ of length $dx$ and radius $r$ be displaced a distance $\xi$ from its undisturbed position $A'B'C'D'$ when a wave passes along the tube (Fig. 1). With no wave in the tube the radius is $r'$, and the internal pressure is $p'$. At all times the external pressure is $p_0$.

The pressure on the fluid arises from the distension of the tube wall and is a function of the radius. Let the instantaneous excess pressure $P$ at $AB$ equal $(p-p')$, where $p$ is the instantaneous absolute pressure at $AB$. Then the excess force on surface $AB$ is $\pi r^2 P$, and the excess force on surface $CD$ is $\pi r^2 P+(\partial/\partial x)(\pi r^2 P)\cdot dx$. The force accelerating the element $ABCD$ in the positive $x$-direction, therefore, is $-(\partial/\partial x)(\pi r^2 P)dx$. But, the mass of this fluid element is $\pi r^2 \rho dx$; so that the equation of motion can be written

$$-\frac{\partial}{\partial x}(r^2 P)=\rho r^2\frac{\partial^2\xi}{\partial t^2}. \qquad (2)$$

The thickness of the element at $A'B'C'D'$ is $(1-\partial\xi/\partial x)dx$ and, since the fluid is incompressible,

$$r^2=r'^2(1-\partial\xi/\partial x). \qquad (3)$$

Equation (2) can now be written

$$\frac{\partial^2\xi}{\partial t^2}=\frac{1}{\rho}\left\{P(1+\partial\xi/\partial x)\frac{\partial^2\xi}{\partial x^2}-\frac{\partial P}{\partial x}\right\}. \qquad (4)$$

This is the equation for the pulse-wave.

## TUBES WITH HOOKIAN WALLS

For tubes with walls having a constant value of elastic modulus and following Hooke's law, Korteweg used the simple relation in which the wall thickness is assumed not to change. For this case the instantaneous excess pressure

$$\begin{aligned}P&=Ee_0(1/r'-1/r)\\&=-(Ee_0/2r')(\partial\xi/\partial x).\end{aligned} \qquad (5)$$

On inserting this value of $P$ in the general equa-

---

[5] A. L. King, J. App. Phys. 17, 501 (1946).

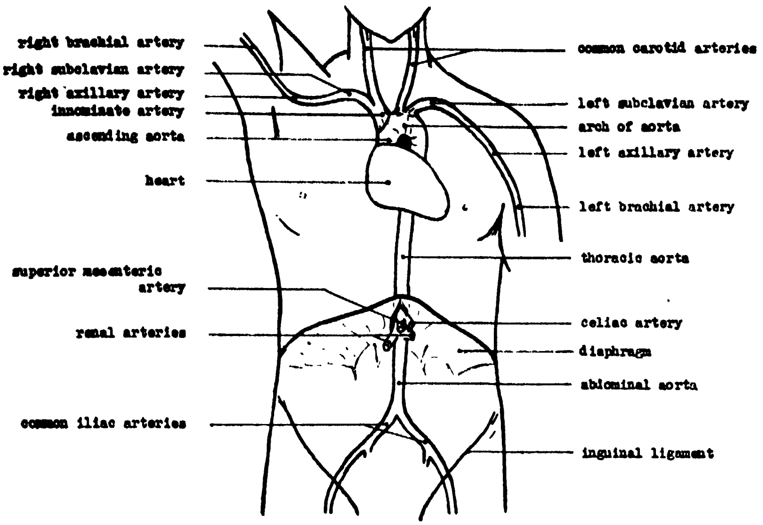

FIG. 2. Schematic drawing showing the approximate positions of the aorta and some of its branches.

tion for the pulse-wave and on neglecting terms involving the square of $\partial\xi/\partial x$, the wave equation,

$$\frac{\partial^2\xi}{\partial t^2}=(Ee_0/2\rho r')\frac{\partial^2\xi}{\partial x^2}, \qquad (6)$$

is obtained. The velocity of the wave is

$$v=(Ee_0/2\rho r')^{\frac{1}{2}}, \qquad (7)$$

namely, the Moens-Korteweg formula with $F$ equal to unity.

In general, the thickness of the tube wall does not remain constant. If this effect is taken into account, the instantaneous excess pressure is given by

$$\begin{aligned}P&=2e_0E(r-r')/(2-\sigma)r_0^2\\&=-\{Ee_0r'/(2-\sigma)r_0^2\}(\partial\xi/\partial x),\end{aligned} \qquad (8)$$

where $\sigma$ is Poisson's ratio of the wall material. When this value of $P$ is used in Eq. (4) and terms involving the square of $\partial\xi/\partial x$ are neglected, the wave velocity comes out to be

$$v=\{Ee_0r'/\rho r_0^2(2-\sigma)\}^{\frac{1}{2}}. \qquad (9)$$

This relation for pulse-wave velocity yields a somewhat higher value than that obtained from Eq. (7), since $r'$ is greater than $r_0$ and $\sigma$ ordinarily is positive.

TABLE I. Values of $A$ and $\beta$ for several age groups.

| Age range (years) | 20–24 | 29–31 | 36–42 | 47–52 | 71–78 |
|---|---|---|---|---|---|
| $A$ (mm Hg) | 88 | 74 | 70 | 65 | 44.5 |
| $\beta$ | 0.302 | 0.415 | 0.462 | 0.510 | 0.640 |

## TUBES WITH ELASTOMERIC WALLS

Elastomers are rubber-like substances containing long chains of molecules. They are highly resilient and have the unusual thermoelastic property of contracting on heating, when they are under tension. Living tissues have these characteristics and, in particular, the walls of blood vessels may be considered elastomeric.

For a thin-walled elastomeric tube the instantaneous excess pressure is

$$\begin{aligned}P=A[(r_0/r)^{\frac{1}{2}}\{\mathfrak{L}^{-1}(\beta r/r_0)/\mathfrak{L}^{-1}(\beta)\}\\-(r_0/r')^{\frac{1}{2}}\{\mathfrak{L}^{-1}(\beta r'/r_0)/\mathfrak{L}^{-1}(\beta)\}\\+(r_0/r')^{\frac{1}{2}}-(r_0/r)^{\frac{1}{2}}],\end{aligned} \qquad (10)$$

where $A$ represents $e_0p_0/2r_0$, and $\beta$ is equal to the ratio of the circumference of the tube to the maximum length of a molecular chain.[5] For arteries $\beta$ is an age-dependent parameter. The functions $\mathfrak{L}^{-1}(\beta)$, $\mathfrak{L}^{-1}(\beta r/r_0)$, and $\mathfrak{L}^{-1}(\beta r'/r_0)$ are inverse Langevin functions.

For small variations in the radius, as the wave progresses along the tube, $\mathfrak{L}^{-1}(\beta r/r_0)$ may be expanded about $r'$, and only the first two terms need be retained. The result is

$$\mathfrak{L}^{-1}(\beta r/r_0)=u'\{1-\tfrac{1}{2}(Br'/r_0)(\partial\xi/\partial x)\}, \qquad (11)$$

where

$$B=\beta u'\sinh^2 u'/(\sinh^2 u'-u'^2) \tag{12}$$

and

$$u'=\mathfrak{L}^{-1}(\beta r'/r_0). \tag{13}$$

Eq. (10) now reduces to

$$P=\tfrac{1}{4}A(r_0/r')^{\frac{1}{3}}\{(1-2Br'/r_0)(u'/u_0)\\ -3(r_0/r')\}(\partial\xi/\partial x), \tag{14}$$

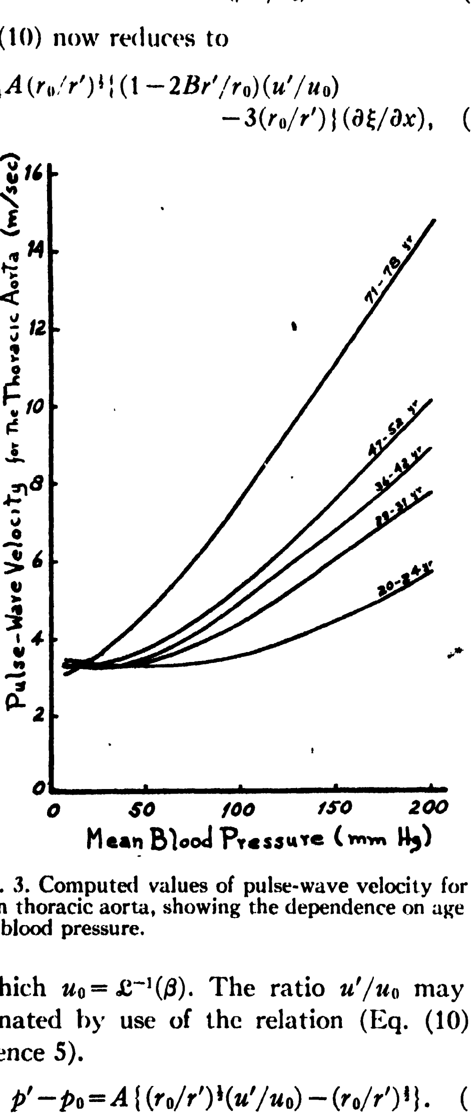

FIG. 3. Computed values of pulse-wave velocity for the human thoracic aorta, showing the dependence on age and mean blood pressure.

in which $u_0=\mathfrak{L}^{-1}(\beta)$. The ratio $u'/u_0$ may be eliminated by use of the relation (Eq. (10) in reference 5).

$$p'-p_0=A\{(r_0/r')^{\frac{1}{3}}(u'/u_0)-(r_0/r')^{\frac{4}{3}}\}. \tag{15}$$

Insert the resultant expression for $P$ in Eq. (4), neglect terms involving the square of $\partial\xi/\partial x$, and solve for the velocity of propagation of a pulse-wave in the elastomeric tube. The velocity is given by the equation

$$v^2=\tfrac{1}{4}(A/\rho)[(2Br'/r_0-1)\\ \times\{(p'-p_0)/A+(r_0/r')^{\frac{4}{3}}\}+3(r_0/r')^{\frac{4}{3}}]. \tag{16}$$

## PULSE-WAVE VELOCITIES IN THE HUMAN AORTA

Equation (16) for pulse-wave velocity may be applied to blood vessels. Note that the velocity increases with a rise in mean pressure within the tube. Also it increases with age, for the parameter $\beta$ in the expression for $B$ is age-dependent. Furthermore, it is higher when the ratio of wall thickness to internal diameter is larger, primarily through the factor $A$. All these conclusions are in qualitative agreement with observations on arteries of dog and man.

For a quantitative study, pulse-wave velocities are computed for that part of a human thoracic aorta just beyond the arch (Fig. 2). Values of $A$ and $\beta$ for several age groups were evaluated elsewhere[5] and are given in Table I. The specific gravity of blood is assumed to equal 1.057 for all ages.[6] The resulting computed velocities at pressures of 7.5, 50, 100, 150 and 200 mm Hg are gathered in Table II and are plotted in Fig. 3. Near zero pressure, the velocity is seen to decrease as the aorta ages. At the normal ranges of aortic pressures, however, there is a general increase of velocity with age. This increase becomes much pronounced in the hypertensive range. As noted in Fig. 3, the pulse-wave velocity is very nearly a linear function of pressure above 120 mm Hg.

Ordinarily, experimental determinations of pulse-wave velocities are made over long arterial paths. For instance, Hallock[7] made an extensive statistical study of aortic velocities in nearly 500 humans ranging in age from 5 to 85 years. His values of mean velocities are based on measurements of differences in distances and propagation times for pulse-waves traveling over the arch, thoracic and abdominal aortas, and the left iliac artery to the inguinal ligament and over the left common carotid artery (Fig. 2). To compute such mean velocities it would be necessary to know the velocity over every element of length along

TABLE II. Pulse-wave velocities for the thoracic aorta in meters per second.

| Age (years) | Pressure (mm Hg) 7.5 | 50 | 100 | 150 | 200 |
|---|---|---|---|---|---|
| 20–24 | 3.47 | 3.29 | 3.57 | 4.50 | 5.74 |
| 29–31 | 3.31 | 3.36 | 4.38 | 6.11 | 7.88 |
| 36–42 | 3.28 | 3.49 | 4.91 | 6.70 | 8.94 |
| 47–52 | 3.26 | 3.71 | 5.32 | 7.53 | 10.16 |
| 71–78 | 3.02 | 4.65 | 7.57 | 11.12 | 14.73 |

---

[6] W. F. Hamilton, Glasser's *Medical Physics* (Year Book Publishers, Chicago, 1944) p. 115.

[7] P. Hallock, Arch. Internal Medicine **54**, 770 (1934).

the path. In such cases, the mean velocity $\bar{v}$ is given by the relation

$$\frac{1}{\bar{v}}=\frac{1}{l}\int_0^l \frac{ds}{v}, \qquad (17)$$

where $l$ is the path length. If aging is uniform over the entire aorta, the ratio of mean velocity to the velocity in the thoracic aorta alone should be independent of age. Furthermore, the ratio should be greater than unity, since the pulse-wave velocity increases as the vessels become smaller in diameter and their walls thicken. On comparing the theoretical values of velocities for the thoracic aorta at a mean blood pressure of 100 mm Hg with Hallock's measured mean velocities, a constant empirical factor of 1.37 can be found. The approximate agreement between the adjusted theoretical values and Hallock's data is shown in Fig. 4.

### PULSE-WAVE VELOCITIES IN OTHER LARGE ARTERIES

Bazett, Cotton, Laplace, and Scott[8] published measured values of average pulse-wave velocities for paths from the heart, through the ascending aorta, arch, and innominate artery, to the subclavian artery, and also from the subclavian, through the axillary, to the branchial artery (Fig. 2). For the three men in the age-range of 20–24 years, whom they investigated, the mean values of these velocities were 3.6 and 5.4 meters/sec., respectively, with less than 10 percent deviation. To obtain the mean velocity between heart and brachial artery from these data, Eq. (17) may be modified. Since the distances from heart to subclavian artery and from subclavian to brachial artery, as described by Bazett and co-workers, are approximately equal, the reciprocal of the mean velocity between heart and brachial artery will be equal to half the sum of the reciprocals of the two measured velocities. This computation yields the value 4.3 meters/sec.

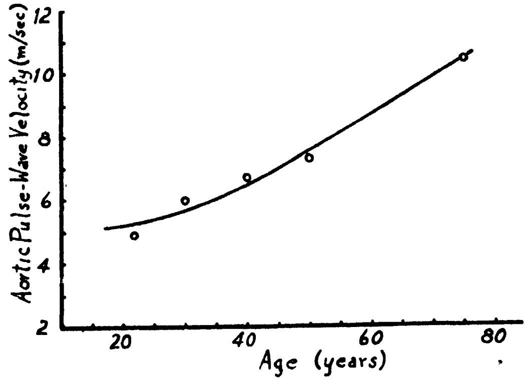

FIG. 4. The curve shows Hallock's values of mean pulse-wave velocities for the entire aorta as a function of age. The points were obtained by multiplying the theoretical values of velocity for the thoracic aorta alone, at a mean blood pressure of 100 mm Hg, by the empiric factor 1.37.

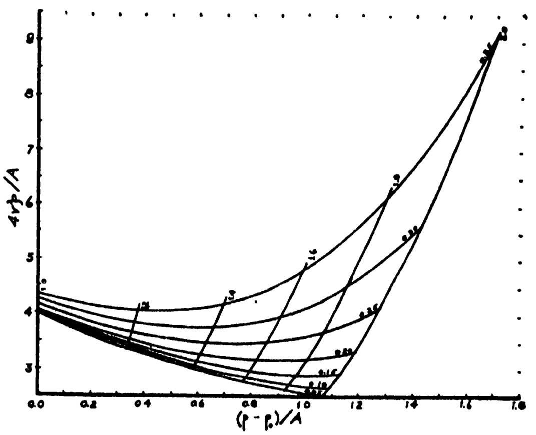

FIG. 5. Graph of $4v^2\rho/A$ as a function of $(p-p_0)/A$ for several values of $\beta$ and $r/r_0$. Values of $\beta$ range from 0.05 to 0.35 in steps of 0.05, and values of $r/r_0$ range from 1.0 to 2.0 in steps of 0.2.

The foregoing result may be compared with the observations of Bazett and Dreyer.[9] These investigators measured the pulse-wave velocity between heart and brachial artery of eight medical students with ages in the range 20–24 years. The mean velocity was equal to 4.1 meters/sec. at a mean blood pressure of 88 mm Hg with an average deviation of ±0.4 meter/sec.

Since the average dimensions of the arteries from aorta to brachial artery are equivalent to those of the common carotid, it may well be expected that the pulse-wave in the carotid should have a velocity of approximately 4 meters/sec. An extension of the analysis in the early part of this paper can be used to compute the velocity in any large artery. It will be applied to the common carotid artery.

## GRAPHICAL ANALYSIS OF THE VELOCITY EQUATION

In Eqs. (15) and (16) $r'/r_0$ and $\beta$ may be considered parameters for the quantities $(p'-p_0)/A$ and $4\rho v^2/A$. There is shown in Fig. 5 a family of curves for which $\beta$ varies between 0.05 and 0.35 in steps of 0.05, and $r'/r_0$ varies between 1.0 and 2.0 in steps of 0.2. Other curves may be drawn for values of $\beta$ and $r'/r_0$ outside these ranges, but for the following computations the curves of Fig. 5 suffice.

In order to use these curves, first $A$ is evaluated from known values of external pressure and ratio of effective wall thickness to internal diameter of the undistended artery. Then from the mean blood pressure within the artery $(p'-p_0)/A$ is computed. A value for $\beta$ next is found by making the reasonable assumption that, for the walls of the large arteries within a given body, the molecular chains all have the same length. For all such arterial walls, therefore, $\beta$ is directly proportional to the internal diameter of the undistended vessel. Since values of $\beta$ already are known for the upper part of the thoracic aorta (Table I), $\beta$ for any other large artery may be found by the relation

$$\beta\,(\text{artery}) = \beta\,(\text{thoracic aorta}) \cdot \frac{d_0(\text{artery})}{d_0(\text{thoracic aorta})}. \qquad (18)$$

From these values of $\beta$ and $(p'-p_0)/A$ a value of $4\rho v^2/A$ may be read off the curves of Fig. 5 by interpolation and the pulse-wave velocity $v$ can then be found.

To illustrate the procedure, a value for the pulse-wave velocity in the common carotid artery of a 20–24 year old person will be computed. From Kani's data[10] the mean ratio of wall thickness to internal diameter is estimated to equal 0.22 for twenty-year olds. For an external pressure $p_0$ of 770 mm Hg, $A$ nearly equals 170 mm Hg. The average pressure within an artery near heart level is assumed to be the mean of the systolic and diastolic pressures. A fifteen percent error in this mean introduces less than two percent error in the computed velocity of the pulse-wave for the carotid artery. As noted earlier, the mean blood pressure for a 20-year old person nearly equals 90 mm Hg. The function $(p'-p_0)/A$, therefore, is equal to 90/170 or 0.53.

The ratio $d_0$(carotid)/$d_0$(thoracic aorta) for 20-year olds approximately equals one-third, so that for the carotid $\beta$ equals 0.10. From Fig. 5, the quantity $4\rho v^2/A$ is found to have the value 3.15 at values of $\beta$ and $(p'-p_0)/A$ equal to 0.10 and 0.53, respectively. But for whole blood the density $\rho$ equals 1.057 g/cc, and here $A$ equals 170 mm Hg, or 226,000 dynes/cm². From these data $v$ is computed to be 4.1 meters/sec.

The foregoing method may be modified so as to obtain values of $\beta$ from measurements of pulse-wave velocity and mean blood pressure.

No doubt other factors than those considered in this development may influence pulse-wave velocities in living systems. The experiments reported by Hamilton and co-workers[1] in their study of this problem, however, suggest that the propagation of a pulse wave along the aorta and large arteries depends almost completely on the mechanical properties of the intact living artery.

# An Electronic Computer for X-Ray Crystal Structure Analyses*

R. PEPINSKY
*Department of Physics, Alabama Polytechnic Institute, Auburn, Alabama*

(Received January 29, 1947)

An electronic synthesizer is described for determination of atomic positions in crystals. The synthesizer sums the two-dimensional Fourier series representing planar, centro-symmetric projections of electron densities in a crystal unit cell; and the projection is presented by a television scan on the screen of a cathode ray oscilloscope. The specific advantage of the device is the immediate observability of effects on the projection of alterations in signs of one or any number of Fourier coefficients.

A METHOD has been developed for rapid visual presentation of the positions of atoms in a crystal structure by supplying x-ray diffraction data to an electronic computer coupled to a cathode ray oscillograph. The computer sums the two-dimensional Fourier series representing the projection on a lattice plane of the electron densities in a crystal unit cell; and the projection is presented by means of a television type of scan on the screen of the cathode ray tube. The method is based upon Huggin's modification[1] of Bragg's earlier photographic summation of simulated interference fringes[2]; in this respect it is related to the sand-deposition method of fringe summation reported by McLachlan and Champayne[3] in the December, 1946 issue of this journal. In contrast to these modifications of the Bragg method, however, accurate projections with various axial ratios and angles are readily permitted in the present computer.

Artificial interference fringes for an (*hk*0) projection are produced on the oscilloscope screen by applying to the CR tube grid intensity-modulating sinusoidal voltage signals of amplitude proportional to $F_{hk0}$ and frequency $f_{hk0}$, the latter being given by the relation:

$$f_0 = f_{hk0} = h\cdot f_V + k\cdot f_H, \tag{1}$$

where $f_V$ and $f_H$ are the vertical and horizontal sweep frequencies respectively. By way of illustration: $f_V$ may be a slow sweep, at 1 c.p.s., and $f_H$ a fast sweep at 1000 c.p.s., and the duty cycle of both sweeps practically 100 percent. One 1000-line scanning frame then appears on the screen each second. The signals for various (*hk*0) fringes are mixed before application to the grid, so that a two-dimensional pattern occurs for each frame. The fluorescent screen is a long-persistence type (3- to 5-second decay period) to permit visualization, and the pattern may be photographed for permanent recording.

Only patterns with centers of symmetry are attempted. The *signs* of the structure factors $F_{hk0}$, which in general are not directly determinable from the x-ray data, are introduced by having each signal available in 0 or 180° phase, and selecting one or the other of these by means of a double-throw switch for each term. Amplitudes are adjusted by means of individual potentiometers for each factor.

It will be seen from Eq. (1) that when $h=0$, so that $f_0$ is some integral multiple of the fast sweep, vertical fringes result on the screen. *Increasing* $f_0$ slightly, with the sweep frequencies unchanged, causes the fringes to tilt (but remain parallel to one another) in one direction, because the intensity-modulating signal *advances* in phase with respect to the fast sweep. *Decreasing* the modulating frequency produces parallel fringes oppositely tilted to the first case. Certain refinements of this simple procedure, involving the use of lower duty-cycle sweeps but of the same sweep speed as indicated above, are required to maintain accurate placement of the fringes. These and other details of the technique will be described and published elsewhere.

A fast sweep of 1000 c.p.s. in the horizontal direction and a slow of 1 c.p.s. vertically have been utilized, and precise synchronization of

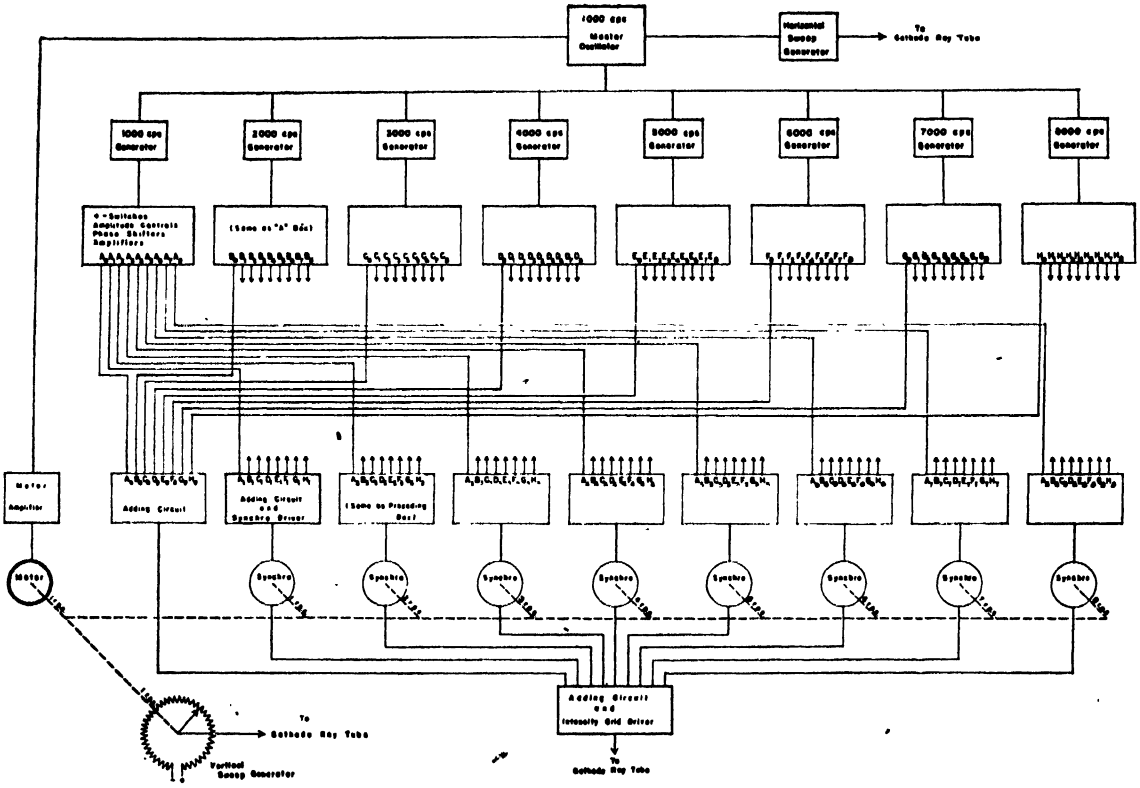

Fig. 1. Block diagram of Fourier synthesizer for (h, k) terms to (8, 8).

these with the grid signals, according to equation (1), is essential. All frequencies are derived from a 1000 c.p.s. base oscillator, which should be fairly frequency stable but need not be strictly so. The fast sweep is synchronized to this; the slow is obtainable through the use of a 1000 cycle motor with a 1 r.p.s. shaft, the motor being driven from a power amplifier.** A series of generators of frequencies 1000·k c.p.s. are synchronized by a heterodyning system to the base oscillator. Phase and amplitude-adjustment controls are available for each of these.

The key to the entire computer is the method for production of the frequencies 1000·k±h c.p.s. These must be accurately related to the base oscillator and to the fast and slow sweep speeds; no drifting whatever from the precise relation can be tolerated. The exactly-related frequencies are obtained as follows. Each 1000·k c.p.s. signal is fed to an integrating feed-back amplifier which produces a 90° phase-shifted signal of the original frequency. Application of these two signals—of equal amplitude and frequency but 90° phase-separation—to the stator windings of a two-phase selsyn produces a rotating electric field in the selsyn of rotational frequency 1000·k c.p.s. If the selsyn rotor remains stationary, a signal of frequency 1000·k c.p.s. appears on its leads. But if the rotor is rotated at h r.p.s. in a direction counter to the field, a signal of frequency 1000·k+h c.p.s. appears on the rotor leads. Rotation of the rotor at h r.p.s. in the *same* direction as the field rotation results in a signal of frequency 1000·k −h c.p.s. The rotor speeds are obtained by gearing in ratios 1:1, 1:2, ···1:h to the 1 c.p.s. shaft driven by the 1000-cycle motor.

All signals with the same h-value can be *mixed* and fed to a *single* selsyn, the rotor speed of which is h r.p.s. The number of selsyns required for the device is thus considerably less

---

** It will be demonstrated in a later paragraph that some of the synchronization here is redundant. Specifically, the motor need not be synchronized to the fast sweep signals and the 1000·k oscillators.

than the number of $F_{hk0}$ terms. The 90° phasing amplifiers are made rather frequency-insensitive, so that only one such amplifier is required for each selsyn; this again reduces the number of components. Because the output signal from the phasing amplifiers will vary with *large* variations in signal frequency, normalizing potentiometers are supplied for each of the 1000·k c.p.s. oscillators.

A 1000·k+h c.p.s. signal is produced, as described, by rotation of the selsyn rotor in a direction counter to the rotating field direction. It is possible to obtain both a 1000·k+h c.p.s. and a 1000·k−h c.p.s. signal from a *single* selsyn by producing rotating fields in *opposite* directions in the same selsyn stator. To accomplish this it is necessary only to alter the phase of one 90° component of one or the other of the 1000·k c.p.s. signals by 180°. (In general, the amplitude of the 1000·k c.p.s. signal which will become a 1000·k+h c.p.s. frequency is different from the 1000·k c.p.s. signal which will become the 1000·k−h c.p.s. frequency, the amplitudes being controlled by the $(h, k, 0)$ and $(h, \bar{k}, 0)$ potentiometers, respectively.) Thus, for a matrix of (20, ±20) terms, only twenty selsyns are required.

A partial block diagram for a system of $F_{hk0}$ terms up to (8, 8, 0) is shown in Fig. 1. The use of lower than 100 percent duty-cycle sweeps has not been indicated in this diagram, but such modifications do not alter the general operation of the system. The illustrated system achieves completely locked-in synchronization of all signals. Once the 1000·k c.p.s. signals have been phased so that their maxima occur at the start of the fast sweep, no drifting of fringes is possible.

A sample fringe, corresponding to $F_{\bar{1}70}$, is illustrated in Fig. 2. The fast sweep, at 1000 c.p.s., is from left to right in the figure; and the slow sweep, at 1 c.p.s., is from top to bottom. The grid signal here has the frequency 6999 c.p.s., as required by the formula:

$$f_{\bar{1}70} = 1\cdot h + 1000\cdot k = 1\cdot -1 + 1000\cdot 7 = 6999 \text{ c.p.s.}$$

The resulting pattern ordinarily will not show any discrete horizontal lines, because the distance between adjacent fast sweep traces is less than the breadth of the electron beam at its finest focus. In order to indicate the direction of the fast sweep here, an additional 60 c.p.s. modulation has been applied to the CR tube grid.

It can be shown, as suggested in the footnote on page 3, that there is a redundancy in the synchronization employed here. It is true that all the 1000·k oscillators and the fast sweep must be synchronized—and this is readily achieved. It is also necessary that the slow sweep and the selsyn rotations be synchronized, and this is achieved through the use of the potentiometer driven from the (approximately) 1 c.p.s. shaft and with the selsyns driven from the shafts geared to this. But it is *not* necessary that the shaft speeds, at multiples of about 1 r.p.s., be synchronized with the 1000 c.p.s. oscillator. If the shaft speed slows down, more horizontal sweeps occur per frame, and the phase-shift of each fringe signal is reduced; but these two effects exactly compensate one another, and the tilt of each fringe remains unaltered. This simplifies the circuitry, and permits the use of a standard (60-cycle) motor.

The fast and slow sweep directions are ordinarily at right angles. By adding to the fast sweep signal a *component* of the slow sweep signal, the angle between the effective slow sweep direction and the fast sweep can be varied over a wide range. The slow sweep component is obtained from another linear potentiometer on the same 1 c.p.s. shaft as the main slow sweep potentiometer. The amplitude of the slow com-

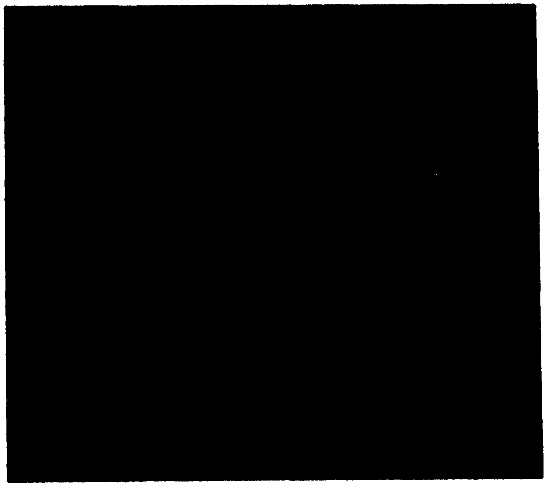

FIG. 2. $F_{\bar{1}70}$ fringe, with added 60 c.p.s. modulation to show fast sweep direction.

ponent is varied by means of the voltage applied across its potentiometer. Variation of the voltage across the main slow sweep potentiometer alters the axial ratio of the projection. Thus cell projections of any desired axial angle and ratio are attainable.

The computer can be built up in stages from one accommodating only a few $F_{hk0}$ terms to one including as large a range of terms as appears necessary. It is intended that terms to (20, ±20, 0) be incorporated into the final synthesizer.

The basic difficulty in general crystal structural analyses arises from the absence of information concerning the phases of the structure factors. Whenever a center of symmetry occurs in a structure or in some projection of the structure (e.g., a projection perpendicular to a two-fold symmetry axis is centro-symmetric), the factors involved in an electron density map for the projection are known except for their algebraic sign. Some partial information as to these signs may be available from auxiliary information (atomic radii and bond angles as determined from related structures, Patterson projections showing interatomic vectors, optical data indicating group or molecular orientations, etc.); and in special cases the signs may be directly determinable.[4] In general, however, trial and error procedures are required. Since the order of from one hundred to several hundred factors are involved in a projection, the number of permutations of signs is overwhelming; and when tedious computations must be carried through each time a change is made, without a great deal of guidance in assignment of the signs structure determinations become unfeasible.

In order to reduce the work involved in the calculations, a good number of computational aids have been developed for structural analyses. These will not be reviewed here. It suffices to say that none of them meet in a satisfactory manner the peculiar requirements of this science, that alterations of signs of the factors be enterable in a simple way into the computer, and the effects of the alterations be very rapidly observable.

It is precisely this requirement of structural analyses which the present synthesizer is designed to satisfy. The signs of individual factors can be introduced and altered at will by simply throwing a switch for each factor; and the "summation" of a two-dimensional series is accomplished within a few seconds after the data is fed into the machine. The pattern corresponding to a specific choice of signs remains on the oscilloscope screen as long as is desired. The effects of changes in signs of one or any number of factors appear almost instantly, and the new pattern remains on the screen until another change is introduced. (The amplitudes of individual factors are equally adjustable, with the effects of such changes just as rapidly observable.) *Thus for the first time systematic variations of structure factor signs, in trial and error procedures, become feasible in a general structure analysis.*

Another advantage of the oscillographic presentation is the ease with which the *contrast* and *background level* of the pattern is alterable. The former is controllable through amplitude control of the final grid-modulating signal; and the background level is controlled through variation of the CR tube grid bias. Since the grid-modulating signals are mixed before their application to the cathode-ray tube, a non-linear relation between the beam current and the light-output of the fluorescent screen does not lead to errors in positions of peaks in the electron-density map. The size of a projection is also controllable, and any section of a projection can be selected and enlarged at will.

The computer should not now be considered as a replacement for accurately calculated contour maps of electron densities in the final stages of a successful structural determination. It is intended to facilitate the deduction of general features of a structure and to avoid the tediousness of trial and error stages of the analysis. It is conceivable that with proper care a device of this sort will be capable of quantitative results, but such is not its prime purpose.

An earlier form of this instrument was described by the writer at the Lake George, New York, meeting of the American Society for X-Ray and Electron Diffraction, June 11, 1946, and oscilloscope fringe patterns were shown there. An extended discussion of the system will be published elsewhere.

# Resonant Cavities for Dielectric Measurements*

C. N. WORKS
*Research Laboratories, Westinghouse Electric Corporation, East Pittsburgh, Pennsylvania*

(Received March 3, 1947)

Fixed and variable length re-entrant resonant cavities designed for the measurement of dielectric constant and dissipation factor are described. These cavities operate in the frequency decade of $10^8$ to $10^9$ cycles per second, a region avoided by many experimenters because the frequency is too high for the application of circuit techniques and not high enough for the convenient use of coaxial lines or wave guides. The theoretical considerations in the design of these cavities are presented. The well-known susceptance variation method, widely used in the frequency range of $10^4$ to $10^8$ cycles per second, was extended to apply to these cavities; it yields a rapid measuring technique and very simple expressions for calculating the values of the dielectric properties. The performance of this apparatus is discussed and the results of the measurements of a few typical dielectrics are given.

## I. INTRODUCTION

DIELECTRIC constants and losses of materials had been measured even at ultra-high frequencies as early as 1895.[1] The early techniques were relatively crude compared with those developed within the last few years. Coaxial transmission line and wave guide methods, discussed by von Hippel,[2] Lamont,[3] Englund,[4] and Benoit,[5] in which a section of (usually resonent) coaxial line or wave guide is filled with dielectric, are used at present, especially at frequencies greater than 1000 megacycles per second.

The frequency band of 100–1000 megacycles has been avoided by most experimenters in dielectric measurements because the frequency is too high for the application of the usual circuit techniques and not high enough for the convenient use of the coaxial line or wave guide. The search for a simple and rapid method of making measurements in this frequency range has resulted in the development of two types of re-entrant cylindrical cavities in which small disk-shaped samples are used. This paper will be concerned with the description of these cavities as well as with their theory and performance.

## II. DESCRIPTION OF THE APPARATUS

### 1. The Fixed Cavity

This instrument, which is shown in Fig. 1, operates in the frequency range of 400–600 megacycles per second. It is similar to an early model developed for the frequency range of 100–300 megacycles,[6] except that as a result of

experience with this earlier instrument, a number of mechanical improvements have been made.

The sample required is a disk one inch in diameter and from 0.050 to 0.250 inch thick. It is inserted through the port near the bottom and placed between the re-entrant posts or electrodes for the measurement of its dielectric constant and dissipation factor.[7] This port is located in a portion of the cavity where the current is small. It is closed by a tapered plug. It has been found that the resonant frequency of the cavity is not altered by removal and replacement of the plug. The upper electrode is movable and is connected with the coaxial portion of the cavity by a sylphon bellows which eliminates all sliding contacts. The separation between these electrodes is controlled by a precision micrometer (Van Keuren Company) with a six-inch dial. The constructional details of this cavity are shown in Fig. 2.

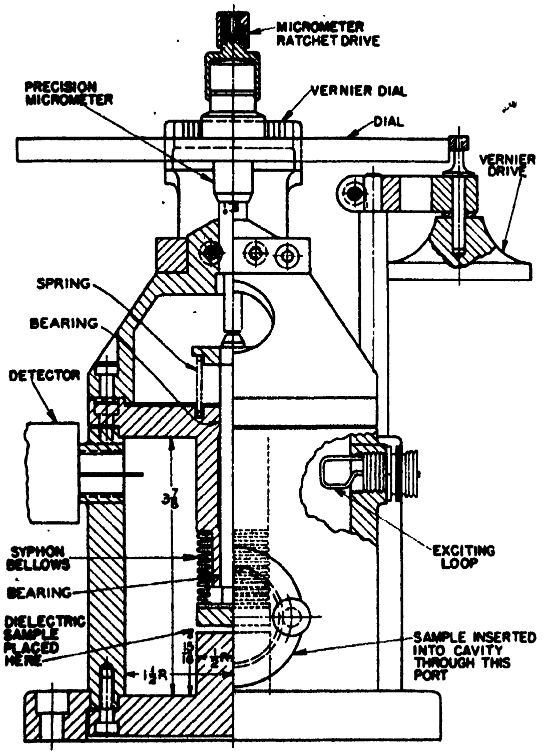

FIG. 2. 400–600-Mc dielectric measuring apparatus.

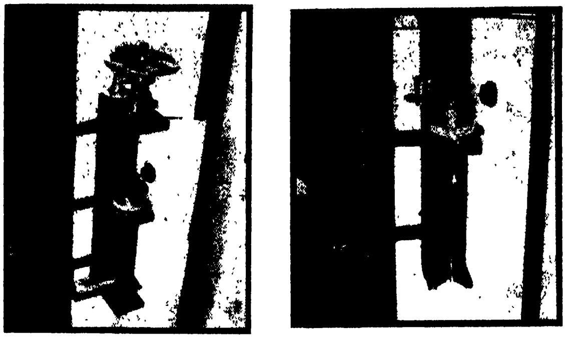

Assembled Cavity

Outer Cylinder of Cavity Removed Showing Internal Details

FIG. 3. 300–1000-Mc variable length re-entrant resonant cavity for measuring dielectric properties of materials.

Energy is coupled into the cavity by a loop as shown. By varying the size and position of this loop, the measured $Q$[8] of the cavity may be varied from less than 50 to about 2000. The detector consists of two type 1N21 crystals (Sylvania) side by side with ends of opposite polarity connected to the probe.

The fixed cavity has the limitation that the frequency at which the measurement of a given sample is made depends on the dielectric constant and dimensions of the sample. By a reasonable variation in the thickness of a sample, however, measurements may be made over the frequency band previously designated for this cavity.

## 2. The Variable Cavity

Because there may be cases where it is desirable to select the exact frequency at which a measurement is to be made, and also to obtain a single instrument useful over a wide band of frequencies, a variable length re-entrant cavity was designed for a frequency range of 300–1000 megacycles per second. Photographs of this instrument are shown in Fig. 3. Details of the cavity proper, which are not evident from these illustrations, appear in Fig. 4.

The length of the cavity is controlled by the position of a shorting plug. It might be emphasized that in this method variation in contact does not introduce an error in the measurements. The plug is driven by a threaded tube which is restrained from turning by a key on the extension

---

[7] Dissipation factor ($\tan\delta$) is the tangent of the loss angle. This angle is the complement of the phase angle whose cosine is the power factor. Therefore, for the small loss angles usually found in good dielectrics, the dissipation factor is equal to the power factor for all practical purposes.

[8] $Q$ is usually defined as the ratio of the amount of energy stored per cycle to the amount of energy dissipated per cycle. $Q$ is thus the reciprocal of the dissipation factor.

of the center post. This tube is propelled by a nut to which the dial (see Fig. 3) for indicating the length of the cavity is attached. A vernier drive is also provided.

The separation of the electrodes is controlled in the same manner as in the fixed cavity. In fact, all other details of the cavity are similar to the fixed cavity except that the former is smaller in diameter and has smaller electrodes, as indicated in Fig. 4. This smaller diameter results in a lower $Q$. By adjusting the coupling, the measured $Q$ may be caused to vary from less than 50 to about 1000. This maximum value of $Q$ still gives good sensitivity in measuring the dissipation factor of low loss materials. The sample required is a small disk 0.480″ or less in diameter, and from 0.040″ to 0.125″ thick. The auxiliary equipment used with these cavities is described in reference 6.

## III. THEORY

### 1. General Considerations in the Design of the Cavities

The well-known susceptance variation method[9,10] for the measurement of the dielectric constant and dissipation factor in the frequency range $10^4$ to $10^8$ cycles per second has a number of advantages. It combines a simple and rapid measuring technique with simple relations for rapid computation of results with an accuracy greater than that obtainable by most other methods. It has been found possible to apply this technique to measurements at higher frequencies. Expressions were derived for the dielectric constant and loss of samples, measured by placing them in the re-entrant end of a cavity and using a measuring procedure similar to that of the conventional susceptance variation technique. These are identical, except for an additional correction term, with those used in the usual application of this technique at radio frequencies, provided the dimensions of the sample are so restricted that it can be considered as a lumped capacitance.

If the sensitivity to low loss samples is to be satisfactory, the $Q$ of the cavity must be high. The expression for the theoretical $Q$ of such cavities is[11]

$$Q=4\pi(G/10)^{\frac{1}{2}}b\frac{\log_e b/a}{b/a+1}(f)^{\frac{1}{2}}\times 10^{-4}, \qquad (1)$$

where $G$ is the conductivity of metal covering inside of cavity in mhos per centimeter ($5.8\times 10^5$ for copper), $b$ is the inside radius of the outer conductor of the cavity in centimeters, $a$ is the outside radius of inner conductor of cavity in centimeters, and $f$ is the frequency in cycles per second. The optimum $Q$ is obtained with a ratio of $b/a$ of about 3.6. Examination of the curve[12] of $Q$ *versus* the ratio $b/a$ shows that this curve is fairly flat for values of $b/a$ between 3 and 4, and falls off rapidly on either side of these values. In the frequency band being considered, a theo-

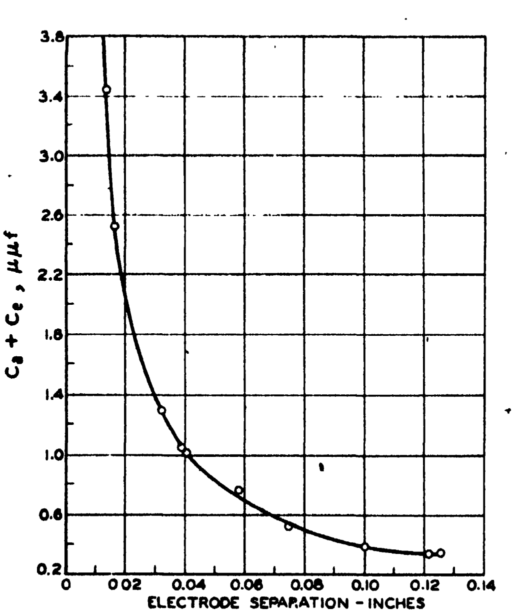

FIG. 5. Curve for the determination of $(C_{a2}+C_{e2})-(C_{a1}+C_{e1})$.

retical $Q$ of about 4000 may be obtained for values of $b$ as small as 2 cm. Because of energy absorbed by the probe and the effect of the coupling loop, the theoretical $Q$ is never obtained. Measured $Q$ of one-quarter to one-half of the theoretical $Q$ may be obtained under practical operating conditions.

Having established the restrictions imposed to obtain satisfactory $Q$ values, the next step is to determine the dimension of cavities, which resonate in the desired frequency band. The resonant frequency of the singly re-entrant cavity for the general case is treated by Hansen.[13] This case is so complex that it is at once apparent that it would be desirable to impose restrictions on the shape of the cavity which would result in simpler relations. E. U. Condon[14] gives an approximate treatment, which assumes that $b$ is small compared with a quarter wave-length. He also shows that this treatment corresponds to applying the standard engineering form of transmission line theory. Therefore, this restriction will be applied to these cavities, and transmission line formulae used to calculate the resonant frequency or resonant length. The resonant frequency of a short circuited loss-free transmission line with a capacitor at one end is given by the equation[11]

$$Z_0 \tan\frac{2\pi fS}{c}=\frac{1}{2\pi fC}, \tag{2}$$

where $Z_0$ is the characteristic impedance of coaxial part of cavity, $S$ is the length of internal conductor, $c$ is the velocity of light, and $C$ is capacitance between the ends of the re-entrant posts in the cavity at resonance. The resonant length of the cavities, as calculated from this relation, checked the resonant length as determined experimentally within two percent.

Experiments with a singly re-entrant cavity indicated that the fringing of the field is excessive, especially for very short gaps. Therefore, the doubly re-entrant cavities of Figs. 2 and 4 were selected in which one of the re-entrant posts is much shorter than the other. On first consideration, it would seem that the re-entrant posts should be the same length, giving a symmetrical cavity which might be easier to analyze. However, the requirement of variable gap length would disturb this symmetry. It was observed that for small gap spacings (less than $0.02S$) and for the short post less than $0.25S$, the resonant frequency of the doubly re-entrant cavity varied

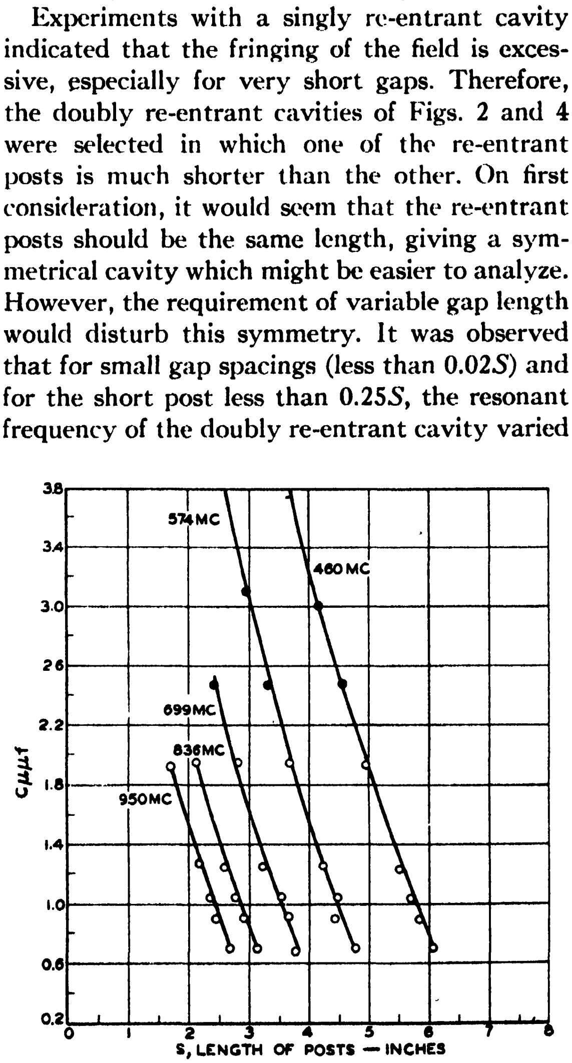

FIG. 6. Curves showing relation between geometric capacitance, $C$, between electrodes *versus* length of posts at constant resonant frequency.

[14] E. U. Condon, "Principles of Microwave Radio," Rev. Mod. Phys. 14, 341–389 (1942).

very slightly from that of a singly re-entrant cavity of the same total length and same gap spacing. This observation confirms the experimental results obtained by Barrow and Mieher.[15]

The lowest mode of oscillation of this cavity corresponds to that of a conventional coaxial line short circuited at one end and capacitatively loaded at the other. It is usually designated $TM_{0,0,p}$ where $p$ is less than unity. Since the diameter of our cavities has been restricted so that the resonant frequency could be calculated by transmission line methods, it is unlikely that higher modes could exist. Calculation of the cut-off frequency for the next higher mode verified this.

## 2. Expressions for the Dielectric Constant

By definition, the dielectric constant, $e'$, of any dielectric sample is given by

$$e' = C_x/C_a, \tag{3}$$

where $C_x$ is the capacitance of the sample, and $C_a$ is its equivalent air capacitance. The capacitance of the sample, $C_x$, is given by the equation[6]

$$C_x = (C_{a2} + C_{e2}) - (C_{a1} + C_{e1}) + C_{a1} - \frac{dC}{dS}\Delta S. \tag{4}$$

Except for the last term, this is the same expression used in the conventional susceptance variation method.[10]

In applying this equation to the cavities, the more complicated case of the variable length cavity will be considered first. The capacitance of the electrode arrangement of two parallel cylinder faces is determined at lower frequencies by calibration against a standard capacitor in the case of the conventional susceptance variation circuit. In the frequency band being considered here, neither a standard capacitor nor the technique of comparing it to an unknown is available. Therefore, the calibration was determined experimentally, using two materials having considerably different values of dielectric constant, polystyrene and Insanol (mica-filled lead borate). The dielectric properties of samples of these materials were known from measurements made at higher and lower frequencies by other independent methods.

From the measurement of these materials of known properties, the calibration curve of Fig. 5 was obtained. This corresponds to the correction for fringing usually applied in the case of the conventional susceptance variation circuit. By obtaining the relation of the capacitance between electrodes to the length of the posts at constant resonant frequency, the curves of Fig. 6 were obtained. The curve of Fig. 7 was then obtained by plotting the slope of these curves *versus* electrode separation. Multiplying the ordinate of this curve by $\Delta S$, the change in the gap spacing to retune the cavity to resonance upon removal of the sample, gives the last term of Eq. (4). This term is the correction for the small change in length of the coaxial part of the cavity which necessarily takes place when one of the posts is extended inward to diminish the gap.[16]

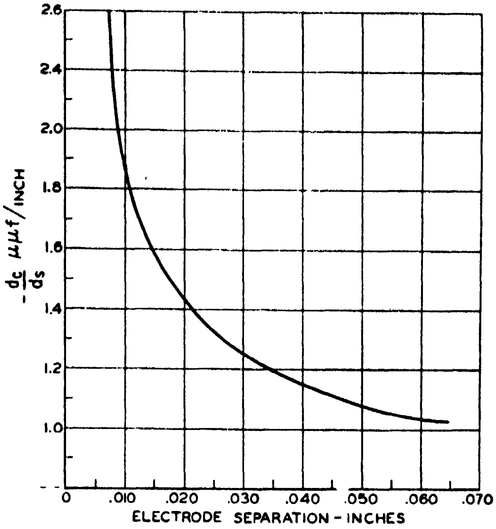

FIG. 7. Curve for the determination of $dC/dS$ for any electrode separation.

Now Eqs. (3) and (4) may be solved as follows to obtain the value of the dielectric constant of any material. The quantities $(C_{a2}+C_{e2})-(C_{a1}+C_{e1})$, and $-dC/dS$ are read from the curves in Figs. 5 and 7, respectively. The value of $C_{a2}+C_{e2}$

---

[15] W. L. Barrow and W. W. Mieher, "Natural Oscillations of Electrical Cavity Resonators," Proc. I.R.E. **28**, 184–191 (April 1940).

[16] The reader who may wish to perform the experiments described should refer to the thesis "A Variable Length Re-entrant Resonant Cavity for the Continuous Measurement of Dielectric Properties from 300–1000 Mc," University of Pittsburgh, 1946, for a detailed discussion of the method used to obtain Figs. 5, 6, 7.

is read from the ordinate of Fig. 5, corresponding to the value of electrode separation with the sample removed. Similarly, the value of $C_{a1}+C_{e1}$ is found from the separation with the sample in place.

In the case of the fixed cavity, samples of various thicknesses, whose dielectric constants were accurately known, were measured over the frequency range of 400–600 megacycles per second. Using the computed theoretical values for the correction term, $(dC/dS)\Delta S$, the measurements all checked the known values within one percent. This indicated that fringing could be neglected in the range of frequency in which this equipment operates, and that the term $(dC/dS)\Delta S$ gives the total required correction. Then Eq. (4) may be written

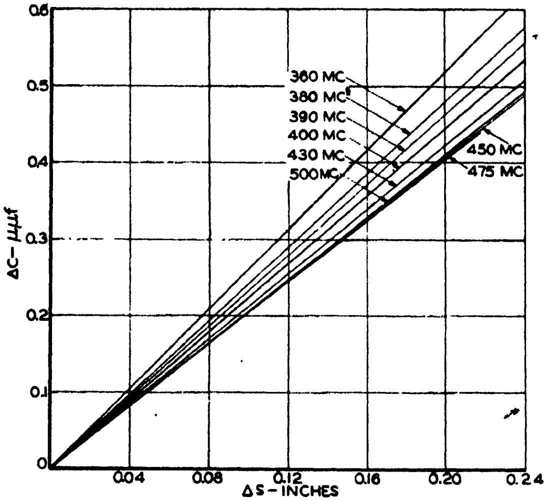

Fig. 8. Correction curve for the 400–600-Mc fixed cavity.

$$C_x=C_{a2}-\frac{dC}{dS}\Delta S. \qquad (5)$$

Replacing the term $-(dC/dS)\Delta S$ by its value, $\Delta C$, as obtained from the curves of Fig. 8 and writing for $C_{a2}$ its value for the case of electrodes 1″ in diameter, the following expression is obtained

$$C_x=\frac{0.1764}{\begin{array}{c}\text{Gap spacing (inches) at}\\ \text{resonance with sample}\\ \text{removed}\end{array}}+\Delta C\ \text{u.u.f.} \qquad (6)$$

The simplicity of Eqs. (3) and (6) permits very rapid calculation of the dielectric constant.

### 3. Expressions for the Dissipation Factor

An expression for the dissipation factor of a sample placed between the ends of the posts of a re-entrant cavity was derived in an earlier paper.[6] It is identical with the equation used for the "Change of Voltage Procedure" in the well-known susceptance variation method used at radiofrequencies.[10] The final result is given by the following expression:

$$\mathrm{Tan}\,\delta_x=(\Delta C_2/2C_x)(E_2-E_1)/E_1, \qquad (7)$$

where $E_1$ is the voltage at resonance with the sample in place, and $E_2$ is the voltage at resonance with the sample removed. The term $\Delta C_2/2C_x$ should be recognized as the dissipation factor of the empty cavity. $\Delta C_2$ is the change in capacitance necessary to tune from one half power level of resonance to the other.

## IV. PERFORMANCE

The dielectric constant and dissipation factor of a number of materials over a frequency range of 60 cycles per second to 10,000 megacycles per second are shown in Figs. 9 to 11. These curves are given to show the agreement in the results obtained using the instruments and techniques described with values obtained by independent methods. Symbols as listed on each curve are used to identify the method used to obtain a particular value.

Figure 9 shows the dielectric properties of polystyrene. The properties of this material are known to be practically constant over the frequency range shown on this curve. Therefore, the measurement of this material provides a

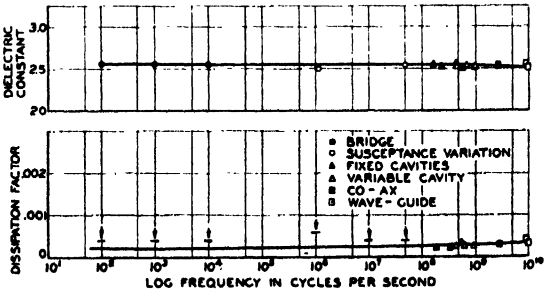

Fig. 9. Dielectric properties of polystyrene.

convenient check as to whether the measurements made by the method described agree with measurements made by independent means at higher and lower frequencies. Inspection of the curve for the dielectric constant shows that the values for the frequency decade $10^8$ to $10^9$ cycles per second lie along a curve already well defined by values determined by independent methods. Likewise, Fig. 10 shows that the values for the dielectric constant of insanol, which has a value of about 8, in the frequency decade in which we are interested do not depart from the curve. This shows that the accuracy does not vary with change in the value of the dielectric constant. The accuracy of the value of dielectric constant, as indicated by these curves, and other unreported measurements, is about ±1 percent.

The value of the dielectric constant of most solid materials is usually between two and ten. In the case of those unusual materials whose dielectric constant is considerably greater than ten, the samples should be much smaller than the electrodes.[17] A sample with a dielectric constant much greater than ten, which occupies the entire space between the electrodes, shortens the effective length of the cavity to such an extent that even when the physical length of the cavity has been made a minimum, it is not possible to resonate the cavity at frequencies in the upper portion of the band for which the instrument was designed.

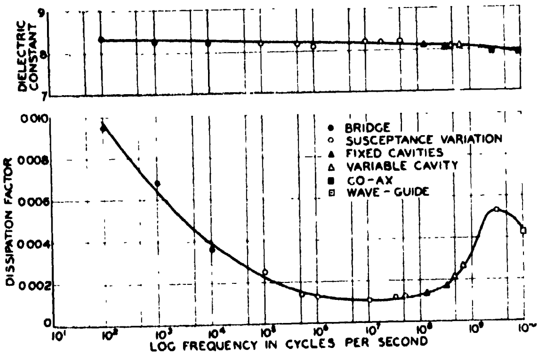

FIG. 10. Dielectric properties of insanol (mica-filled lead borate).

The error in the dielectric constant caused by variation in voltage across the face of the electrodes was investigated and the proper correction made in all cases where the error was not negligible. When materials having dielectric constants greater than five are measured at frequencies over 500 megacycles in the cavities described, a correction should be made for the variation in voltage across the electrode faces.[18]

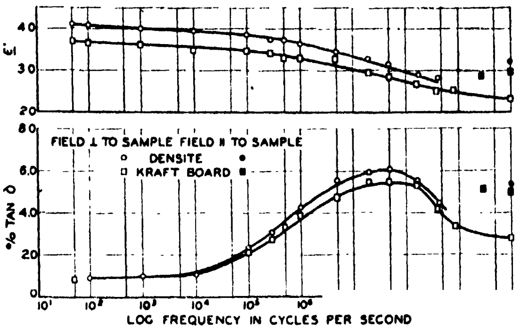

FIG. 11. Dielectric properties of kraft board dried at 105°C for 16 hours.

The curve for the dissipation factor, Fig. 9, shows that these values are in line with the values at higher frequencies obtained by wave guide measurements. At lower frequencies, the precision of the apparatus is ±0.0002 so that all that may be stated with certainty is that the dissipation factor is less than 0.0004. Further examination of the curves of dissipation factor, Figs. 9 and 10, shows that the accuracy of these values, as obtained by both the fixed and variable cavities, is ±0.00005 for small values of tan$\delta$.

In spite of the fact that certain approximations and empirical calibrations have been made to keep the measuring procedure and calculations nearly as simple as those of the conventional

---

[17] When the sample is smaller than the electrodes, Eq. (4) is applied to determine the over-all dielectric properties of the space between the electrodes (with the sample in place between the electrodes), and then standard equations for dielectrics in parallel (sample and air) are applied to determine the properties of the sample.

[18] The capacitance and, therefore, $e'$ of a sample placed between electrodes varies as: $e_0' = e_m'(E_{\max}/E_{\mathrm{Av}})$ where $e_c'$ is the corrected dielectric constant and $e_m'$ is the dielectric constant as calculated by Eq. (3). The average voltage is given by the expression $E_{\mathrm{Av}} = E_{\max}[1-(\pi^2 e' r^2 f^2/2c^2)]$ where $r$ is the radius of the sample, and the remaining symbols have been defined previously. This last equation may be derived by using Eqs. (7′12), (7′6), and (7′2) of reference 12, expanding $J_0$ in an infinite series, and taking the average. Because only the first two terms of the expression are given, $r$ must be less than $\lambda/8$, where $\lambda$ is the wavelength in air.

susceptance variation method, the accuracy of the values of the dielectric constant is very nearly the same as that obtained through the use of this technique at lower frequencies. The accuracy of the values of low dissipation factors is much greater than that obtained by any of the methods used at lower frequencies. This is due to the fact that very high values of $Q$ are obtained with the resonant cavity. This property of the resonant cavity may be taken advantage of through suitable techniques to obtain the dissipation factor of low loss dielectrics to very great precision.[19]

The curves of Fig. 11 are included because they illustrate the usefulness of apparatus operating in this frequency range, and point out some interesting properties of dielectrics. These materials have a dispersion region. The dielectric constant decreases as the dissipation factor goes through a maximum between $10^7$ and $10^8$ cycles per second. The apparatus described made possible an accurate determination of these curves throughout the dispersion region. Few laboratories have an apparatus for the measurement of solids operating in the frequency band of $10^8$ to $10^9$ cycles per second. These materials have another interesting property that should be mentioned in passing. The direction of the electric field in the sample makes a considerable difference in the values of the dielectric properties. When this material is placed in a wave guide with the same face against the end of the guide which was in contact with the electrode, the direction of the field in the sample is changed by 90°. Therefore, when changing from an instrument with electrodes to a wave guide, consideration should be given to the direction of the field in the sample in the case of materials which may be non-isotropic.

## V. CONCLUSION

Although the calibration of the apparatus described in this paper was accomplished by empirical methods, it has many advantages to recommend its use over methods which are mathematically more rigorous.

The sensitivity of these re-entrant cavities is so great that very small disk-shaped samples can be used. This makes it possible to sample directly the material to be measured. Thus, a piece of dielectric material may be removed from a cable or other apparatus and tested. When large samples of intricate shapes are required, as in the case of coaxial transmission line methods, especially at frequencies near the lower end of the frequency band (100–1000 Mc) considered in this paper, samples molded or cast in the laboratory may not be representative of a commercial grade of the same material. The simple disk shape of the samples required for this method makes their preparation easy.

Measurements may be made rapidly, and the calculation of results is extremely simple. The accuracy obtained from this method is usually better than that of other methods operating in this frequency range.

## VI. ACKNOWLEDGMENT

The author wishes to make grateful acknowledgment to Drs. L. J. Berberich and T. W. Dakin of the Westinghouse Research Laboratories, and to Dr. E. W. Montroll of the University of Pittsburgh for the many helpful suggestions given during the course of this work.

# A Variable Capacitor for Measurements of Pressure and Mechanical Displacements; A Theoretical Analysis and Its Experimental Evaluation*

JOHN C. LILLY, VICTOR LEGALLAIS, AND RUTH CHERRY
*E. R. Johnson Foundation for Medical Physics, University of Pennsylvania, Philadelphia, Pennsylvania*

(Received December 13, 1946)

A variable capacitor is described for measuring (1) small displacements, (2) small volume changes, and (3) pressure differences. The capacitor consists of a deflectable diaphragm and a fixed electrode. The diaphragm is metallic, plane-parallel, clamped at the edges, and at ground potential; the electrode, at an a.c. potential, has a plane surface parallel to the undeflected plate across an air gap. For use in displacement measurements, the diaphragm's center is deflected by a point contact from a mechanical link to the observed system, or by a uniform pressure load from a fluid link to the system. The fluid link is used also when measuring volume changes and pressure differences. The plate deflection results in a change in the air gap, and thus generates a capacitance signal. This signal is measured by electrical methods.

A theoretical analysis of this variable capacitor is presented; sensitivity and alinearity factors for the three uses of the device are derived. The experimental performance shows reasonably satisfactory agreement with the derived theory. The displacement of the plate's center was measured with an interferometric method, using a yellow He line as a standard of reference; the applied pressure, with a liquid manometer; and the capacitance signal, with a standard capacitor substitution procedure. The gauge can be used so as to give quantitative electrical indications of displacement, volume change, or pressure difference; or can be used as a null indicator device in which an unknown pressure is balanced against a known one on opposite sides of the diaphragm. In order to achieve large volume an displacement sensitivities, small air gaps ($5.10^{-4}$ cm) are employed. Details of a construction method to assure small values are presented.

## INTRODUCTION

To anyone who has attempted the design or the construction of a diaphragm capacitance gauge for precise pressure or volume-change measurements, the lack of an adequate theory to handle the many variables encountered is rather discouraging. The important variables are the diaphragm diameter, thickness, and material; the air gap, the electrode diameter, the applied pressure, and the capacitance signal. The magnitude of the pressure signal and the desired capacitance signal are known. But what about the values to be assigned the first five variables in order to achieve the desired pressure-capacitance relation? It was an attempt to answer this question that led to this analysis.

Though the theory presented here was evolved in response to a need in the biological field, the treatment and the results are sufficiently general to be of interest to the physicist, the chemist, or the engineer who may want a gauge for other applications. For the benefit of those who may apply the gauge to biological systems, and for the benefit of those interested in why biological applications are as strict in their requirements as the physical ones, the peculiarities of the living systems are presented and discussed in relation to the capacitor gauge design. For those interested only in gauge design, this discussion on biological problems may be neglected, and a start made on the later, theoretical derivation section.

## THE GAUGE DESIGN PROBLEM IN BIOLOGICAL APPLICATIONS

The pressure gauge design problems encountered in the biological field are different from those in other fields of research. Certain limitations are placed on the pick-up unit design by the special properties of animals. In general, the pressure systems in animals are buried within the body, loosely supported, of variable distensibility, in constant motion, and are fragile in construction. These structures react locally to probing, puncturing, and tearing by bleeding and by constricting. Blood in the vessels may clot on inserted objects, and thus plug pressure taps. The whole animal also reacts by moving and by markedly changing the blood pressure, the heart rate, and other variables one may be measuring. Anesthetics can be used to abolish many of these undesired effects; but these drugs can exert other actions which are also unwanted.

---

* The work described in this paper was done under a contract recommended by the Committee on Medical Research, between the Office of Scientific Research and Development and the University of Pennsylvania.

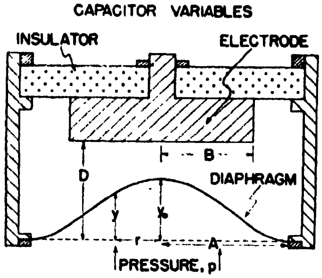

FIG. 1. Diagram of a diaphragm capacitor. The variables used in developing the capacitor theory are illustrated here; capital letters refer to fixed geometrical properties, small letters to variables generated by a displaced diaphragm. Tables I and II give the definitions and the units of all variables. The diaphragm is shown in an approach deflection; in a recession deflection the diaphragm would bulge downward. Both the air gap and the center deflection are greatly magnified in relation to the diameters of the diaphragm and of the electrode. The form of the deflected diaphragm is that of a stiff, edge-clamped plate; Figs. 2 and 3 give quantitative details of the two extreme idealized diaphragm forms assumed in the theory.

The pressure phenomena occurring in animals have both a static level and superimposed rapid pulsations. It is important to record these phenomena faithfully.

Because of these special properties of the animal, some form of transmission of the pressure signal from the interior to the exterior is necessary. At the present time, tubing containing liquid usually conducts the signal; ultimately, electrical transmission may be substituted. To avoid undesired local stimuli, the tubing is small.

From these considerations, some requirements for a pressure gauge pick-up can be deduced. (1) The pick-up must reproduce static level signals. (2) For the faithful reproduction of rapidly changing pressures transmitted through small bore tubing, and to minimize the length of the tube bore exposed to coagulable blood, the volume change of the unit with respect to an applied pressure must be minimal. (3) The pick-up size and the weight should be as small as possible. (4) The connection between the pick-up unit and the recorder must be long and very flexible. (5) The pick-up and its leads should be insensitive to vibration and to changes in position.

Many types of diaphragm pressure gauges have been used in recording static and kinetic pressures in animals.[1–8] The ones with the greatest promise of meeting the above requirements are the photoelectric[6, 7] and the electrical capacitor[8] types. The latter type is the one analyzed here.

With the above conditions in mind, it was considered important to examine the theoretical basis of the pick-up unit of a diaphragm-type capacitor pressure gauge previously applied to the recording of pressure in the vascular system.[8] The examination, presented below, was undertaken in order (1) to find out what factors were of importance in an optimal design for a pick-up unit for a minimal volume change and maximal capacitance signal in response to a given applied pressure; (2) to facilitate making design compromises in the presence of construction difficulties in special units; (3) to find and to evaluate those factors in the design which determine the alinearity and the sensitivity of the gauge; and (4) to explain and thus make allowances for the observed differences in gauge

TABLE I. Measured and calculated variables for a given gauge.

| I. Measured variables | Units | Method |
|---|---|---|
| 1. Electrode radius | $B$ cm | |
| 2. Diaphragm radius | $A$ cm | By micrometer |
| 3. Diaphragm thickness | $T$ cm | |
| 4. Applied pressure | $p$ dynes/cm² | By liquid manometer |

The variables are defined in Figs. 1, 2, and 3, and in Table I. (1) Fundamental integral: $s = [(4D/A^2)\int_0^B (rdr)/2(D \pm y)] - N$. Solutions: [from (1) and equations of Figs. 2 and 3].

performance in the case in which the diaphragm is deflected away from the electrode in contrast to the case of diaphragm-electrode approach.

In addition to the measurement of pressure, a diaphragm-type capacitor has desirable characteristics for use as an ultramicrometer (displacement) and as a dilatometer (volume change). In the theory below, the condenser characteristics for these three uses are most easily discussed in the order: displacement, volume, and lastly, pressure. (In the theory, displacements are considered only as measured by means of a fluid link; in practice, point contact mechanical links can be used, but this theory does not apply in this case, even with a stiff plate.)

The following sections give a summary of a derivation of a diaphragm capacitor theory, and some applications of the theory in the design and in the testing of diaphragm capacitors. Later sections deal with the results of an experimental check of the theory, a consideration of electrical circuits for recording with the gauge, and a method used in the construction of some pick-up units.

## DERIVATION OF A THEORY OF A DIAPHRAGM-TYPE CONDENSER

### A. Configuration of the Capacitor

In deriving a theory of a diaphragm-type capacitor an expression is first developed which relates the displacement of the diaphragm to the resultant capacitance signal, for the geometrical arrangement shown in Fig. 1. In the following discussion, variables generated by a diaphragm deflection are represented by small letters, and the constants of a given gauge, by capital letters (see also Tables I and II).

The diaphragm is a circular plane-parallel metal plate or membrane clamped near the periphery and is assumed to be deflected by a uniform pressure load on one side or the other. The effective radius of this diaphragm, $A$, is that of the periphery at the inside edge of the clamp.

The electrode is a circular metal structure with a plane surface placed parallel to the undeflected plate, across an interposed air gap of a thickness $D$. The effective electrode radius, $B$,

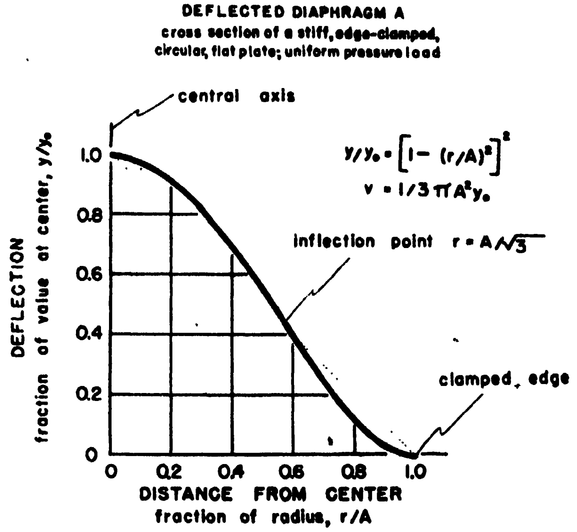

FIG. 2. The form taken by a stiff plate deflected by a uniform pressure. A radial section is cut through the diaphragm, from the axis of rotation at the left, to the clamped edge at the right. This method of showing the form greatly magnifies the amount of the deflection in relation to the radius by a factor of about one to ten thousand. The equation of this curve is derived on the assumptions that the absolute deflection is less than about 1/50 the thickness of the diaphragm, that the thickness is less than about 1/50 of the radius, and that the edge is uniformly and rigidly clamped, without exerting a radial tension in the undeflected position of the diaphragm (no initial stretching). All strains are assumed to be within the proportional elastic limit. It is further assumed that, in the undeflected state, the diaphragm is a plane, parallel, homogeneous, and isotropic structure. The equation of this curve is given in the figure; the variables are defined by Fig. 1. The volume swept out by the diaphragm as it is deflected, $v$, was found by integration of the equation for the curve; the resulting expression gives the dimensions of a cone of equivalent volume.

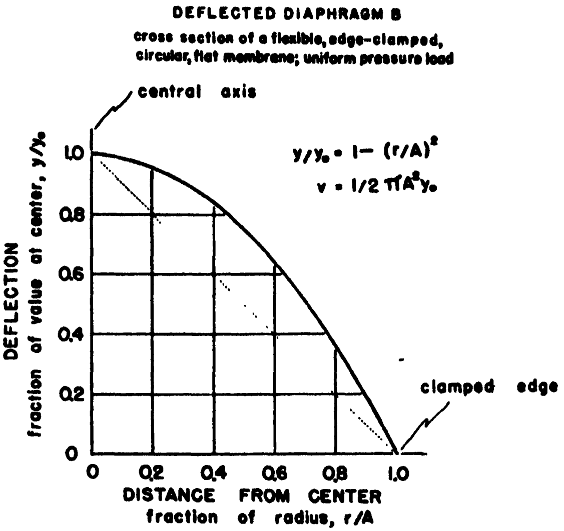

FIG. 3. The form taken by a flexible membrane deflected by a uniform pressure. The general statements made under Fig. 2 apply to this figure. The same limiting assumptions apply to this equation as to the stiff-plate one, except that it is assumed that the membrane is subjected to a uniform tension of $G/4$ cm/dyne (item 15, Table II) in all directions in its own plane in the undeflected state. In this diaphragm the inherent stiffness is assumed to be negligible, and hence the clamped periphery bends with a practically infinitesimal radius of curvature. The volume swept out by the diaphragm as it is deflected, $v$, equals that of a cylinder of a height equal to one-half the central deflection and a base of an area equal to that of the undeflected diaphragm.

is that of the plane surface presented to the air gap.

The diaphragm and the electrode have a common axis passing through their centers, normal to their facing surfaces (Fig. 1).

Since the ratio of the electrode periphery to the air-gap thickness, $2\pi B/D$, is usually of the order of magnitude of 750–7500; edge effects are considered to be negligible and are omitted in the following analysis.

### B. Derivation Summary

An equation defining the relation of the relative change in capacitance of this capacitor to the deflection of the diaphragm (Fig. 1) can be derived in the following manner:

1. Consider an elemental capacitor consisting of an annulus of infinitesimal width, lying in the surface of the electrode and concentric with the central axis, and of a similar strip directly across the air gap, lying in the surface of the diaphragm. Let both strips have a radius of $r$, defined as the distance along a normal from the annulus to the axis. Assume that, as the plate is moved by a pressure load, the capacitance of this elemental capacitor, $dc$, (in centimeter units) varies inversely with the distance between the strips, and varies directly with the area of one strip ($2\pi r dr$) (Eq. (1), Table III, note).

In the usual case, the deflection of the diaphragm center is only about 1/500 to 1/5000 of the diaphragm radius; therefore it can be shown that the above assumption is justified.

2. Consider the annular element in the surface of the diaphragm in the deflected position. The displacement of this element from the undeflected position is taken as $y$, and that of the diaphragm center as $y_0$. The relation between the radius of the annulus, $r$, and $y$, should be con-

sidered for at least two extreme cases, the thin, stiff plate and the thin, flexible membrane.[9]

The equation relating $y$, $y_0$, $r$, and $A$ for the stiff plate is given in Fig. 2; and that for the flexible membrane in Fig. 3. (These equations are taken from Love's *The Mathematical Theory of Elasticity*, and reference 9.) The equations are exact only for values of $y_0/A$ which are very small compared with unity. Other assumptions and limits for these equations are given in the Figs. 2 and 3 captions.

3. By setting up the differential equation implied in assumption 1 above, substituting the expression for assumption 2, for the two diaphragm types and integrating the result, the equations of Table III can be derived. These equations, in Table III, state the relation between the relative capacitance signal, $s$, and the relative change in the air gap, $w$ (equals $y_0/D$). In these expressions the parameter is the electrode-diaphragm radius ratio, $B/A$. All of the deflections of the diaphragm toward the electrode are treated as the "approach case," and deflections away from the electrode as the "recession case.[10] The equations of these two cases differ fundamentally only in the algebraic sign of the central diaphragm displacement term, $y_0$, which is positive in recession and negative in approach.

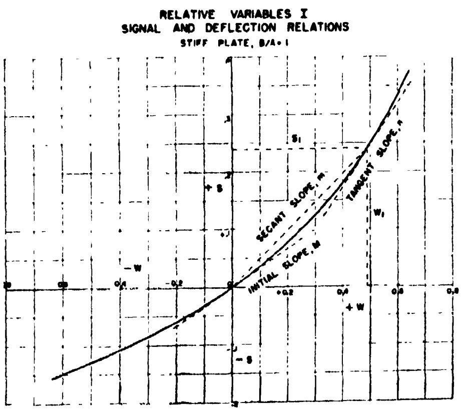

Fig. 4. Relation between the relative displacement and the relative capacitance change for a stiff plate. This curve is for an electrode and a stiff plate diaphragm (Fig. 2) of equal radii. For any condenser with a given radius ratio, $B/A$ (Fig. 1), the fractional, or relative, capacitance change, $s$, is defined as the capacitance change, $c$, divided by the undeflected state capacitance, $C_0$, of a condenser with a $B/A$ of unity and the same initial air gap, $D$ (Fig. 1 and item 13, Table I). The fractional air-gap change or the relative displacement, $w$, is defined as the central diaphragm deflection, $y_0$, divided by the air gap, $D$, in the undeflected state (Fig. 1). This figure serves to define the relative displacement sensitivities, $M$, $m$, and $n$ in terms of the slopes of the $s$ and $w$ curve. The secant $m$, and the tangent $n$, are both defined at any point on the curve, $s_1$ and $w_1$; the initial slope, $M$, is that at the origin, $s=w=0$. The sole dependence of the initial slope, $M$, on the radius ratio, $B/A$, is shown in the next figures. Both $m$ and $n$ approach $M$ as the deflection, $w$, becomes infinitesimal. For the assumptions and the theory of this curve see text. It is to be noted that the variables used in this and in most of the rest of the figures have zero dimensions.

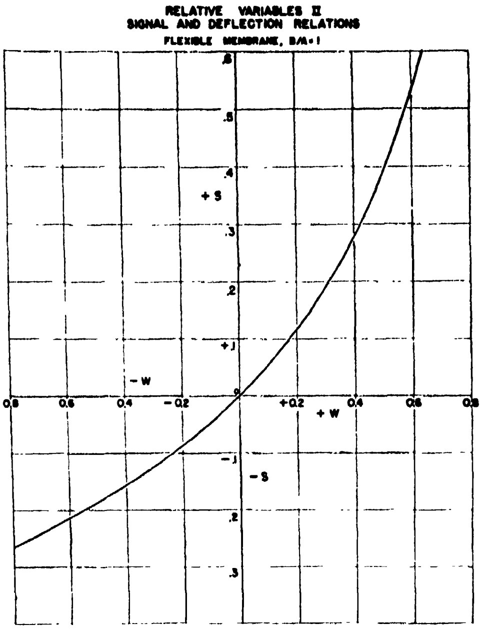

Fig. 5. Relation between the relative displacement and the relative capacitance change for a flexible membrane. The figure is the same as Fig. 4 with the exception that the diaphragm here is a flexible membrane (Fig. 3) instead of a stiff plate. The definitions of the variables are given under Fig. 4; the theory is developed in the text.

For calculation purposes, the arc tangent, the arc hyperbolic tangent, and the logarithmic forms of the solution were used for numerical values of $y_0/D$ greater than 0.10, and the series forms for the lesser values (0.00 to 0.10).

## USE OF THE THEORY IN THE DESIGN OF PICK-UP UNITS

### A. Factors Influencing the Sensitivity

In general the final objective in a problem of the design of a pick-up unit is reached when the unit produces a capacitance signal of the mag-

[10] Roess gives a stiff plate approach case equation which is equivalent to the inverse hyperbolic tangent function in Table III. [L. C. Roess, Rev. Sci. Inst. 11, 183 (1940).]

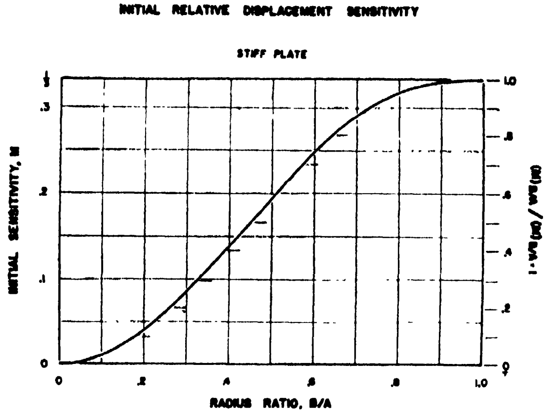

FIG. 6. The dependence of the initial relative displacement sensitivity on the radius ratio for a stiff plate. As is shown in the theory in the text, the initial relative displacement sensitivity, $M$ (Fig. 4), is a function solely of the radius ratio, $B/A$ (Fig. 1). The right-hand scale shows the sensitivity at a given $B/A$ as a fraction of that at the maximum value, at $B/A$ of unity. The initial absolute sensitivity, defined as the absolute capacitance change, $c$, divided by the absolute central deflection, $y_0$ (Fig. 1), can be calculated from these values of $M$, the electrode radius $B$, the diaphragm radius $A$, and the initial air gap, $D$ (see text). The ratios of the secant, $m$, and the tangent, $n$, relative sensitivities (Fig. 4) to $M$ for a number of radius ratios is shown in later figures.

nitude required by a chosen electrical circuit in response to an applied displacement, volume, or pressure change of a size determined by the system in which measurements are to be made. In other words, the designer's problem is to achieve a definite gauge sensitivity. In most biological applications to pressure recording, as was shown above, an additional part of the final objective is to have the volume of the gauge change a minimal amount. In some applications, a minimal alinearity of the calibration curve is also desirable.

Two useful types of sensitivity factors can be defined for diaphragm gauges; the absolute and the relative types. The absolute factors are defined in terms of the variables measured while the gauge is in use, which are the displacement, the volume, or the applied pressure, and the resulting capacitance signal. The relative sensitivity factors are expressed in terms of dimensionless quantities, such as those used in the theoretical equations developed above. After the gauge constants are known, the absolute sensitivity factors can be calculated from the relative sensitivity ones. This calculation will be dealt with in a later section.

## B. Relative Sensitivity

Figures 4 and 5 show the graphs of the function relating the relative capacitance signal, $s$, to the relative displacement factor, $y_0/D$, for a radius ratio, $B/A$, of 1.00 (Tables I and III). As the plate or membrane deflects an infinitesimal amount in either direction ($y_0/D$ approaching zero), the slope of this curve has a definite value. From inspection of the series forms of the equations in Table III, it can be seen that this slope at the origin is a function only of the radius ratio, $B/A$; this slope is called the "initial relative displacement sensitivity," $M$, for a given value of the radius ratio, $B/A$. Figures 6 and 7 show the relation between $M$ and $B/A$ for the two extreme diaphragm types.

As the relative displacement, $w$ (equal to $y_0/D$, Table I), increases beyond an infinitesimal value, the relative sensitivity changes from the initial value, $M$. Two useful types of relative sensitivity factor can be defined for the rest of the curve; these two types are illustrated in Fig. 4. The slope of a straight line from any point on the

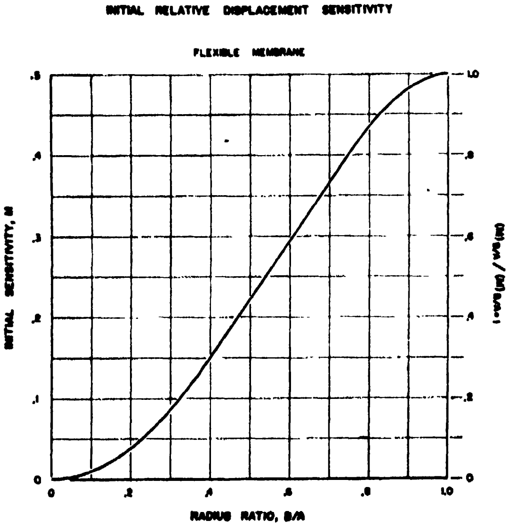

FIG. 7. The initial relative displacement sensitivity and the radius ratio for a flexible membrane. The statements under Fig. 6 apply also to this figure. It is to be noted that the maximum value of $M$ at a $B/A$ of unity for the flexible membrane is one-half, and that for the stiff plate (Fig. 6) is one-third. From the expression for the initial absolute volume sensitivity, $S_v$, (item 22, Table II), and these values of $M$ and the volume constant, $k$ (16 and 17, Table I), it can be shown that the initial absolute volume sensitivity for the stiff plate is equal to that of the flexible membrane considering all other geometrical values as identical, and $B/A$ as unity.

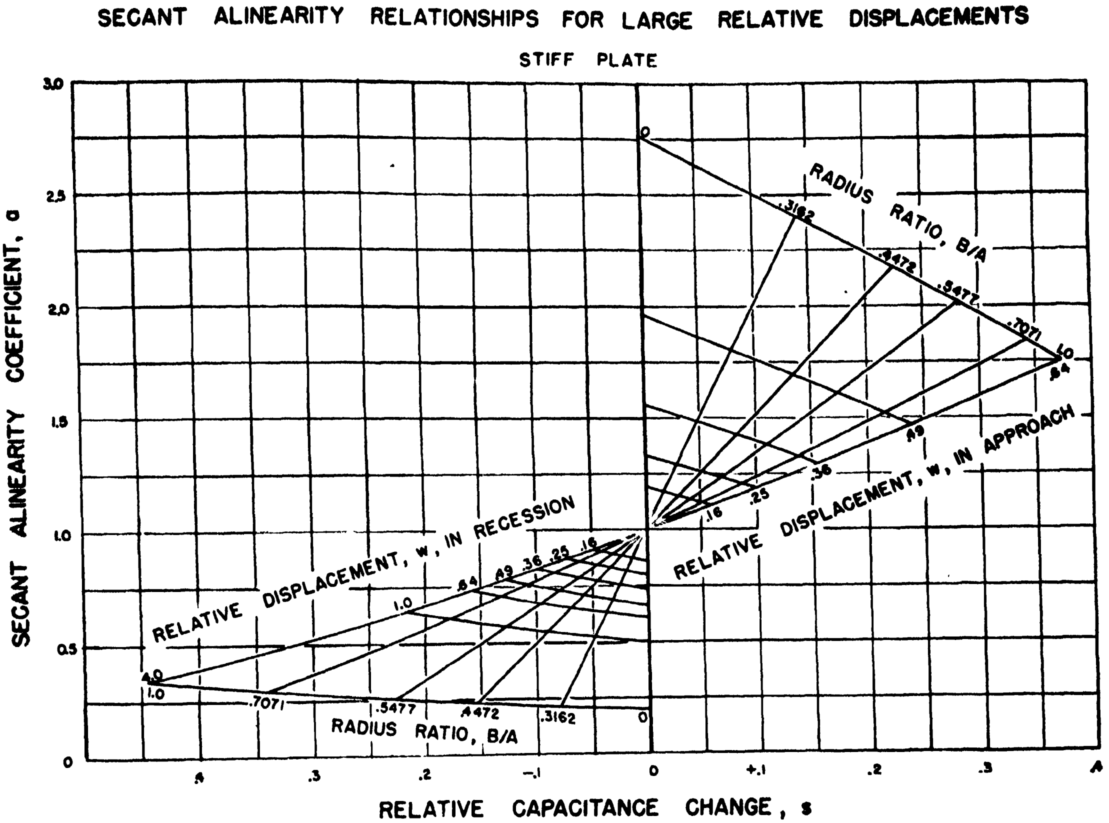

FIG. 8. The secant alinearity coefficient and the relative capacitance signal relations for a stiff plate for large relative deflections. Some of the variables used in this graph are defined under Fig. 4, all variables are defined in Tables I and II. The secant alinearity coefficient, $a$, is the ratio of the secant relative displacement sensitivity, $m$, to the initial displacement sensitivity, $M$. This figure shows the dependence of $a$ on $B/A$, $s$, and $w$ for a stiff plate. A point to be noted is the large deviations from linearity in the approach condition as contrasted with the smaller deviations in recession, for corresponding values of $w$.

curve to the origin is called the "secant relative sensitivity," $m$, which is equal to $s/w$, Table I.

The slope of the curve itself at the same point is the "tangent relative sensitivity," $n$, which is equal to $\partial s/\partial w$. Both $m$ and $n$ approach the initial relative sensitivity value, $M$, as the relative displacement approaches zero, this property of these functions provides a convenient definition for two useful alinearity coefficients.

## C. Gauge Alinearity

Two alinearity coefficients, $a$ and $b$, can be derived from the two displacement sensitivity factors, $m$ and $n$. The "secant alinearity coefficient," $a$, is defined as the ratio of the secant sensitivity to the initial sensitivity, $m/M$, and the "tangent alinearity coefficient," $b$, as $n/M$. Both of these coefficients are defined for a constant value of the radius ratio, $B/A$, and are a function of $w$.

These two coefficients have the value of 1.00 as the relative displacement of the diaphragm approaches zero, i.e., a capacitor gauge is most linear for those diaphragm deflection values which are a very small fraction of the air gap value. This relation is true for the opposite cases of recession and approach, for both types of diaphragm; in recession, the coefficient values are less than 1.00; in approach, greater than 1.00. Figures 8 through 13 show these relations between $a$, $b$, $s$, $w$, and $B/A$ for the two diaphragms.

If the displacement of the center of the diaphragm, $y_0$, is a linear function of the volume change, $v$, or of the applied pressure, $p$, both coefficients give the alinearity values for actual

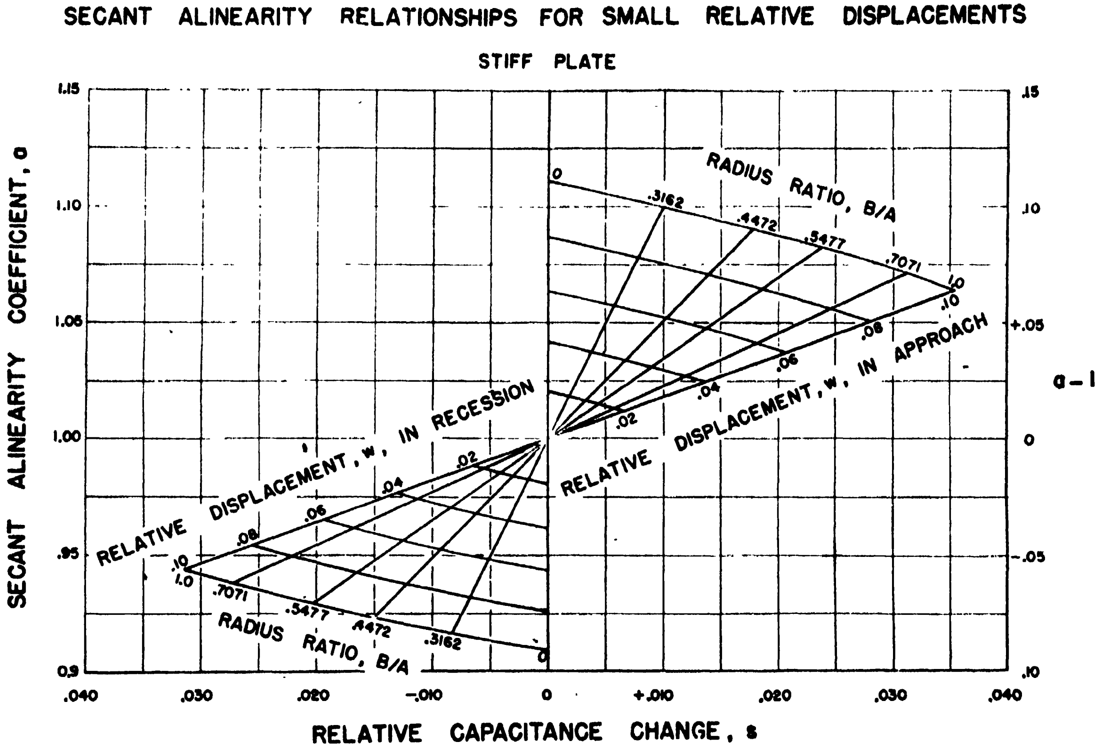

FIG. 9. The secant alinearity coefficient relationships for a stiff plate for small values of the relative displacement. This figure is an amplification of the part of Fig. 8 near zero capacitance change. In those uses of the gauge requiring a high degree of linearity, the variables are restricted to the range on this plot or to an even smaller range. The considerations mentioned under Fig. 8 apply also to this figure.

volume and pressure gauges. In other words, for a constructed gauge the ratio of the slope of the volume change-capacitance curve, or of the pressure-capacitance curve at a given pressure or volume, to the initial slope is given directly by the value of the alinearity coefficients at a given $s$, the relative capacity signal for a given radius ratio, $B/A$. A mechanical design which has a fairly linear pressure-deflection relation is discussed in the section on experimental performance.

### D. Absolute Types of Sensitivity

The absolute sensitivity factors are divided into the two general types, secant and tangent, defined above for the relative displacement factors.

It is convenient to define each of the secant factors as the ratio of the capacitance signal, $c$, to the displacement, $y_0$, to the volume, $v$, or to the pressure, $p$. The tangent sensitivities are defined as the rate of change of the capacitance with respect to each of the three variables. All of these absolute factors are calculable from the gauge constants, $A$, $B$, $D$ (or $C_0$) and the corresponding relative displacement sensitivities, $m$ and $n$; however, it may be easier to use these constants, the initial relative displacement sensitivity, $M$, and the two alinearity coefficients, $a$ and $b$. The equations for these calculations are given in Table II.

The absolute displacement sensitivity, $(c/y_0)$, for a given value of $B/A$, can be shown to be equal to one-fourth the product of the square of the ratio of the diaphragm radius to the air gap, $(A/D)^2$, and the relative sensitivity, $M$ (Table II); $c/y_0$ has an initial value of $(c/y_0)_0$ when $m$ equals $M$. The corresponding tangent factor, $dc/dy_0$, is similarly calculable by substitution of $n$ for $m$ (Table II). The values of $a$ for these and later calculations for various values of $B/A$ and $w$ are given in Figs. 8, 9, and 10; the $b$ values, in Figs. 11, 12, and 13.

In other words, the absolute displacement

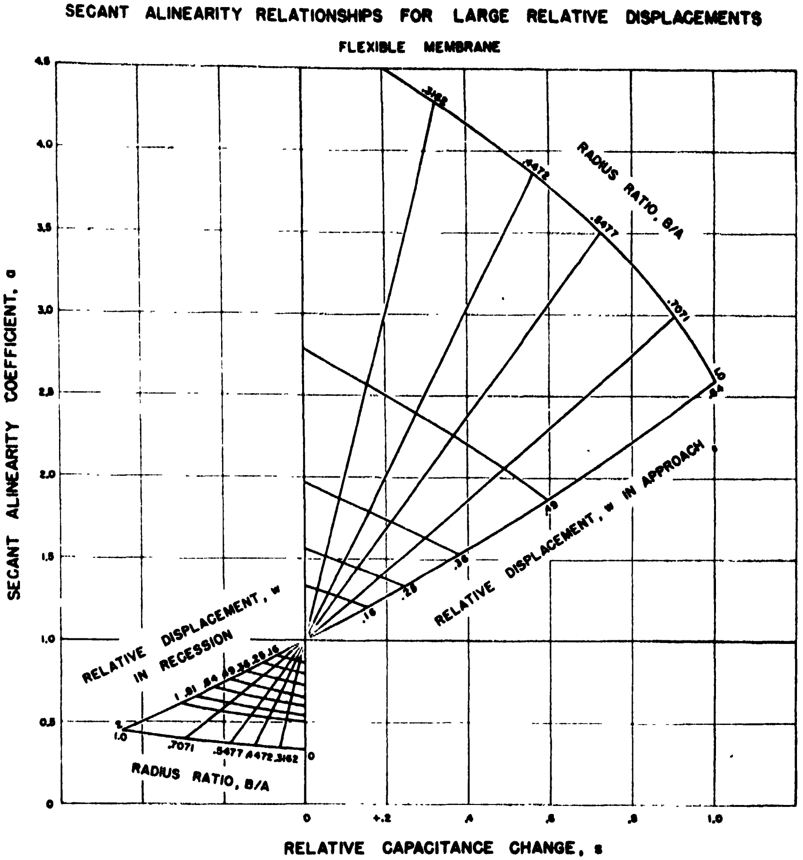

FIG. 10. The secant alinearity relationships for a flexible membrane. This plot for a flexible membrane is of the same type as the one for the stiff plate shown in Fig. 8. Comparing this figure with number 8 it can be seen that the flexible membrane has greater deviations from ideal linearity ($a$ equal to 1.0) than does the stiff plate for the same value of the relative displacement, $w$.

sensitivities, secant and tangent, are independent of the absolute values of the diaphragm radius, thickness, and material; of the electrode radius; and of the air gap. However, these factors are dependent on the ratio of the diaphragm radius to the air gap, and on the relative displacement sensitivity.

The absolute volume sensitivity factors, for a given value of $B/A$ are calculable by the equations given in item 22, Table II; or as in the case of $c/y_0$, by the substitution of $M$ and $a$ or $b$, for $m$ or $n$ in the equations. By these equations it can be shown that the two absolute volume sensitivities for both diaphragm types are independent of the absolute value of the diaphragm radius, thickness, and material; and of the electrode radius. However, the volume sensitivity varies inversely with the absolute value of the initial air gap. This result suggests that the air gap be designed and constructed with as small a value as is practicable in those gauge applications in which the volume change is desired minimal.

There are two alternative ways of calculating the absolute pressure sensitivities; the equations are given as items 23 and 23a in Table II. The first method (item 23) in the stiff-plate case involves knowing at least two of the elastic constants of the material of the diaphragm (Table I, item 14; Young's modulus and Poisson's ratio) with sufficient accuracy for the design problem, and using these to calculate the deflection constant.[11] In the case of the flexible membrane, it involves knowing the value of the initial stretch tension ($G/4$, item 15, Table I) in the membrane to calculate the deflection constant.[9] It was quickly found that the literature lacks the data necessary for a highly accurate calculation of the deflection constant for a stiff plate; and that the methods of measuring or calculating the initial stretch were unsatisfactory in the case of the flexible membrane. However,

[11] R. J. Roark, *Formulas for Stress and Strain* (McGraw-Hill Book Company, Inc., New York, 1938), p. 171, Case 6.

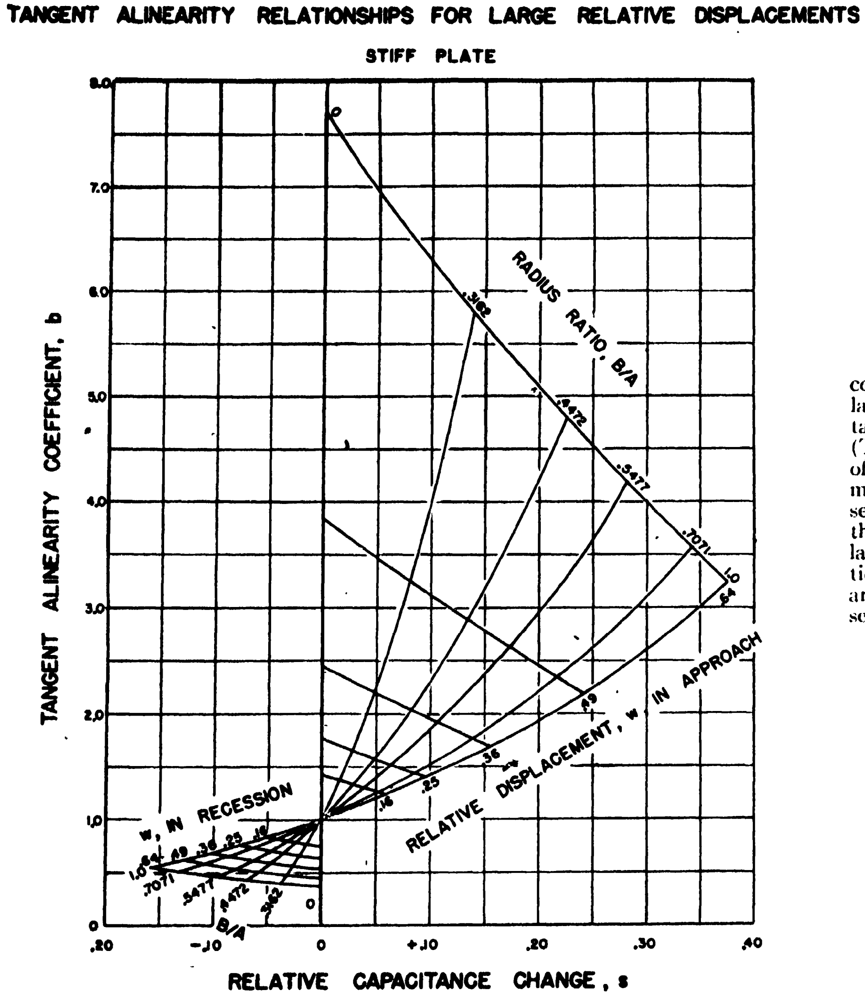

FIG. 11. The tangent alinearity coefficient for a stiff plate for large relative displacements. The tangent alinearity coefficient, $b$, (Table II), is defined as the ratio of the tangent relative displacement sensitivity, $n$, to the initial sensitivity $M$. A comparison of this plot with Fig. 8 shows the large deviations of the variational sensitivity ($n$) from linearity compared with the secant sensitivity, $m$.

for a first approximation in a design problem, this first method is useful.

The second method (item 23a, Table II) of calculating the pressure sensitivity envolves an independent measurement of $y_0/p$ with a diaphragm of the desired material, thickness, and radius. Figure 14 shows such a measurement on a stainless steel diaphragm by an interferometer method. With the determined value of $y_0/p$, the deflection constant can be calculated (Table I) and used in further design modifications to obtain any desired $c/p$ in an actual gauge. The data of Fig. 14 were used to calculate theoretical values of $c/p$ in the evaluation of this design theory (Fig. 15).

## EVALUATION OF THE DESIGN THEORY

Using a stiff-plate gauge shown in Figs. 16 through 19, data were taken on the pressure-capacitance performance ($c/p$ ratios) in the approach and recession conditions (Fig. 15). To check these data against the theory, theoretical $c/p$ values were calculated from the equation in item 23a (Table II) using the measured values of the electrode radius, $B$, the diaphragm radius, $A$, the initial capacitance, $C_0$, the displacement-pressure ratio, $y_0/p$, the value of $M$ from Fig. 6, and the values of $a$ from Figs. 8 and 9. The values of the $y_0/p$ ratio were determined by an interferometric method (Fig. 14), rather than by the less accurate method of calculation from the elastic constants. The results of these calculations are plotted on the graph of Fig. 15 with the experimental data. Figure 15 shows that the stiff-plate theory can be used with a fair degree of accuracy for design purposes, even in the

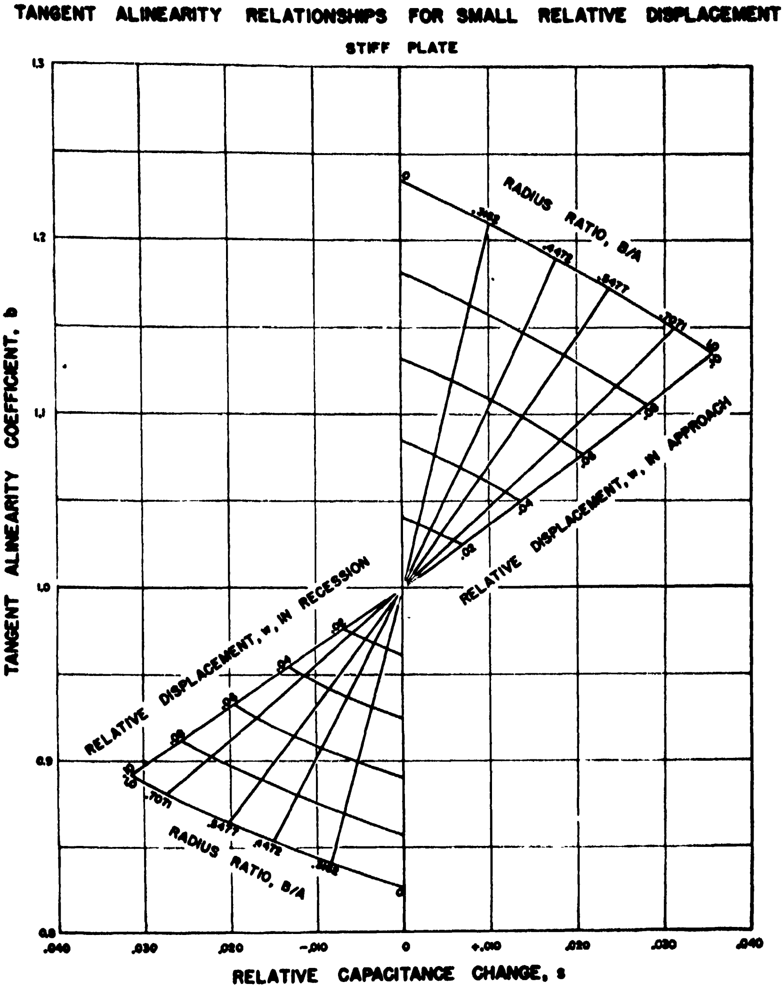

FIG. 12. The tangent alinearity coefficient for a stiff plate for small relative displacements. This plot is an enlarged view of Fig. 11 near the relative displacement of zero magnitude. This is a companion figure to number 9 for designs involving a high degree of linearity.

extreme cases involving large relative displacements ($w = \pm 0.49$) in approach and in recession. The flexible membrane theory still awaits confirmation; it is hoped that this can be done and reported in the near future; there are a few unpublished data which show that reasonably accurate predictions of performance can be expected from the flexible membrane theory.

## SPEED OF RESPONSE OF A CONSTRUCTED GAUGE

Figure 20 shows the response of a gauge with an attached needle to a sudden drop in pressure level. Details of the technique of obtaining the records is given under the figure; the gauge itself is pictured in Figs. 17, 18, and 19. These records show the importance of having a homogeneous conducting medium between the source and the gauge diaphragm. They also show that fairly high speed pressure recording can be accomplished through small conduction tubing with a relatively incompressible fluid, if the volume change of the gauge is small and if the tubing wall is relatively stiff. The volume change (Table I) for the full pressure range in Fig. 20 is approximately $2 \times 10^{-5}$ cc. The contained liquid volume is 0.4 cc; therefore an additional 20 percent must be added to the gauge volume change to allow for the compression of the contained water at a pressure of 150-mm Hg above 1 atmosphere.

For the speed of response of the gauge without an attached fluid system it was found that it was difficult to obtain a step change in pressure level sufficiently fast to approach the lowest natural mode of vibration of the stiff-plate diaphragms used (10 to 60 kilocycles). However, the applica-

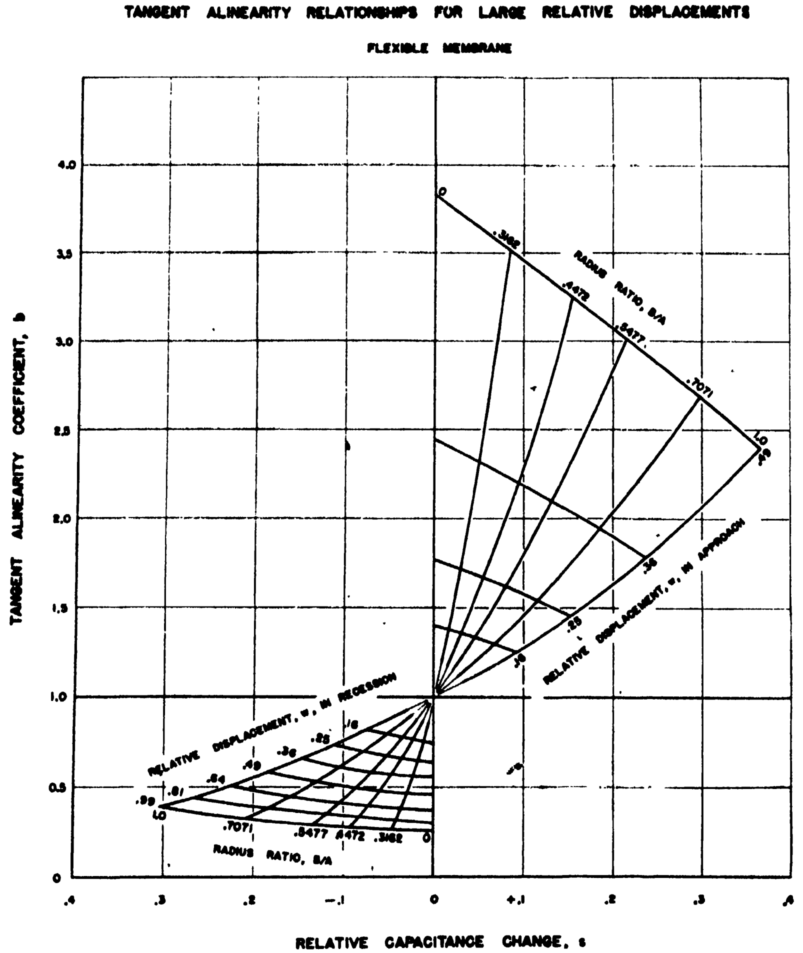

FIG. 13. The tangent alinearity coefficient for a flexible membrane. This figure is to be compared to Fig. 11 for a stiff plate. The tangent alinearity coefficients of the two cases do not differ to a great degree, in contrast to the secant alinearity coefficients (Figs. 8 and 10).

tions of the gauge to date have not made full use of the available speed of response.

## CONSTRUCTION DETAILS TO OBTAIN SMALL AIR GAPS

Standard machining is performed on all components (Fig. 16) except those having critical surfaces which require special techniques as follows:

In the electrode barrel assembly, the electrode (2, Fig. 16) and its lava insulators (6) are assembled to the barrel (4) with bakelite laquer, riveted (12, Fig. 17) and baked. This assembly is faced in the lathe and hand-lapped on a plate-glass lap, until the face of both the electrode and its barrel are in the same flat plane. The electrode spacing is generated by hand-lapping the electrode face with a brass lap. The amount of spacing thus generated is gauged by placing the assembly against a flat metal gauge block and measuring the electrical capacitance between the electrode and the gauge block. If the desired spacing is exceeded, correction may be made by lapping the face of the barrel on the plate glass.

For a given diameter, diaphragms are handled differently as they vary in thickness. A diaphragm of $\frac{11}{16}''$ outside diameter could be classified thick if it were 0.008″ and over, medium 0.004″ to 0.008″, thin 0.004″ and under.

Thick diaphragms are machined from bar stock and hand-lapped to size on plate glass. Frequent turning of the diaphragm, exposing first one face then the other to the lap, will minimize warping from strain release. The thickness of the diaphragm is gauged with a micrometer. The flatness is checked by optical means or by substituting the diaphragm for the gauge block in the capacitance test described above.

Medium diaphragms are disks cut from polished, hard rolled strip metal of the required thickness. The disks are generally curved in a cylindrical plane but approach a flat surface when clamped in position.

Thin diaphragms are disks cut from polished, half-hard rolled metal of the desired thickness. They require stretching while clamping to present flat surfaces. The stretching mechanism (not shown) consists of a recess in the electrode barrel face into which the diaphragm is pressed by a ring member. The ring member is designed with clearance to insure positive seating of the diaphragm.

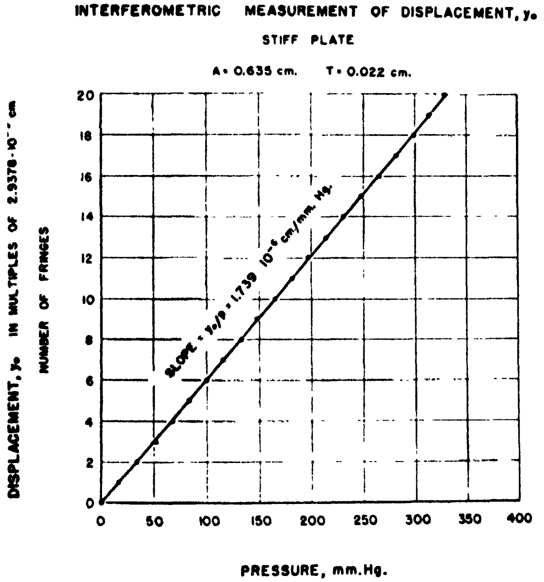

FIG. 14. Experimental determination of the pressure-displacement relation for a stiff plate. The plate is edge-clamped, and corresponds to the diaphragm of the type shown in Fig. 2. The capacitance-pressure relations for this unit are presented in Fig. 15, and the unit itself in Figs. 17, 18, 19, and 20. The absolute central diaphragm displacement, $y_0$ (Table I) was measured with a vertical incidence Newton's fringe type of interferometer, using a yellow line (5875.6 Angstroms) of a helium discharge tube. The fully aluminized plate (1×3×3 mm) of the interferometer was moved toward the 60 percent aluminized fixed plate by displacement of the diaphragm's center by an applied pressure. The pressure was measured with a compensated mercury manometer with an accuracy of ±0.1 mm Hg. The fringes were counted by means of a microscope and an eyepiece scale. Each fringe counted represents a movement of the diaphragm center of one-half of a wave-length of the He line, given on the left of the figure. The pressure range usually used with this gauge unit is that represented by the first two fringes, or 30 mm Hg. The diaphragm displacement is away from the electrode, i.e., in the recession condition.

The strict proportionality between the displacement and the applied pressure up to at least 300 mm Hg (ten times the range actually used) shows that this diaphragm is operated well inside of the proportional elastic limit.

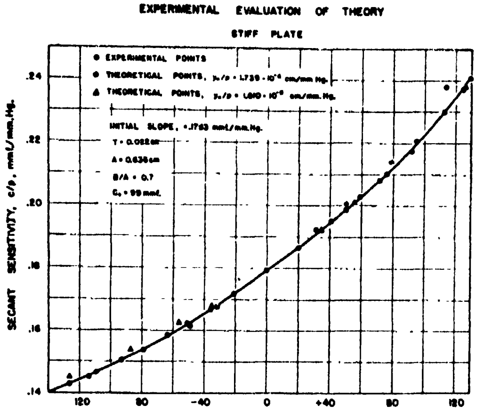

FIG. 15. An experimental evaluation of the design theory for a stiff plate. The capacitance change, $c$, and the initial capacitance, $C_0$, were measured with a "$Q$" meter at a frequency of 3.0 megacycles and by substitution of a precision condenser (General Radio Company). The pressure was measured with the Hg manometer mentioned under Fig. 14. The absolute pressure secant sensitivity factor, $c/p$, was calculated from the measured values of $c$ and $p$; the solid dots and the drawn curve represent these experimental data. The dotted circles are theoretical points calculated from the value of the recession state $y_0/p$ given in Fig. 14, the $B/A$ value of 0.7 (measured $B$ and $A$), the $C_0$ value of 99 mmf, the $M$ value of Fig. 6, and the secant alinearity coefficient values of Fig. 8, by means of the equation given as item 23a in Table II. It can be seen that in recession these points fit the experimental curve fairly well, but deviate from the curve in the high pressure region in the approach state. It was then found, by the interferometric method of Fig. 14, that the value of $y_0/p$ in the approach direction was smaller than in recession (value given in this figure). The points calculated with this value of $y_0/p$ are the triangles. Presumably the difference of $y_0/p$ in the two directions is due to unsymmetrical clamping supports on the two sides of the plate.

The main body (3, Fig. 16) has an interior seat against which the diaphragm is clamped. This seat is hand-lapped to a flat surface with a formed brass lap. The exterior faces of the main body are hand-lapped on plate glass to present flat seats to the mating attachments (13 and 15, Fig. 17), which are similarly finished.

All lapping operations referred to above were performed with a fine grain abrasive and light oil. Silicon carbide No. 400B was used for coarse grinding and No. 600B for finish.

## ELECTRICAL CIRCUITS FOR USE WITH THE GAUGE

The circuit actually used with these gauges will be published later. The choice of a given

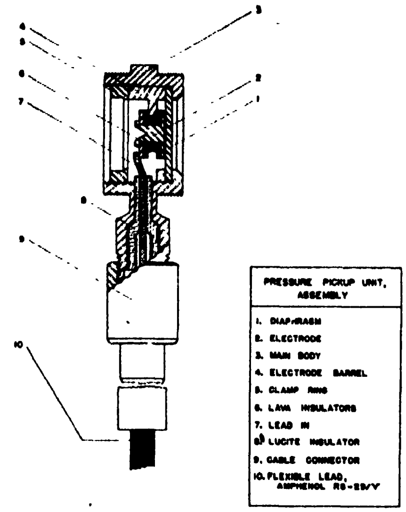

FIG. 16. Sectional drawing of a variable capacitor. The active diaphragm (1) diameter is 0.50 inches. The radius ratio $B/A$ is 0.70. The electrode-diaphragm air gap is $5.10^{-4}$ cm. (0.0002 inch). The pertinent parts are labeled in the figure. The lead-in (7) carries the r.f. voltage to the electrode; the rest of this unit is grounded. It is to be noted that the electrode side of the diaphragm is kept as open as possible to allow quick venting of the gas in this space in applications in which large ambient pressure changes occur, such as in the explosive decompression of pressurized aircraft cabins in altitude chambers. The lava insulators (6) are supported by three equally spaced legs protruding inward radially from the electrode barrel (5); only one of these legs shows in this section. This construction allows the quick venting mentioned above. The construction details to assure small air gaps are given in the text.

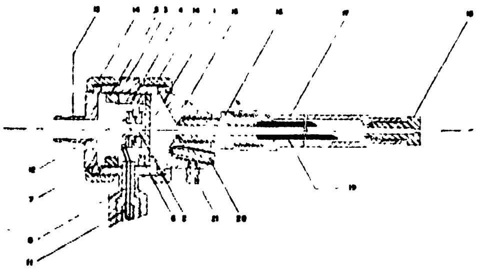

FIG. 17. Sectional drawing of a capacitor with an attached liquid system. Through number 8, the parts are the corresponding ones of Fig. 17. Photographs of this unit are shown in Figs. 18 and 19. A tubing attachment (13) for pressure calibration purposes is shown fastened to the electrode side of the unit by the retaining ring (14). A liquid system (15) with an attached hypodermic needle (16 and 19) is fastened to the diaphragm side of the unit. For the sake of clear reproduction the needle is greatly enlarged; the true relative size is shown in Fig. 18; a side tube (21) and a needle valve (20) are used for filling the liquid system. A needle guard (17) and its terminal plug (18) keep the needle wet and sterile until ready for use. This type of unit has been used for blood pressure, intrathoracic pressure and intraspinal pressure recording (Figs. 21 through 24); its response is shown in Fig. 20.

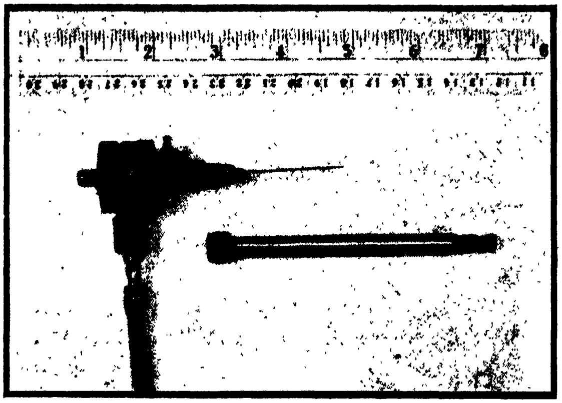

FIG. 18. Internal body pressure condenser gauge. A cross section drawing of this unit and its details is shown in Fig. 17. A photograph of this unit and its attachments is given in Fig. 19. The needle guard is below the needle. This unit is used for blood pressure and other internal body pressure recording (Figs. 23 and 24).

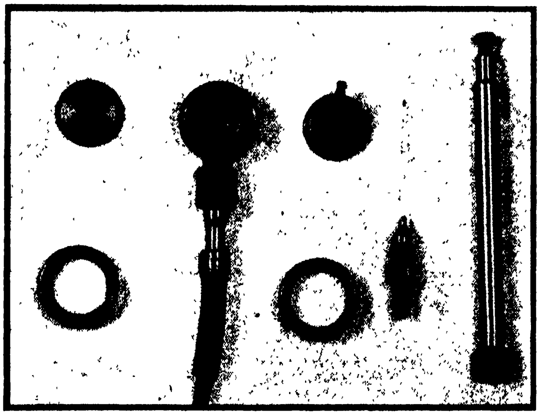

FIG. 19. Pressure gauge with attachments. This is the gauge of Fig. 18 with the tubing connector (left), the liquid system, the needle and its guard (right), removed. The one-half-inch diameter active diaphragm surface is seen as a central ring on the face of the pickup unit. All parts and the gauge itself are made of stainless steel.

circuit depends on the application; several satisfactory ones have been published.[8, 9, 12, 13] One requirement for biological work is that the electrical system record sustained capacitance changes, i.e., record the direct current component as well as the alternating current ones. Cathode-ray oscillographs and oscillograph galvanometers have both been used with success for recorders.

## APPLICATIONS OF THE GAUGE TO MECHANICAL MEASUREMENTS IN BIOLOGICAL SYSTEMS

Various applications of the gauge to pressure recording during the war are presented in Figs. 21 through 25. Since the applications are described under the figures, no further comments will be made here. Other uses of the gauge as an ultramicrometer or a dilatometer in biological systems might be mentioned. The gauge may be used to measure the movements of the body resulting from recoil caused by heart and blood motions in an electrical ballistocardiograph. An obvious use is as a high speed, isometric "lever" for recording the tension developed by muscles during fast or sustained contractions; it may be possible to use it for single muscle fibers. As a dilatometer, the gauge can be used in plesthysmography, thermometry, and respirometry. The volume changes in muscle during fast contractions may possibly be recorded. It may be used in the measurement

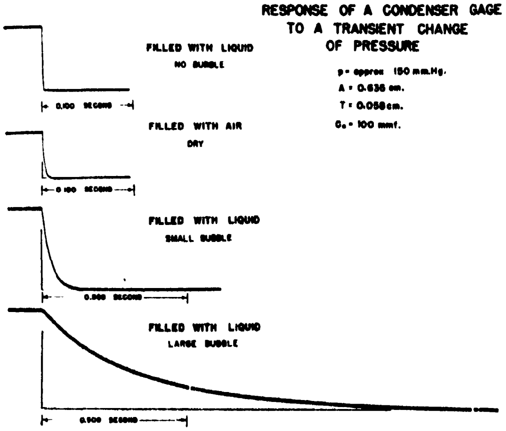

FIG. 20. Response of a capacitor gauge with attached needle to a sudden fall in pressure level. The gauge itself is of the type shown in Figs. 18 and 19. The attached hypodermic needle was a number 23, one-inch long. The volume of the liquid system is 0.4 cc. The needle was immersed in liquid or in air in a short ½-inch diameter well in the face of a 6-inch diameter, horizontal plate, over which was stretched a thin paper diaphragm. The pressure in the air space between the plate and the paper diaphragm was raised with an air supply, and the paper diaphragm was "exploded" away with a mouse trap lever traveling at high speed. The paper broke completely away over the whole plate surface, causing a rapid fall in pressure over the well containing the needle. The conditions causing the various rates of fall of the gauge response are given in the figure. The top record shows a response time of about one-thousandth of a second, which is an upper limit, presumably set by a time constant in the electrical circuit used for recording, rather than by the response time of the mechanical system. (To fill the system with liquid without bubbles, the contained air was flushed out with pure carbon dioxide gas before filling; any bubbles formed of $CO_2$ quickly dissolve in the liquid, leaving the system completely liquid filled.)

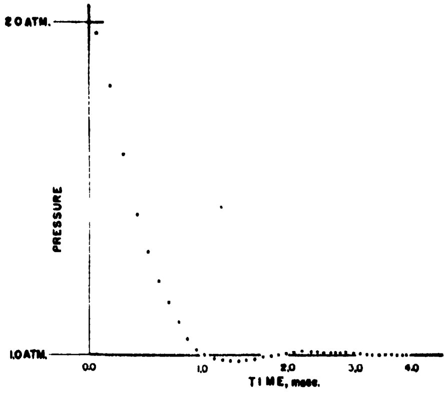

FIG. 21. Explosive decompression of a short cavity. The condenser pressure gauge (of the type shown in Fig. 17) was placed in the bottom of a well 3 inches long and ¾-inch in diameter and containing air. By the technique described under Fig. 20, the pressure at the mouth of this well was suddenly dropped to the ambient pressure from twice the ambient value. This retouched record of the pressure was photographed on a cathode-ray oscilloscope. The time between dots is one ten-thousandth of a second. Note the relatively small after-vibrations in contrast with those of Fig. 22. This gauge was subsequently used in recording the pressure fall in explosively decompressed pressurized cabins in an altitude chamber; the minimum time of pressure fall recorded in these cabins was about four times the value shown here.

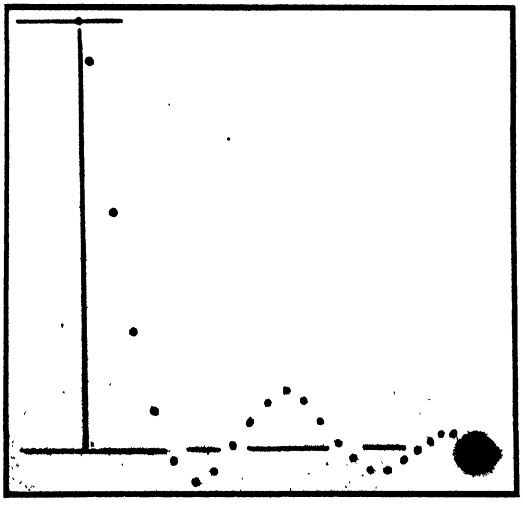

FIG. 22. Explosive decompression of a long air cavity. The technique and the pressure range are the same as those of Fig. 21. The ¾ inch diameter cavity in this case, however, is 3 feet long. The time between dots is two ten-thousandths of a second. The amplitude of the first after-vibration is 2.0 pounds per square inch, after an initial fall of 15 pounds per square inch. This record shows some of the artifacts created by trying to measure relatively large rapid changes in pressure through a long pressure lead, filled with air.

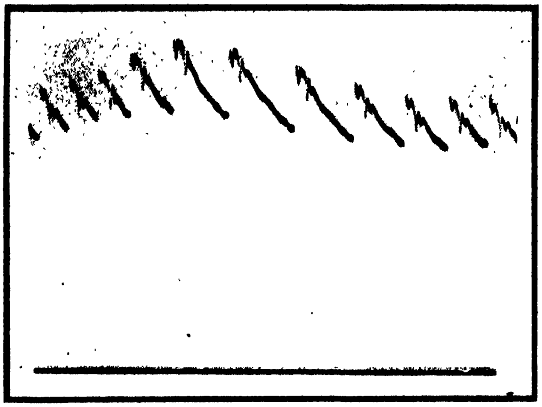

FIG. 23. A blood pressure record in the carotid artery of a dog. The pressure base line is at the bottom of the figure. The peak pressure is approximately 150 mm Hg. The record was taken with a pressure gauge of the type shown in Figs. 18 and 19. This record is shown through the kindness of H. C. Bazett.

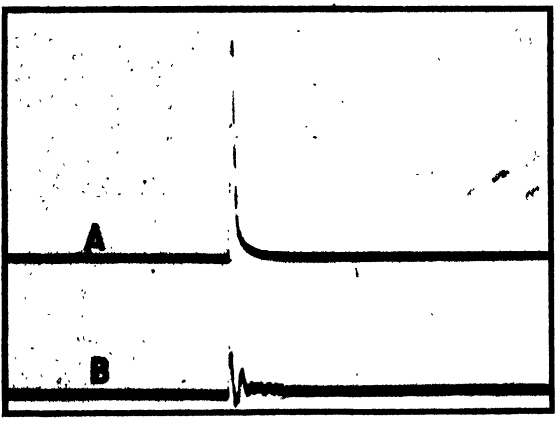

FIG. 24. Record of the intrathoracic and the intraspinal pressure in an explosively decompressed dog. $A$ is the intrathoracic pressure record, and $B$ the intraspinal pressure record. The breaks in the falling phase of record $A$ are at 1/120 second intervals. The condenser gauge used was of the type shown in Figs. 18 and 19. The dog was in a small chamber at an equivalent pressure of 8000 feet; a thin film diaphragm separated this chamber from a larger one at a lower pressure. When the diaphragm was ruptured, the air pressure around the dog fell in 0.03 seconds to that equivalent to 50,000 feet. The two gauge pick-up units were liquid filled, with an electrode side open to ambient pressure and its changes (Fig. 16). The needles were in their respective body spaces. The pressure rise with respect to ambient (about 30 mm Hg in $A$) is apparently due to the relative delay of the air flowing from the lungs. This figure is reproduced through the courtesy of Fred A. Hitchcock, Ohio State University.

of the stimulus of nerve or muscle when pressure or mechanical stresses are applied in a slow or

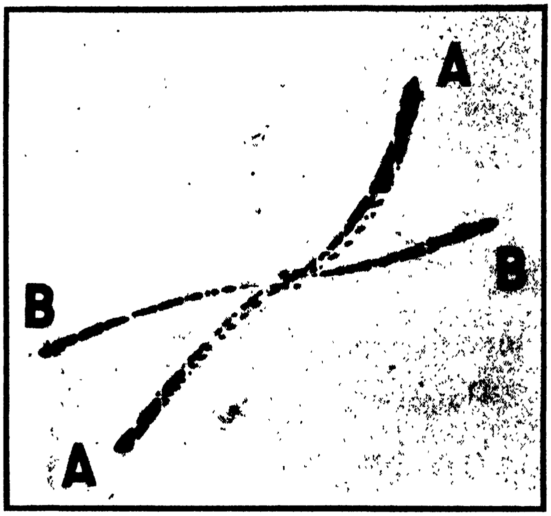

FIG. 25. Pressure-flow curves for air through the nasal passageway. Two, flexible membrane-type pressure gauges with a pressure range of 100 mm of water and 10 mm of water for a capacitance change of 5 mmf were used for recording air pressure and air flow, respectively. The record is a photograph of a cathode-ray tube screen, with flow appearing on the horizontal axis and pressure on the vertical axis. Zero flow and zero pressure are at the center of the record where the two lines cross. Expired gas flow and pressure are in the right upper quadrant, inspired values in the lower left one. The flow values cover about ±50 liters/minute; the pressure about ±80 mm of water. The flow is recorded by measuring the pressure drop across a laminar-flow type glass wool resistor, placed in the tube exit from an oxygen mask covering the subject's nose and mouth. The pressure was measured differentially between the inside of the mask and in $A$–$A$, the subject's oropharynx, and in $B$–$B$, his nasopharynx. In both cases, one nostril is plugged; in $A$–$A$ the pressure tap tube goes into the mouth; in $B$–$B$ the tube goes through the plugged nostril. Record courtesy of Forman and Benevides.

in a fast manner. It is hoped that the design theory presented above will be an aid in extending the applications of this type of gauge in biological research and in the engineering and physical fields.

## ACKNOWLEDGMENTS

The authors wish to express their thanks to Dr. D. W. Bronk for his encouragement during the course of this work; to A. J. Rawson and J. P. Hervey for their help and suggestions; and to J. R. Pappenheimer and G. A. Millikan for their stimulating applications for this gauge.

# Conductivity of Metallic Surfaces at Microwave Frequencies[*]

E. MAXWELL
*Research Laboratory of Electronics, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received February 4, 1947)

Methods of measuring effective conductivities at microwave frequencies are described. These consist of either measuring the transmission loss in a long waveguide, or in measuring the $Q$'s of resonant cavities. Both methods have been applied to measurements at 1.25 cm. Results for a number of metals are presented. Deviations from d.c. conductivity are thought to be due to surface roughness.

## 1. INTRODUCTION

IN the course of development of microwave components it was early observed that the high frequency conductivity of many metallic surfaces was frequently lower than the d.c. conductivity. This phenomenon was especially noticeable in the 1.25-cm region. The work described here was done for the purpose of collecting data on the conductivities of representative surfaces in the region of 1.25 cm.

The r-f conductivity is important in at least two applications. These are:

(1) Long transmission systems where the total attenuation is governed by the conductivity.

(2) Cavity resonators, in which the maximum attainable $Q$ is limited by the effective conductivity.

The effective conductivity of metals at microwave frequencies is governed by a superficially thin surface layer. The current density inside the metal decreases exponentially with depth according to $J=J_0\exp-[(\omega\mu\sigma/2)]^{\frac{1}{2}}x$, where $J_0$ = current density at the surface, $\omega$ = angular frequency, $\mu$ = permeability, $\sigma$ = conductivity, and $x$ = distance into conductor measured along the normal.

When $x=(2/\omega\mu\sigma)^{\frac{1}{2}}$, $J=J_0/e$. This value of $x$ is defined as the skin depth $\delta$. It is easy to show that the total loss, obtained by integrating $J^2/2\sigma$ with respect to $x$, (between 0 and $\infty$), is equal to $J_0^2/2\sigma\delta$. For purposes of calculating losses one may consider the current confined to a skin of thickness $\delta$ within which the current density is uniform and equal to $J_0$. Actually of course 37 percent of the total current flows at depths below $\delta$.

This formulation is rigorously correct only for an infinite plane surface. However, it remains an excellent approximation for curved surfaces whose radii of curvature are large compared to $\delta$. In computing losses one evaluates the integral

$$\int\int_S \frac{J_0^2}{2\sigma}ds=\int\int_S \frac{H_t^2}{2\sigma}ds$$

taken over the surface of the waveguide or cavity. $H_t$ is the tangential component of magnetic field. (The factor 2 comes in since we are interested in average power dissipation, and $J_0$. and $H_t$ are both maximum values of sinusoidal time functions.) If the metal surface is not smooth but has surface irregularities and scratches whose dimensions are comparable with $\delta$, the foregoing treatment is evidently an over-simplification. The presence of scratches may alter the current distribution especially if the scratches are in a direction orthogonal to the lines of current flow. The scratches could conceivably act like constrictions in the effective cross section, thereby increasing the resistance.

## 2. MEASURING TECHNIQUES

Two general methods of measurement have been employed. In the first method the sample to be measured is in the form of a long piece of waveguide or equivalent transmission system. If one end of the waveguide is shorted, the standing-wave ratio seen looking into the other end is a known function of the guide attenuation, which in turn depends on the conductivity. Thus, from a single measurement of standing-wave

---

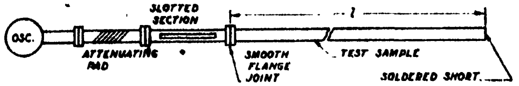

FIG. 1. Attenuation measurement by long guide technique. Rectangular guide.

ratio, the effective conductivity may be computed.

In the second method, the sample forms the walls of a resonant cavity. The $Q$ of the cavity is a known function of the conductivity, and hence the conductivity may be calculated from the measured $Q$. A variation of this method was found quite useful. The input conductance at resonance is directly proportional to the losses in the cavity, or more precisely, to the square root of the wall resistivity. The constant of proportionality depends on the coupling and, if known, a single measurement of the input standing-wave ratio at resonance permits one to calculate the resistivity.

### 2.1 DETAILS OF FIRST METHOD

The measurement set-up for rectangular wave guide is illustrated in Fig. 1. If $r$ is the measured voltage standing-wave ratio, and $l$ is the length of the wave guide, the attenuation is given as follows:

$$\text{Attenuation per unit length} = \alpha$$

$$= \frac{10}{l}\log_{10}\left(\frac{r-1}{r+1}\right)\ \text{db}$$

$$= \frac{1}{2l}\log_e\left(\frac{r-1}{r+1}\right)\ \text{nepers.}$$

The attenuation and conductivity are related by the following expression:

$$\alpha = \frac{1}{2b}\cdot\frac{1}{[1-(\lambda_0/\lambda_c)^2]^{\frac{1}{2}}}\cdot\left(\frac{4\pi}{\lambda_0\mu c\sigma}\right)^{\frac{1}{2}}\cdot\left[1+\frac{2b}{a}\left(\frac{\lambda_0}{\lambda_c}\right)^2\right],$$

where $\alpha$ = attenuation in nepers per meter, $\sigma$ = conductivity in mhos per meter, $a$ = wave guide width in meters, $b$ = waveguide height in meters, $\lambda_0$ = free space wave-length in meters, $\lambda_c = 2a$ = guide cut-off wave-length in meters, $\mu_0$ = permeability of free space (M.K.S.) $= 4\pi \times 10^{-7}$, and $c$ = velocity of light $= 3\times 10^8$ meters per second. This expression is for the $TE_{10}$ mode only. For $0.170'' \times 0.420''$ wave guide at 1.25 cm, the formula reduces to:

$$\alpha = 299/(\sigma)^{\frac{1}{2}}\ \text{nepers per meter.}$$

The length of waveguide is conveniently chosen so as to have a voltage standing-wave ratio of about 5 or 6. At 1.25 cm with common materials, this usually means a waveguide length of the order of six feet. The correction for losses in the slotted section is then negligible.

The far end of the waveguide should be shorted by means of a soldered plate. A choke plunger is unsatisfactory for this purpose, since some power may leak past. If the waveguide is suspected of inhomogeneities or bad spots, a quarter wave-length should be removed from the shorted end and the test repeated. This will shift the standing-wave pattern by a quarter wave-length, and if bad spots are present, the measured loss will probably be different in the two cases. The loss in the short circuiting plate is of course negligible in comparison to that in the wave guide itself.

The foregoing procedure is straightforward enough when dealing with rectangular wave guide. Frequently, however, one wishes to use circular waveguide. This can be done by using a round-to-rectangular transition piece, or transformer, between the round pipe and the slotted section, but a special technique must be employed to avoid errors due to elliptical polarization in the pipe.

It is inevitable that any long piece of round pipe will have both ellipticity and skewness which will cause the incident wave to split up into a pair of cross-polarized waves. Each of these cross-polarized waves will be reflected at the short and come back down the pipe, but only the vertical component of each will couple into the rectangular waveguide. This will cause the observed standing-wave ratio in the rectangular slotted section to be less than the true standing-wave ratio at the sending end of the round pipe.

This difficulty may be eliminated as follows. It may be shown theoretically that given any skewed elliptical pipe, it is possible to choose a direction of polarization for the incident wave, such that the reflected wave arrives with that same polarization. The reflected wave then couples completely into the rectangular wave guide. and the standing-wave ratio observed in the slotted section is the true standing-wave ratio.

If the pipe is a perfect elliptic cylinder, it is clear that either of the principal axes of the ellipse may be taken as the preferred direction. An actual pipe is more apt to resemble a twisted cylinder in which both the orientation of the axes and the ellipticity are functions of position along the axis of propagation. Thus there may be cross-coupling between the modes, and the reflected wave will not generally have the same orientation as the incident wave.

In practice the round wave guide is arranged so that it may be rotated with respect to the transformer (see Fig. 2). The wave guide is rotated until the position of the maximum standing-wave ratio is found. This is the condition for which the reflected wave returns with the same polarization as the incident wave. A convenient type of round-to-rectangular transformer is a quarter wave-length of oval cross section intermediate in shape between the round and rectangular sections. The loss in such a transformer is quite negligible.

This technique was applied in measuring the effective conductivity of mercury. A circular waveguide was constructed by immersing a polystyrene rod in mercury. The details of this experiment are described in the Appendix.

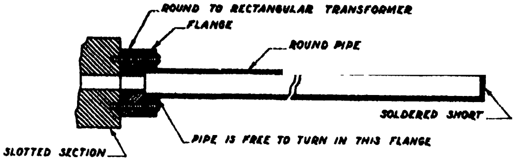
### 2.2 DETAILS OF SECOND METHOD

In any resonant cavity, the unloaded $Q$ is given by

$$Q_0 = \text{const.} \times \frac{\lambda}{\delta},$$

where $\lambda$ is the resonant wave-length, and $\delta$ is the skin depth. The constant of proportionality is a function of the resonator geometry and is known for many of the simpler cases. Thus if one measures $Q_0$, it is simple to compute the effective conductivity from $\delta$ (if the resonator geometry is one for which the theoretical problem has been solved).

In practice, one couples a waveguide into the cavity by means of a coupling window of some sort and measures the variation of input standing-wave ratio with frequency. The half width of the resulting resonance curve determines $Q_L$, the loaded $Q$. Thus,



ROUND TO RECTANGULAR TRANSFORMER FLANGE
ROUND PIPE
SOLDERED SHORT
PIPE IS FREE TO TURN IN THIS FLANGE
SLOTTED SECTION

FIG. 2. Attenuation measurement by long guide technique. Round guide.

$$\frac{1}{2Q_L} = \frac{\omega_{\frac{1}{2}} - \omega_0}{\omega_0} \tag{1}$$

where $\omega_0$ is the resonant frequency and $\omega_{\frac{1}{2}}$ the frequency corresponding to the half-power point. (The half-power point is the frequency at which the power absorbed by the cavity is half the power absorbed at resonance.) The ordinates of the half-power points are given by

$$\beta_{\frac{1}{2}} = \frac{\beta_0 + 1 + (\beta_0^2+1)^{\frac{1}{2}}}{\beta_0 + 1 - (\beta_0^2+1)^{\frac{1}{2}}}, \tag{2}$$

where $\beta_0$ = the voltage standing wave ratio at resonance, and $\beta_{\frac{1}{2}}$ = the voltage standing wave ratio at the half-power point.

The loaded and unloaded $Q$'s are related by

$$\frac{Q_0}{Q_L} = 1 + \frac{Y_0}{G}, \tag{3}$$

where $Y_0$ = the line admittance, and $G$ = the input conductance of the cavity. If the cavity is undercoupled,

$$Y_0/G = 1/\beta_0 \tag{4a}$$

and if overcoupled

$$Y_0/G = \beta_0. \tag{4b}$$

The existence of undercoupling or overcoupling is determined experimentally by the presence of a minimum or a maximum, respectively, at the input window.

A calculating technique which makes somewhat better use of the data is as follows: The equation of the resonance curve is:

$$\left(\frac{2\Delta Q_0 G}{Y_0}\right)^2 \frac{Y_0}{G} + \frac{Y_0}{G} + \frac{G}{Y_0} = \frac{1+\beta^2}{\beta}, \tag{5}$$

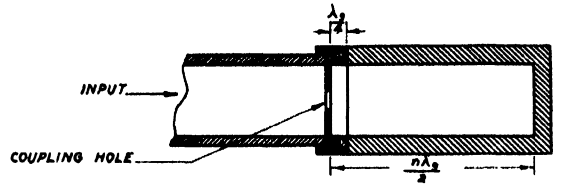


FIG. 3a. Two part resonator.

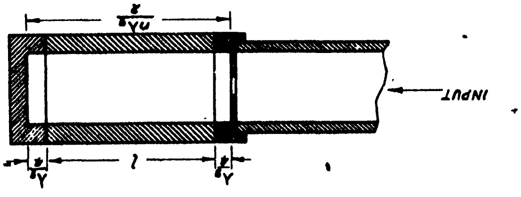

FIG. 3b. Three part resonator.

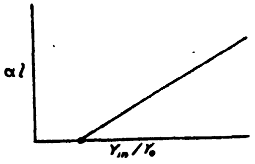

FIG. 3c. Calibration plot.

where $\Delta=(\omega-\omega_0/\omega_0)$, and $\beta$ = voltage standing wave ratio at frequency $\omega$. If one plots $(1+\beta^2/\beta)$ *vs.* $\Delta^2$, a straight line is obtained. By fitting the best straight line to the experimental data, one may evaluate $Q_0$, $Q_L$, and $Y_0/G$. This procedure makes use of the entire resonance curve and not merely three points.

It is thus clear that one may determine $Q_0$ from bandwidth measurements and, having found it, calculate the corresponding effective conductivity of the wall material. In principle then, one may construct a series of cavities from the various materials to be tested and evaluate the effective conductivities by the methods described above.

Although this technique is straightforward, there were a number of practical reasons which militated against its use in this investigation. First of all, the active surfaces, being the interior walls of the cavity, would not always be readily accessible for polishing, plating, or other surface treatment. Secondly, the bandwidth measurements were tedious and difficult with the techniques then available, and since many measurements were to be made, they would have proved very time consuming. The bandwidth measurements require stable oscillators and means for measuring accurately small frequency intervals. Although such equipment is available today, it was not at the time this work was begun. Therefore, a modified technique was developed in which a minimum of bandwidth measurements was required.

Suppose we consider a cavity which is feeding power back to the line, instead of absorbing power from the line. This would be the case when the oscillator is shut off, and the field in the cavity starts to decay. Then,

$$Q_0=2\pi\frac{\text{Energy stored in the cavity}}{\text{Energy dissipated in cavity walls per cycle}},\tag{6a}$$

$$Q_L=2\pi\frac{\text{Energy stored in the cavity}}{\text{Energy dissipated in cavity walls}+\text{energy radiated back to line per cycle}},\tag{6b}$$

$$Q_W=2\pi\frac{\text{Energy stored in the cavity}}{\text{Energy radiated back to line per cycle}}.\tag{6c}$$

$Q_W$ is the window $Q$, or external $Q$. It depends only on the shape of the cavity and the geometry of the coupling window and not upon the conductivity of the walls.

Evidently,

$$1/Q_L=(1/Q_0)+(1/Q_W).\tag{7}$$

Also since

$$Q_0/Q_L=1+(Y_0/G),\quad Y_0/G=Q_0/Q_W.\tag{8}$$

Equation (8) means that the standing-wave ratio at resonance, or its reciprocal, is proportional to the unloaded $Q$.

Thus in principle, if we have a series of cavities which are identical in all dimensions, including those of the coupling window, the input standing-wave ratio of each cavity will be proportional to its $Q$, and the constant of proportionality is the same for all cavities. A bandwidth measurement on just one of the cavities will suffice to determine the window $Q$, and thus the constant of proportionality. The fact is, however, that the window $Q$ varies very rapidly with the coupling window dimensions, so that it is impracticable to maintain the necessary tolerances.

A more practical approach is to build a cavity in two or more demountable sections, such that the test piece may form one of these sections. Examples of this type of construction are indicated in Figs. 3–6.

The first one tried was the $TE_{011}$ resonator of Fig. 5a. The removable sample is the end plate. The lines of current flow are coaxial circles and nowhere cross the contact surface, so that the losses in the oscillating mode are not affected by the contact resistance. There is considerable advantage in having the sample in the form of a flat plate, since this is the most convenient form for cleaning, polishing, plating, etc. This resonator had two serious disadvantages, however. First of all, the $TE_{011}$ mode is intrinsically degenerate with the $TM_{111}$ odd and even modes, so that extreme care must be taken to avoid exciting these modes (if it can be avoided at all). Secondly, there are a number of non-resonant modes present in the cavity which influence the window $Q$ in an undesirable fashion. This trouble seems to arise whenever we use a resonator whose dimensions are such that more than one mode can propagate in the cavity, even though the unwanted modes are non-resonant. For the cavity shown in Fig. 5a, the $TE_{11}$, $TM_{01}$, and $TE_{21}$ modes, which are lower than the $TE_{01}$, will certainly propagate along the axis of the cylinder, and in addition many higher ones will also propagate because of the relatively large diameter. (A squat cavity was chosen in order to make the ratio of sample loss to total loss as large as possible.) These extraneous modes are excited because the presence of the coupling hole, or slit, imposes boundary conditions which cannot be satisfied by the resonant mode alone. The currents which flow, as a result of these modes, do cross the contact surfaces and are therefore controlled by the contact resistance.

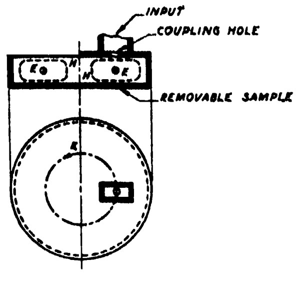

FIG. 5a. $TE_{011}$ mode resonator.

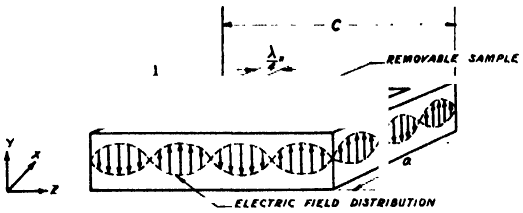

FIG. 6. Rectangular resonator.

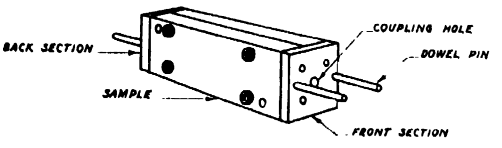
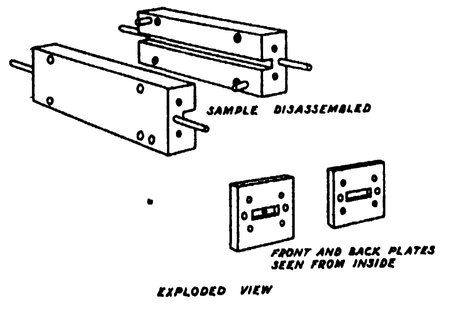


PICTORIAL VIEW



EXPLODED VIEW

FIG. 4. Rectangular resonator details.

The energy stored in these modes determines the equivalent susceptance of the coupling iris and hence the window $Q$. In other words, the window $Q$ depends upon the contact resistance which is not a reproducible quantity. Therefore, the window $Q$ varies from measurement to measurement and must be redetermined each time. Since it was desired to eliminate bandwidth measurements, this type of resonator was discarded.

There is, however, considerable merit in using flat plate samples. With the stabilized oscillators now available,[1] bandwidth measurements in the region of 24,000 Mc are no longer difficult so that the method of the preceding paragraph is entirely practicable today. The $TE_{011}$ cavity is not the best choice, however, owing to the degeneracy with the $TM_{111}$ modes. A suggested cavity, using a removable flat plate sample, is illustrated in Fig. 6. This would operate in the $TE_{l0n}$ mode. By choosing the dimensions such that $b<\lambda_0/2$, and if $a$ and $b$ are incommensurable, one may avoid accidental degeneracies. The resonant wave-length $\lambda_0$ is determined from the relation $(2/\lambda_0)^2=(l/a)^2+(n/c)^2$ in which $l$ and $n$ are equal to the number of half-period variations along the $x$ and $z$ axes, respectively. The contact surfaces are at current nodes. A cylindrical cavity in the $TM_{0m0}$ mode could be used as well, in which case the sample plate would be circular.

Figure 5b illustrates another type of demountable cavity in which the sample is the removable center conductor. This resonator operates in the principal mode. The breaks in the inner and outer conductors occur at points of zero current. One version of this was tried in which the diameter was large enough so that the $TE_{11}$ mode could propagate. Here again it was found that the window $Q$ was not reproducible.

The cavity finally chosen for making most of the measurements was the demountable rectangular type illustrated in Figs. 3 and 4. This was taken as the best compromise between the conflicting requirements of convenient sample shape and simplicity of measuring technique. The cavity operates in the lowest mode, the $TE_{10n}$. The cross-sectional dimensions are standard waveguide dimensions for 1.25 cm, and therefore modes higher than the $TE_{10}$ cannot propagate. The higher modes generated in the vicinity of the coupling window are damped out very rapidly. The breaks in the walls occur across lines of no current flow and are sufficiently removed from the neighborhood of the coupling window so that the higher mode amplitude is practically nil.

Both two- and three-section cavities were used, although the three-section type is preferred because it is easier to get at the active surfaces. An exploded view of the three-part resonator is shown in Fig. 4.

The normalized input conductance at resonance is:

$$G/Y_0=Q_w/Q_0. \tag{8a}$$

For the simple rectangular resonators used this may be written in the form

$$\frac{G}{Y_0}=\frac{n\pi B^2}{2Q_0}\left(\frac{\lambda_g}{\lambda_0}\right)^2=\left(\frac{B}{Y_0}\right)^2(\alpha l+R), \tag{9}$$

where $n=$ the axial length in numbers of half wave-lengths, $\lambda_g=$ the guide wave-length, $\lambda_0=$ the free space wave-length, $B=$ the susceptance of the coupling window, $\alpha=$ the attenuation in the sample portion in nepers/meter, $l=$ the length of the sample portion, and $R=$ a resistance which represents the dissipation in the front and back quarter-wave sections.

In the above formula $(\alpha l)$ is the total attenuation in the sample. The relation between $(\alpha l)$ and $G/Y_0$ is linear. A convenient way to calibrate a pair of front and back quarter-wave sections is as follows. The attenuation in a long piece of waveguide is measured by the short-circuited guide technique described earlier in this paper. Samples with different values of $(\alpha l)$ are obtained by cutting this piece up into short sections, each one of which is a different multiple of a half wave-length. From the data taken with these samples a calibration plot of total attenuation in the sample *vs.* input conductance is obtained as in Fig. 3c.

This calibration plot is then used to determine the attenuation in unknown samples. The sample

[1] Unless otherwise noted, figures are for $TE_{10}$ mode, $\lambda = 1.25$ cm in rectangular guide of dimensions of 0.170″×0.420″.

[2] Theoretical attenuation for $TE_{10}$ mode in 0.170″×0.420″ rectangular waveguide at 1.25 cm is $2590\sigma^{-\frac{1}{2}}$ db/m where $\sigma$ is given in mho/meters. For the $TE_{11}$ mode in round pipe at 1.25 cm, the attenuation is $3330\sigma^{-\frac{1}{2}}$ db/m.

[3] 0.345″ I.D., $TE_{11}$ mode.

[4] No nickel undercoat.

[5] This surface was somewhat rougher than most machined surfaces.

[6] For method of measurement refer to the Appendix. Figures are expressed for a guide of 0.170″×0.420″ cross section.

[7] Only one sample of these was tested.

may be any multiple of a half wave-length. However, for any given window susceptance there is a range of sample attenuations which produce conveniently measurable standing-wave ratios. It is a good idea to plate the front and back sections with some corrosion-resistant material to insure permanence of calibration.

### 3. EXPERIMENTAL RESULTS

The more important available data on conductor losses at 1.25 cm are summarized in Table I. These are expressed in terms of attenuation of the $TE_{10}$ mode in standard 0.170″×0.420″ waveguide at 1.25 cm, or in some cases for the $TE_{11}$ mode in round pipe of 0.345″ diameter. The first column records the value of the experimentally measured attenuation, the second that of the theoretically computed attenuation, and the third column gives the ratio of the two; the fourth and fifth columns list the effective conductivity at 1.25 cm and the d.c. conductivity, respectively.

The theoretical attenuations are computed by means of the formulas given in the footnotes of Table I. The conductivities used in these formulas are the d.c. conductivities listed in the fifth column. The d.c. conductivity of the samples was measured wherever possible but in some cases it was not convenient or possible to do so. In these other cases, the sources from which the d.c. conductivity data were taken, are indicated. In comparing theoretical and experimental performance it is important to have accurate data on the d.c. conductivities if the comparison is to have much significance. In the case of fairly pure materials, such as mercury or electrodeposited metals, the conductivity figures given in handbooks for pure metals are probably good enough, but for commercial metals and alloys there may be discrepancies between tabulated and actual values.

Although the listing is far from complete, many of the common conductor materials are present. There is usually some variation in conductivity among different specimens of the same material, particularly in machined and electroplated surfaces. Where the variation among specimens was more than a few percent, the outside limits of attenuation are stated in the table. Some of the figures are based on a single specimen and are so indicated. In the other cases anywhere from two to about six samples were tested. The probable error to be associated with the attenuation figures is estimated as less than two percent. In the case of the soft solder the error may be of the order of 10 percent since the measurement quoted here is of an earlier vintage than the others and the technique employed was less accurate.

The surfaces examined fall into three categories: drawn, machined, and electrodeposited. The drawn surfaces are as a rule quite good and although their losses are greater than theory predicts, the discrepancy is not large. In the case of brass it may amount to only 5 percent. Machined surfaces are frequently poorer, while plated surfaces seem to vary a good deal.

It seems reasonable to assume that the increase in r-f conductivity over the d.c. value is due primarily to surface roughness. It is difficult, however, to establish such a correlation on the basis of the observed data since no reliable index of surface roughness is available for the samples tested.

The measurement of the r-f conductivity of mercury, which was briefly mentioned earlier, is of interest in this connection. In this experiment the attenuation was measured in a waveguide made by immersing a smooth polystyrene rod in mercury. Because of the surface tension of the mercury, the resulting surface was considered to be free from the usual multitude of scratches and crevices present on solid metallic surfaces. Furthermore, since the skin depth is about eight times as big in mercury as in copper or silver, such irregularities as remain are relatively less important. The measured attenuation agreed with the calculated value within 2 percent which was about as accurately as the standing-wave ratio could be measured. Actually, however, the experimental figure may be in doubt by 4 or 5 percent as a result of a possible uncertainty in the assumed value of the conductivity of coin silver which enters into the experiment. The fact that agreement was attained here between theory and experiment again implies that the lack of agreement observed in other cases is due to surface irregularity. This matter is discussed in the Appendix where the experiment is described in detail.

TABLE II. Conductor losses in K-band waveguide with protective coatings.

| Material | Measured attenuation in db/meter |
|---|---|
| Palladium flash ($10^{-5}$ in.) on coin silver | 0.6 |
| Rhodium flash ($10^{-5}$ in.) on coin silver | 1.0 |
| Sperry f710 lacquer on copper plate | 1.2 |
| Same surface without lacquer | 0.6 |
| Zinc chromate olive drab primer on 17S aluminum alloy | 1.0 |

It should be noted that for the monel sample also, there is substantial agreement between observed and calculated attenuations. The skin depth in monel is approximately the same as in mercury. Thus one may infer that because of the greater skin depth the scratches are less important.

Many attempts were made to improve the conductivity of samples by polishing the active surfaces by both mechanical and electrolytic methods, but none of these were successful. Probably something of the order of a metallographic or optical polish is necessary, but it was not possible to approach this degree of excellency on account of the awkward shape of the surfaces to be polished. In this connection, flat samples would be decidedly advantageous.

The reverse process was possible. The conductivity was definitely lowered in many cases by abrading the surface. For example, when some yellow brass waveguide tubing was broached out, the attenuation was increased from 0.68 db/m to 0.74 db/m.

Thin oxide films are not harmful as long as the oxide resistivity is high. It may be shown that the effect of oxide films is small as long as the skin depth in the oxide material is large compared to the oxide layer thickness.

The effect of a few protective coatings in increasing attenuation is shown in Table II.

Of all the solid metals listed mild steel has the greatest loss. This behavior has been explained by Kittel on the basis of the magnetic properties.[2]

## ACKNOWLEDGMENT

I am indebted to Dr. E. M. Purcell, formerly of the Radiation Laboratory, for many helpful suggestions.

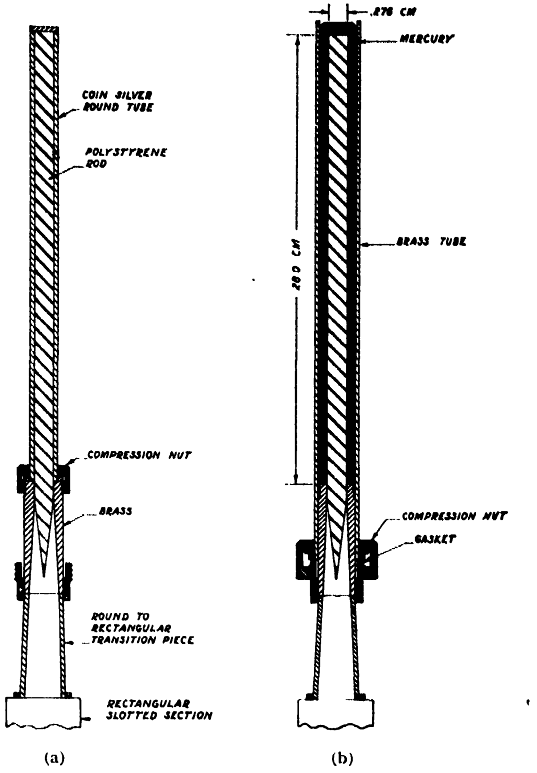
## APPENDIX

### The Mercury Waveguide Experiment

The experimental setup is indicated in Figs. 7a and 7b. The wave guide consisted of a round polystyrene rod immersed in mercury. This was tapered into a round air-filled guide as shown in Fig. 7b. A round-to-rectangular transition coupled the round guide to a standard rectangular slotted section. The rod was then treated as a shorted round waveguide and the attenuation measured by the techniques described under method I for round guide.

The dielectric losses were separated from the conductor losses in the following manner. Before setting up the mercury guide a tightly fitting drawn coin silver tube was slipped over the polystyrene rod, as in Fig. 7a. The input standing-wave ratio was measured, and from this the total attenuation in the polystyrene-silver guide was calculated. The silver tube was then removed and the polystyrene rod immersed in mercury as in Fig. 7b. The standing-wave ratio was again measured and the attenuation in the polystyrene system calculated. The difference between these two figures is the conductor attenuation in the mercury minus the conductor attenuation in the coin silver. The attenuation in the coin silver was calculated by using the effective conductivity established from previous measurements on drawn rectangular coin silver wave guide, and the attenuation due to the mercury was determined. The attenuation thus found agreed with theory within 2 percent.

An estimate of the limit of error was made on the following basis. The attenuation in the polystyrene-silver system was 1.46 db; in the polystyrene-mercury system it was 3.29 db, mercury attenuation less silver attenuation



FIGS. 7a and 7b. Mercury wave guide.

=1.83 db. The effective conductivity of coin silver wave guide is $3.3\times 10^7$ mhos per meter. The conductor attenuation for the $TE_{11}$ mode in the silver tube was 0.40 db for a 28 cm length (see Fig. 7b). The net loss due to the mercury alone was therefore 2.23 db or 8.0 db per meter. The value calculated by using the tabulated figure of $0.1044\times 10^7$ mhos per meter for mercury at 20°C, was 8.10 db per meter. The error depends largely on the accuracy of the assumed attenuation for the coin silver. By assuming a 20 percent error in estimating the attenuation in silver, which should certainly be an outside figure, the uncertainty in the mercury attenuation would be less than 4 percent.

It should also be pointed out that residual mismatch in the taper or transition causes very little error because of the fact that the mismatch appears in both measurements and almost completely cancels out in the final result. As a preliminary part of the experiment, taper and transition mismatch was investigated by slipping

some close fitting poly-iron sleeves over the polystyrene rod, in place of the silver tube, so as to obtain a matched absorbing load. The voltage standing-wave ratio looking in was 1.08. It may be verified by calculation that in the worst case this would make an error of less than ½ percent.

*Formula Used in Computing Attenuation:*[3]

$$\alpha=\frac{1}{a}\left(\frac{\pi\epsilon\nu}{\sigma}\right)^{\frac{1}{2}}\left[1-\left(\frac{\nu_{11}'}{\nu}\right)^{2}\right]^{\frac{1}{2}}\times\left[\left(\frac{\nu_{11}'}{\nu}\right)^{2}+\frac{1/u_{11}'^{2}}{1-1/u_{11}'^{2}}\right].$$

$a$ = radius of polystyrene rod, $\epsilon=2.52\epsilon_0$ for polystyrene, $u_{11}'=1.84$, $\nu_{11}'=[u_{11}'/2\pi a(\epsilon\mu)^{\frac{1}{2}}]$, and $\nu$ = frequency. M.K.S. units used.

# Note on Circular Loop Antennas with Non-Uniform Current Distribution

G. Glinski
*Northern Electric Company, Montreal, Quebec, Canada*

(Received February 6, 1947)

In this paper are presented the approximate formulas for the components of radiation vectors of a short-circuited circular loop with non-uniform current distribution. The formulas are valid for the ratio of loop perimeter to wavelength of the order of 0.5 or less, and assume the current distribution of the hyperbolic cosine form. These formulas lead to the radiation intensity formula from which the expressions for the horizontal and vertical field patterns are derived. The latter formulas are further simplified assuming that the attenuation constant is much smaller than the phase constant. From the expression for horizontal field pattern, it follows that the pattern is symmetrical about the loop axis of symmetry. Moreover, this horizontal pattern exhibits a directional effect with maximum field in the direction of the feeder end of the loop. This directional effect is a function of loop dimensions. The theoretical horizontal pattern agrees very closely with the experimental one. From the expression for vertical field pattern, it follows that the non-uniform current distribution produces a pattern intermediate between that for horizontal dipole and horizontal small loop with uniform current distribution. The field intensity in the zenithal direction is again a function of loop dimensions. Using the expression for radiation intensity, formulas for a radius of equivalent circular horizontal field pattern, power gain, average power gain, and radiation resistance are derived. It is shown that the average power gain is essentially a function of loop radius and decreases with the increase of the latter. Finally, the approximate expression for the attenuation constant of the transmission line equivalent to the loop is derived.

The purpose of this note is to present formulas for radiation pattern and gain of circular loop antennas with non-uniform current distribution. Although the problem is of considerable practical importance for the designer of some f-m broadcast antennas[1–4] whose elements are often circular loops or may be considered as such to the first approximation, there appears to be very little in the literature on the subject.[5, 6]

The general problem of current distribution on a circular radiating loop has been treated previously.[7, 8]

In the following, the actual current distribution will be approximated by that on the equivalent uniform transmission line.[9] The effect of radiation will be included in the attenuation of this line.[10]

## GENERAL FORMULA FOR RADIATION VECTOR OF CIRCULAR LOOP

Consider the circular loop in $(\theta=\pi/2)$-plane of the spherical coordinate system $r$, $\varphi$, $\theta$ of

[10] S. A. Schelkunoff, *Electromagnetic Waves* (D. Van Nostrand Company, Inc., New York, 1943), p. 200.

Fig. 1. The center of the loop is at the origin of the coordinate system.

Consider two diametrically opposite loop elements $A$ and $B$ with the coordinates $\bar{r}$, $\bar{\varphi}$, $\pi/2$, and $\bar{r}$, $\bar{\varphi}+\pi$, $\pi/2$, and currents of complex amplitudes $I_A$ and $I_B$, respectively.

Following Schelkunoff[11] the components of elementary radiation vectors are

$$\begin{aligned} dN_{A,x} &= -I_A\bar{r}\sin\bar{\varphi}d\bar{\varphi}e^{jt},\\ dN_{A,y} &= I_A\bar{r}\cos\bar{\varphi}d\bar{\varphi}e^{jt},\\ dN_{B,x} &= I_B\bar{r}\sin\bar{\varphi}d\bar{\varphi}e^{-jt},\\ dN_{B,y} &= -I_B\bar{r}\cos\bar{\varphi}d\bar{\varphi}e^{-jt}, \end{aligned} \tag{1}$$

where $t=\beta\bar{r}\sin\theta\cos(\varphi-\bar{\varphi})$.

The components of equivalent elementary radiation vector are therefore

$$\begin{aligned} dN_x &= -I_1\bar{r}\sin\bar{\varphi}d\bar{\varphi},\\ dN_y &= I_1\bar{r}\cos\bar{\varphi}d\bar{\varphi}, \end{aligned} \tag{2}$$

where $I_1=I_Ae^{jt}-I_Be^{-jt}$.

It is convenient to introduce the symmetrical and anti-symmetrical components of currents defined by

$$\begin{aligned} I_A &= (I_s+I_a)/2,\\ I_B &= (I_s-I_a)/2. \end{aligned} \tag{3}$$

In terms of $I_s$ and $I_a$, formulas (2) can be written as:

$$\begin{aligned} dN_x &= -I_1\bar{r}\sin\bar{\varphi}d\bar{\varphi},\\ dN_y &= I_1\bar{r}\cos\bar{\varphi}d\bar{\varphi}, \end{aligned} \tag{4}$$

where $I_1=jI_s\sin t+I_a\cos t$.

In the case of f-m broadcast antennas, $\beta\bar{r}$ is of the order of 0.5. It is quite accurate therefore to replace the trigonometric functions in formula (4) by first terms of their Bessel expansion[12] (Appendix 1). To the first approximation therefore

$$\begin{aligned} dN_x &\cong -I_2\bar{r}\sin\bar{\varphi}d\bar{\varphi},\\ dN_y &\cong I_2\bar{r}\cos\bar{\varphi}d\bar{\varphi}, \end{aligned} \tag{5}$$

where $I_2=J_0(\beta\bar{r}/2)[j4I_sJ_1(\beta\bar{r}/2)\sin\theta\cos(\varphi-\bar{\varphi})+I_aJ_0(\beta\bar{r}/2)]$.

The components of total radiation vector are found by summing up the contributions of all elementary components of radiation vectors:

$$N_x=\int_0^{\pi} dN_x,\quad N_y=\int_0^{\pi} dN_y. \tag{6}$$

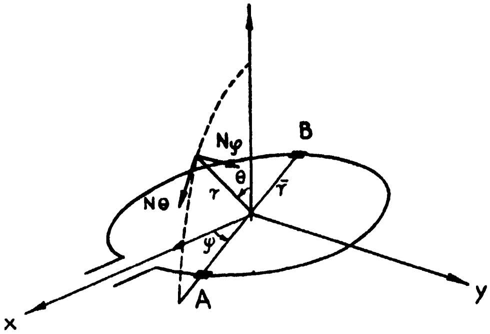

FIG. 1. Coordinate system used.

## RADIATION VECTOR OF SHORT-CIRCUITED CIRCULAR LOOP

Consider the important practical case of the loop fed at $\bar{\varphi}=0$, and short-circuited at $\bar{\varphi}=\pi$. The current distribution on the equivalent transmission line is

$$I_l=I\cosh\gamma l; \tag{7}$$

where $I$ = current at the short-circuit; $\gamma$ = propagation constant $=\alpha+j\beta$; $l$ = distance from the short-circuit. $I_A$ and $I_B$ of formulas (3) are:

$$\begin{aligned} I_A &= I\cosh\gamma\bar{r}(\pi-\bar{\varphi}),\\ I_B &= I\cosh\gamma\bar{r}\bar{\varphi}. \end{aligned} \tag{8}$$

Therefore,

$$\begin{aligned} I_s &= I[(\cosh\gamma\bar{r}\pi+1)\cosh\gamma\bar{r}\bar{\varphi}\\ &\qquad -\sinh\gamma\bar{r}\pi\sinh\gamma\bar{r}\bar{\varphi}],\\ I_a &= I[(\cosh\gamma\bar{r}\pi-1)\cosh\gamma\bar{r}\bar{\varphi}\\ &\qquad -\sinh\gamma\bar{r}\pi\sinh\gamma\bar{r}\bar{\varphi}]. \end{aligned} \tag{9}$$

The elementary integration and reduction (Appendix 2) of formulas (6), using the values of $I_s$ and $I_a$ from formula (9), gives

$$N_x=I\bar{r}J_0\left[-jJ_1\sin\theta\frac{16\sin j\gamma\bar{r}\pi}{j\gamma\bar{r}(4+\gamma^2\bar{r}^2)}\sin\varphi\right], \tag{10}$$

$$\begin{aligned} N_y=I\bar{r}J_0\Bigg[&jJ_1\sin\theta\frac{8(2+\gamma^2\bar{r}^2)\sin j\gamma\bar{r}\pi}{j\gamma\bar{r}(4+\gamma^2\bar{r}^2)}\cos\varphi\\ &-J_0\frac{2j\gamma\bar{r}\sin j\gamma\bar{r}\pi}{1+\gamma^2\bar{r}^2}\Bigg], \end{aligned} \tag{11}$$

where $J_0\equiv J_0(\beta\bar{r}/2)$, $J_1\equiv J_1(\beta\bar{r}/2)$.

The spherical components of total radiation vector are, therefore,[13]

[13] S. A. Schelkunoff, reference 10, p. 234.

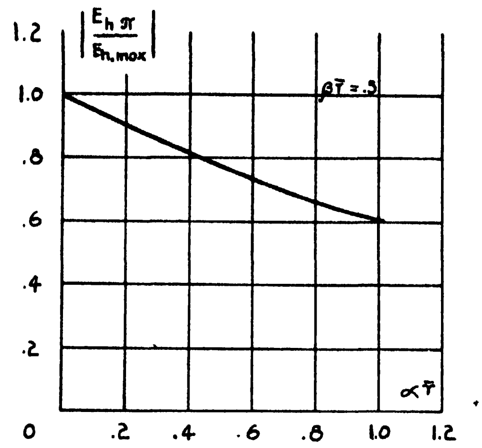

FIG. 2. Ratio of electrical field intensities in ($\varphi=\pi$)- and ($\varphi=0$)-directions in the plane of the loop *versus* attenuation constant $\alpha\bar{r}$ for $\beta\bar{r}=0.5$.

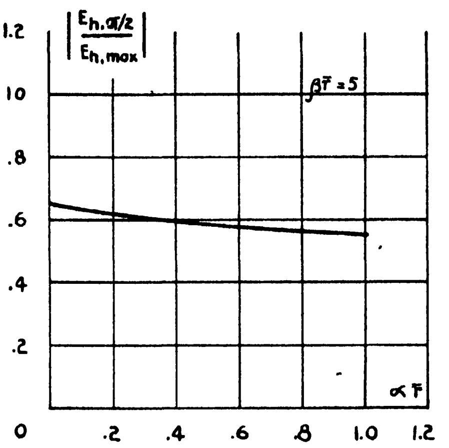

FIG. 3. Ratio of electrical field intensities in ($\varphi=\pi/2$)- (or $3\pi/2$) and ($\varphi=0$)-directions in the plane of the loop *versus* attenuation constant $\alpha\bar{r}$ for $\beta r=0.5$.

$$N_\theta=(N_x\cos\varphi+N_y\sin\varphi)\cos\theta$$

$$=A\left[-j\frac{J_1}{J_0}\frac{\sin 2\theta\sin 2\varphi}{4+\gamma^2\bar{r}^2}-\frac{\cos\theta\sin\varphi}{1+\gamma^2\bar{r}^2}\right];\quad(12)$$

where $A=2I\bar{r}J_0{}^2j\gamma\bar{r}\sin j\gamma\bar{r}\pi$,

$$N_\varphi=-N_x\sin\varphi+N_y\cos\varphi$$

$$=A\left[-j\frac{J_1}{J_0}\frac{4(2+\gamma^2\bar{r}^2\cos^2\varphi)\sin\theta}{\gamma^2\bar{r}^2(4+\gamma^2\bar{r}^2)}-\frac{\cos\varphi}{1+\gamma^2\bar{r}^2}\right].\quad(13)$$

Using the approximations of Appendix 3, the formulas (12) and (13) reduce to:

$$\begin{aligned}N_\theta=A[(&-f(J_1/J_0)\sin 2\theta\sin 2\varphi-a\cos\theta\sin\varphi)\\&+j(-e(J_1/J_0)\sin 2\theta\sin 2\varphi\\&\qquad+b\cos\theta\sin\varphi)],\end{aligned}\quad(14)$$

$$\begin{aligned}N_\varphi=A[(&-8d(J_1/J_0)\sin\theta\\&-4f(J_1/J_0)\sin\theta\cos^2\varphi-a\cos\varphi)\\&+j(-8c(J_1/J_0)\sin\theta\\&-4e(J_1/J_0)\sin\theta\cos^2\varphi+b\cos\varphi)].\end{aligned}\quad(15)$$

## FIELD PATTERN OF SHORT-CIRCUITED CIRCULAR LOOP

The radiation intensity[14] is

$$\Phi=\frac{15\pi}{\lambda^2}(N_\theta N_\theta{}^*+N_\varphi N_\varphi{}^*),\quad(16)$$

where asterisk denotes conjugate quantity. Therefore, using formulas (14) and (15)

$$\begin{aligned}\Phi=\frac{15\pi|A|^2}{\lambda^2}\Bigg[&\left(f\frac{J_1}{J_0}\sin 2\theta\sin 2\varphi+a\cos\theta\sin\varphi\right)^2\\&+\left(e\frac{J_1}{J_0}\sin 2\theta\sin 2\varphi+b\cos\theta\sin\varphi\right)^2\\&+\left(8d\frac{J_1}{J_0}\sin\theta+4f\frac{J_1}{J_0}\sin\theta\cos^2\varphi+a\cos\varphi\right)^2\\&+\left(8c\frac{J_1}{J_0}\sin\theta+4e\frac{J_1}{J_0}\sin\theta\cos^2\varphi-b\cos\varphi\right)^2\Bigg].\end{aligned}\quad(17)$$

In practical antennas $d\gg f$ and $c\gg e$; therefore, neglecting the terms of the order of $f$ and $e$ in the last two round brackets:

$$\begin{aligned}\Phi=\frac{15\pi|A|^2}{\lambda^2}\Bigg[&\left(f\frac{J_1}{J_0}\sin 2\theta\sin 2\varphi+a\cos\theta\sin\varphi\right)^2\\&+\left(e\frac{J_1}{J_0}\sin 2\theta\sin 2\varphi+b\cos\theta\sin\varphi\right)^2\\&+\left(8d\frac{J_1}{J_0}\sin\theta+a\cos\varphi\right)^2\\&+\left(8c\frac{J_1}{J_0}\sin\theta-b\cos\varphi\right)^2\Bigg].\end{aligned}\quad(18)$$

The field intensity[15] is $|E|=(240\pi\Phi)^{\frac{1}{2}}/r$. Using

---

[14] S. A. Schelkunoff, reference 10, p. 235.

[15] S. A. Schelkunoff, reference 10, p. 333.

formula (18), the horizontal field pattern is:

$$|E_h| = B\left[\left(8d\frac{J_1}{J_0}+a\cos\varphi\right)^2+\left(8c\frac{J_1}{J_0}-b\cos\varphi\right)^2\right]^{\frac{1}{2}}, \tag{19}$$

where $B=60\pi|A|/r\lambda$.

From the definition of the coefficients $a$, $b$, $c$, and $d$, it follows that: $a>0$, $b>0$, $c<0$, $d>0$. Therefore, the maximum field intensity in the horizontal plane is for $\varphi=0$

$$|E_{h,\max}| = B\left[\left(8d\frac{J_1}{J_0}+a\right)^2+\left(8c\frac{J_1}{J_0}-b\right)^2\right]^{\frac{1}{2}}. \tag{20}$$

The field intensity in the horizontal plane for $\varphi=\pi$ is

$$|E_{h,\pi}| = B[(8d(J_1/J_0)-a)^2 + (8c(J_1/J_0)+b)^2]^{\frac{1}{2}}. \tag{21}$$

The ratio of field intensities in $\varphi=\pi$ and $\varphi=0$ directions is, therefore,

$$|E_{h,\pi}|/|E_{h,\max}| = \left[\frac{(8d(J_1/J_0)-a)^2+(8c(J_1/J_0)+b)^2}{(8d(J_1/J_0)+a)^2+(8c(J_1/J_0)-b)^2}\right]^{\frac{1}{2}}. \tag{22}$$

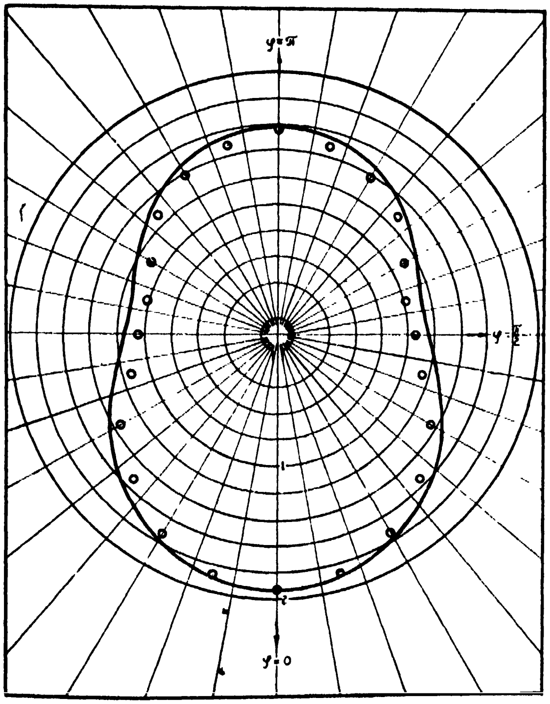

FIG. 4. Horizontal field pattern for $\alpha\bar{r}=0.04$ and $\beta\bar{r}=0.5$. Encircled points were obtained experimentally.

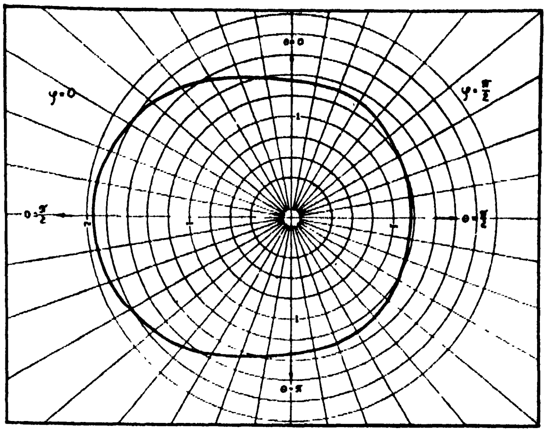

FIG. 5. Vertical field pattern in ($\varphi=0$)-(left) and ($\varphi=\pi/2$)-(right) planes for $\alpha\bar{r}=0.04$ and $\beta\bar{r}=0.5$.

From the last formula and the definition of coefficients $a$, $b$, $c$, $d$, it follows that the ratio of field intensities in $\varphi=\pi$ and $\varphi=0$ directions is a function of $\alpha\bar{r}$ and $\beta\bar{r}$. Figure 2 shows this ratio *versus* $\alpha\bar{r}$ for the important practical case of $\beta\bar{r}=0.5$.

The field intensity in the horizontal plane for $\varphi=\pi/2$ (or $3\pi/2$) is

$$|E_{h,\pi/2}| = B\left[\left(8d\frac{J_1}{J_0}\right)^2+\left(8c\frac{J_1}{J_0}\right)^2\right]^{\frac{1}{2}}. \tag{23}$$

The ratio of field intensities in $\varphi=\pi/2$ and $\varphi=0$ directions is

$$|E_{h,\pi/2}|/|E_{h,\max}| = \left[\frac{(8d(J_1/J_0))^2+(8c(J_1/J_0))^2}{(8d(J_1/J_0)+a)^2+(8c(J_1/J_0)-b)^2}\right]^{\frac{1}{2}}. \tag{24}$$

This ratio is again a function of $\alpha\bar{r}$ and $\beta\bar{r}$. Figure 3 shows this ratio *versus* $\alpha\bar{r}$ for $\beta\bar{r}=0.5$. Figure 4 is the plot of horizontal field pattern according to formula (18) for $\alpha\bar{r}=0.04$, and $\beta\bar{r}=0.5$. The encircled points represent the experimental pattern plotted to the same scale, and having the same value of $|E_{h,\pi}|/|E_{h,\max}|$ as the theoretical one.

It can be concluded that the horizontal field pattern of the circular short-circuited loop has the following characteristics:

1. The pattern is symmetrical about the $(0, \pi)$-direction.
2. There is the maximum field intensity in ($\varphi=0$)-direction (feeder end).

The vertical field pattern is

$$|E_v| = B[(f(J_1/J_0)\sin 2\theta \sin 2\varphi + a\cos\theta \sin\varphi)^2 + (e(J_1/J_0)\sin 2\theta \sin 2\varphi + b\cos\theta\sin\varphi)^2 + (8d(J_1/J_0)\sin\theta + a\cos\varphi)^2 + (8c(J_1/J_0)\sin\theta - b\cos\varphi)^2]^{\frac{1}{2}}. \quad (25)$$

In any $\varphi$-direction, the field intensity has a maximum value for $\theta=\pi/2$, that is in the horizontal plane.

The zenithal value of the field intensity ($\theta=0$) is

$$|E_{v,z}| = B(a^2+b^2)^{\frac{1}{2}}, \quad (26)$$

and is independent of $\varphi$.

Figure 5 is the plot of vertical field pattern according to formula (24) for $\alpha\bar{r}=0.04$ and $\beta\bar{r}=0.5$, for $\varphi=0$ and $\varphi=\pi/2$.

## RADIUS OF EQUIVALENT CIRCULAR HORIZONTAL FIELD PATTERN

The field intensity of the equivalent circular horizontal field pattern can be found from the formula

$$\pi|E_{h,\mathrm{Av}}|^2 = \tfrac{1}{2}\int_0^{2\pi} |E_h|^2 d\varphi. \quad (27)$$

Using formula (19) and after the elementary integration (Appendix 4)

$$|E_{h,\mathrm{Av}}| = B[64(J_1/J_0)^2(d^2+c^2)+0.5(a^2+b^2)]^{\frac{1}{2}}. \quad (28)$$

## POWER GAIN OF SHORT-CIRCUITED CIRCULAR LOOP

The radiation intensity from formula (18), when reduced to the unity maximum, is

$$\Phi^1 = \frac{\Phi}{\Phi_{\theta=\pi/2,\,\varphi=0}} = \frac{1}{64(J_1/J_0)^2(d^2+c^2)+16(J_1/J_0)(ad-bc)+(a^2+b^2)}[(J_1/J_0)^2(e^2+f^2)\sin^2 2\theta\sin^2 2\varphi + 2(J_1/J_0)(af+be)\sin 2\theta\cos\theta\sin 2\varphi\sin\varphi + (a^2+b^2)\cos^2\theta\sin^2\varphi + 64(J_1/J_0)^2(d^2+c^2)\sin^2\theta + 16(J_1/J_0)(ad-bc)\cos\varphi\sin\theta + (a^2+b^2)\cos^2\varphi]. \quad (29)$$

The radiated power[16] is

$$P = \int_{\theta=0}^{\theta=\pi}\int_{\varphi=0}^{\varphi=2\pi} \Phi^1 \sin\theta d\theta d\varphi. \quad (30)$$

Therefore (Appendix 5):

$$P = \frac{(8\pi/3)\{(J_1/J_0)^2[0.4(e^2+f^2)+64(d^2+c^2)]+(a^2+b^2)\}}{64(J_1/J_0)^2(d^2+c^2)+16(J_1/J_0)(ad-bc)+(a^2+b^2)}. \quad (31)$$

If short dipole is used as a reference,[17] the power gain is

$$(PG) = \frac{(8\pi/3)}{P} = \frac{64(J_1/J_0)^2(d^2+c^2)+16(J_1/J_0)(ad-bc)+(a^2+b^2)}{(J_1/J_0)^2[0.4(e^2+f^2)+64(d^2+c^2)]+(a^2+b^2)}. \quad (32)$$

## AVERAGE POWER GAIN

In f-m broadcasting, it is customary to base the gain on the equivalent circular horizontal field pattern. Since the average radiation intensity in the horizontal plane is

$$\Phi_{\mathrm{Av}} = r^2|E_{h,\mathrm{Av}}|^2/240\pi = (r^2B^2/240\pi)[64(J_1/J_0)^2(d^2+c^2) + 0.5(a^2+b^2)], \quad (33)$$

and the maximum radiation intensity in the horizontal plane is

$$\Phi_{\max} = \Phi_{\theta=\pi/2,\,\varphi=0} = \frac{r^2B^2}{240\pi}\left[\left(8d\frac{J_1}{J_0}+a\right)^2+\left(8c\frac{J_1}{J_0}-b\right)^2\right]; \quad (34)$$

therefore, the average power gain is

$$(PG)_{\mathrm{Av}} = \frac{\Phi_{\mathrm{Av}}}{\Phi_{\max}}(PG) = \frac{64(J_1/J_0)^2(d^2+c^2)+0.5(a^2+b^2)}{(J_1/J_0)^2[0.4(e^2+f^2)+64(d^2+c^2)]+(a^2+b^2)}. \quad (35)$$

---

[16] S. A. Schelkunoff, reference 10, p. 333.

[17] S. A. Schelkunoff, reference 10, p. 337.

The graph of $(PG)_{\mathrm{Av}}$ *versus* $\beta\bar{r}$ for $\alpha\bar{r}=0.04$ is shown in Fig. 6. (Since $c\gg d$ and $a\gg b$ in the practical range of $\alpha\bar{r}$, the gain computed for $\alpha\bar{r}=0$ may be applied also to the general case when $\alpha\bar{r}\neq 0$.)

## TRANSMISSION LINE EQUIVALENT TO THE CIRCULAR LOOP WITH NON-UNIFORM CURRENT DISTRIBUTION

The radiated power $P$ is given by formula (31). If the maximum current (at $\varphi=\pi$) is $I$, the radiation resistance $R_r$ is

$$R_r=\frac{2P}{I^2}=\frac{16\pi}{3I^2}\frac{(J_1/J_0)^2[0.4(e^2+f^2)+64(d^2+c^2)]+(a^2+b^2)}{64(J_1/J_0)^2(d^2+c^2)+16(J_1/J_0)(ad-bc)+(a^2+b^2)}. \tag{36}$$

Since $P$ in formula (31) was calculated for maximum radiation intensity equal to unity, therefore, from formula (18):

$$I^2=1\Big/\frac{15\pi|A|^2}{\lambda^2}\left[\left(8d\frac{J_1}{J_0}+a\right)^2+\left(8c\frac{J_1}{J_0}-b\right)^2\right]. \tag{37}$$

$$R_r=\frac{80\pi^2|A|^2}{\lambda^2}\left\{\left(\frac{J_1}{J_0}\right)^2[0.4(e^2+f^2)+64(d^2+c^2)]+(a^2+b^2)\right\}. \tag{38}$$

To calculate the attenuation constant $\alpha$ of the equivalent transmission line, let its resistance per unit length be $\rho$, and the current

$$I_{\bar{\varphi}}=I\cos\beta\bar{r}(\pi-\bar{\varphi}).$$

The power dissipated in the entire line is

$$\iota=\int^{\pi}\tfrac{1}{2}I_{\bar{\varphi}}^2\rho\bar{r}d\bar{\varphi}$$

$$=\tfrac{1}{4}I^2\rho\bar{r}\pi[1+(\sin 2\beta\bar{r}\pi/2\beta\bar{r}\pi)]. \tag{39}$$

From the equality of radiated and dissipated power:

$$\pi\rho\bar{r}=\frac{2R_r}{1+(\sin 2\beta\bar{r}\pi/2\beta\bar{r}\pi)}. \tag{40}$$

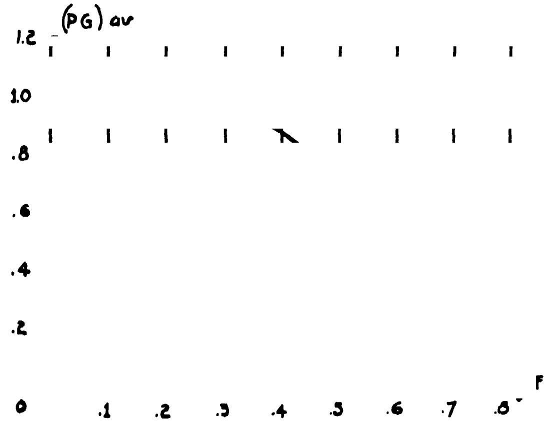

FIG. 6. Average power gain *versus* $\beta\bar{r}$ for $\alpha\bar{r}=0$.

On the other hand[18]

$$\alpha\bar{r}\pi=\frac{\pi\rho\bar{r}}{2Z_0}=\frac{R_r}{Z_0[1+(\sin 2\beta\bar{r}\pi/2\beta\bar{r}\pi)]}, \tag{41}$$

where $Z_0$ is the characteristic impedance of equivalent transmission line. According to Libby[19]

$$Z_0=276\log_{10}(\bar{r}/d), \tag{42}$$

where $\bar{r}$ is the mean loop radius, and $d$ the loop conductor diameter.

## ACKNOWLEDGMENTS

The author wishes to thank Mr. E. S. Kelsey for his help during the preparation of this paper, and Mr. J. C. Murray for computing aid.

## APPENDIX I

### Bessel Expansion of sin*t* and cos*t*

Since $\sin\theta\cos(\varphi-\bar{\varphi})=\frac{1}{2}(\sin\delta+\sin\epsilon)$, where $\delta=\theta+\varphi-\bar{\varphi}$, $\epsilon=\theta-\varphi+\bar{\varphi}$. Therefore,

$$\sin t=\sin\left[\frac{\beta\bar{r}}{2}\sin\delta\right]\cos\left[\frac{\beta\bar{r}}{2}\sin\epsilon\right]+\cos\left[\frac{\beta\bar{r}}{2}\sin\delta\right]\sin\left[\frac{\beta\bar{r}}{2}\sin\epsilon\right].$$

Using first terms of Bessel expansion[12] for sin and cos, $\sin t\leqq 4J_0J_1\sin\theta\cos(\varphi-\bar{\varphi})$, where $J_0\equiv J_0(\beta\bar{r}/2)$, $J_1\equiv J_1(\beta\bar{r}/2)$. Similarly,

$$\cos t=\cos[(\beta\bar{r}/2)\sin\delta]\cos[(\beta\bar{r}/2)\sin\epsilon]-\sin[(\beta\bar{r}/2)\sin\delta]\sin[(\beta\bar{r}/2)\sin\epsilon].$$

---

[18] S. A. Schelkunoff, reference 10, p. 196.

Using again first terms of Bessel expansion for sin and cos, $\cos t \cong J_0^2$, since $J_1^2 \ll J_0^2$.

## APPENDIX II

## Definite Integrals Appearing in Formulas (6)

Using Dwight's "Tables of Integrals" and elementary trigonometric identities:

$$\int_0^{\pi} \cosh\gamma\hat{r}\,\sin\bar{\varphi}\cos(\varphi-\bar{\varphi})d\bar{\varphi} =\frac{1}{4+\gamma^2\hat{r}^2}\left[(1-\cos j\gamma\hat{r}\pi)\cos\varphi+\frac{2\sin j\gamma\hat{r}\pi}{j\gamma\hat{r}}\sin\varphi\right], \tag{A2-1}$$

$$\int_0^{\pi} \sinh\gamma\hat{r}\bar{\varphi}\,\sin\bar{\varphi}\cos(\varphi-\bar{\varphi})d\bar{\varphi} =\frac{j}{4+\gamma^2\hat{r}^2}\left[\sin j\gamma\hat{r}\pi\cos\varphi+\frac{2(\cos j\gamma\hat{r}\pi-1)}{j\gamma\hat{r}}\sin\varphi\right], \tag{A2-2}$$

$$\int_0^{\pi} \cosh\gamma\hat{r}\bar{\varphi}\,\sin\bar{\varphi}d\bar{\varphi}=\frac{1+\cos j\gamma\hat{r}\pi}{1+\gamma^2\hat{r}^2}, \tag{A2-3}$$

$$\int_0^{\pi} \sinh\gamma\hat{r}\bar{\varphi}\,\sin\bar{\varphi}d\bar{\varphi}=-j\frac{\sin j\gamma\hat{r}\pi}{1+\gamma^2\hat{r}^2}. \tag{A2-4}$$

Therefore, after reduction, formula (6) yields

$$N_x=I\hat{r}J_0\left[-jJ_1\sin\theta\frac{16\sin j\gamma\hat{r}\pi}{j\gamma\hat{r}(4+\gamma^2\hat{r}^2)}\sin\varphi\right]. \tag{A2-5}$$

Similarly

$$\int_0^{\pi} \cosh\gamma\hat{r}\varphi\,\cos\bar{\varphi}\cos(\varphi-\bar{\varphi})d\varphi =\frac{1}{4+\gamma^2\hat{r}^2}\left[\frac{(2+\gamma^2\hat{r}^2)\sin j\gamma\hat{r}\pi}{j\gamma\hat{r}}\cos\varphi +(1-\cos j\gamma\hat{r}\pi)\sin\varphi\right], \tag{A2-6}$$

$$\int_0^{\pi} \sinh\gamma\hat{r}\bar{\varphi}\,\cos\bar{\varphi}\cos(\varphi-\bar{\varphi})d\bar{\varphi} =\frac{j}{4+\gamma^2\hat{r}^2}\left[\frac{(2+\gamma^2\hat{r}^2)(\cos j\gamma\hat{r}\pi-1)}{j\gamma\hat{r}}\cos\varphi +\sin j\gamma\hat{r}\pi\sin\varphi\right], \tag{A2-7}$$

$$\int_0^{\pi} \cosh\gamma\hat{r}\bar{\varphi}\,\cos\bar{\varphi}d\bar{\varphi}=\frac{j\gamma\hat{r}\sin j\gamma\hat{r}\pi}{1+\gamma^2\hat{r}^2}, \tag{A2-8}$$

$$\int_0^{\pi} \sinh\gamma\hat{r}\bar{\varphi}\,\cos\bar{\varphi}d\bar{\varphi}=j\frac{j\gamma\hat{r}(1+\cos j\gamma\hat{r}\pi)}{1+\gamma^2\hat{r}^2}. \tag{A2-9}$$

Therefore, after reduction, the second formula (6) yields

$$N_y=I\hat{r}J_0\left[jJ_1\sin\theta\frac{8(2+\gamma^2\hat{r}^2)\sin j\gamma\hat{r}\pi}{j\gamma\hat{r}(4+\gamma^2\hat{r}^2)}\cos\varphi -J_0\frac{2j\gamma\hat{r}\sin j\gamma\hat{r}\pi}{1+\gamma^2\hat{r}^2}\right]. \tag{A2-10}$$

## APPENDIX III

## Approximations to Formula (11)

Write

$$\gamma\hat{r}=\alpha\hat{r}+j\beta\hat{r}=j\beta\hat{r}[1-j(\alpha/\beta)].$$

Since $\alpha \ll \beta$

$$(\gamma\hat{r})^2\cong-(\beta\hat{r})^2\left[1-j\frac{2\alpha\hat{r}\beta\hat{r}}{(\beta\hat{r})^2}\right].$$

Therefore,

$$\frac{1}{1+\gamma^2\hat{r}^2}\cong\frac{1}{1-(\beta\hat{r})^2}-j\frac{2\alpha\hat{r}\beta\hat{r}}{1-2(\beta\hat{r})^2}=a-jb,$$

$$\frac{1}{4+\gamma^2\hat{r}^2}\cong\frac{1}{4-(\beta\hat{r})^2}-j\frac{2\alpha\hat{r}\beta\hat{r}}{16-8(\beta\hat{r})^2}=e-jf,$$

$$\frac{1}{\gamma^2\hat{r}^2(4+\gamma^2\hat{r}^2)}\cong-\frac{1}{(\beta\hat{r})^4[16-8(\beta\hat{r})^2]}-j\frac{2\alpha\hat{r}\beta\hat{r}}{4(\beta\hat{r})^4}=c-jd.$$

## APPENDIX IV

## Integral in Formula for Radius of Equivalent Circular Horizontal Pattern

From formula (19)

$$|E_h|^2=B^2[64(J_1/J_0)^2(d^2+c^2)+16(J_1/J_0)(ad-bc)\cos\varphi +(a^2+b^2)\cos^2\varphi].$$

Therefore, after the elementary integration

$$\int_0^{2\pi}|E_h|^2d\varphi=\pi B^2[128(J_1/J_0)^2(d^2+c^2)+(a^2+b^2)].$$

## APPENDIX V

## Integration of Formula (30)

Using Dwight's "Tables of Integrals," the integrals appearing in formula (30) are:

$$\int_0^{\pi}\sin^2 2\theta\sin\theta d\theta\int_0^{2\pi}\sin^2 2\varphi d\varphi=\frac{16}{15}\pi,$$

$$\int_0^{\pi}\sin 2\theta\sin\theta\cos\theta d\theta\int_0^{2\pi}\sin 2\varphi\sin\varphi d\varphi=0,$$

$$\int_0^{\pi}\sin\theta\cos^2\theta d\theta\int_0^{2\pi}\sin^2\varphi d\varphi=\frac{2}{3}\pi,$$

$$\int_0^{\pi}\sin^3\theta d\theta\int_0^{2\pi}d\varphi=\frac{8}{3}\pi,$$

$$\int_0^{\pi}\sin^2\theta d\theta\int_0^{2\pi}\cos\varphi d\varphi=0,$$

$$\int_0^{\pi}\sin\theta d\theta\int_0^{2\pi}\cos^2\varphi d\varphi=2\pi.$$

# High Speed Compression Tests on Copper

M. Greenfield, *North American Aviation, Los Angeles, California*

AND

E. T. Habib, *David Taylor Model Basin, Carderock, Maryland*

(Received December 19, 1946)

Dynamic shortening of one-half inch long copper cylinders is achieved by striking them with a hardened steel projectile at high velocities. The average strain rate was about 1200 per second. Energy per unit volume absorbed by the copper is plotted against strain. A true stress-logarithmic strain curve is computed. This curve is compared with a similar curve derived from high speed tests on copper in tension.

## INTRODUCTION

THIS work was undertaken originally to provide a dynamic calibration for copper cylinders. These cylinders are used in mechanical gauges which are designed to measure the pressure in the water originating from an under-water explosion. The copper is deformed dynamically in compression in such gauges. The experimental arrangement described below was designed so that the copper cylinders were subjected to the same kind of forces as they were when used in the gauges. However, it was thought that additional information could be obtained from the data which would be of wider interest.

These data have been put in the form of stress *versus* strain curves. Usually stress is defined as the force acting on the specimen divided by the original cross-sectional area of the test portion, i.e.,

$$\sigma_c = F/A_0$$

where $A_0$ is the original cross-sectional area. This stress, $\sigma_c$, is also called the engineering stress. The strain is frequently defined as the change in length per unit original length, i.e.,

$$\epsilon_c = \Delta l/l_0$$

where $l_0$ is the original length.

While some work has been done by Nadai and Manjoine on high speed tension tests of metals,[1] very little has been reported on high speed compression tests such as those described below. It was thought useful to compare the properties of copper in tension with those in compression when the forces are applied rapidly. The parameter chosen to describe the rapidity of the test is the time rate of strain $\dot{\epsilon} = d\epsilon_c/dt$.

For purposes of comparison of the properties of a metal in compression with those in tension, the choice of variables as defined above is poor. In tension tests the cross-sectional area of a specimen is diminished, making the true stress based on actual area greater than the engineering stress. In compression tests this area is increased, making the true stress less than the conventional stress. There is a similar difficulty in the comparison of strains for tension and compression tests. For these reasons it was decided to use the so-called true stress and logarithmic strain. For compression tests these quantities may be defined as follows:

$$\sigma = F/A$$

where $\sigma$ is the true stress, $F$ is the applied force, and $A$ is the instantaneous cross-sectional area of the specimen.

$$\epsilon = \ln A_0/A,$$

where $\epsilon$ is the logarithmic strain, and $A_0$ is the original cross-sectional area of the specimen. The logarithm is in terms of the base $e$.

These quantities $\sigma$ and $\epsilon$ are simply related to the conventional ones $\sigma_c$ and $\epsilon_c$, as follows:

$$\sigma = \sigma_c(1-\epsilon_c), \qquad (1)$$

$$\epsilon = \ln 1/(1-\epsilon_c). \qquad (2)$$

These relations are derived[2] by making the usual assumption for the plastic flow of metals

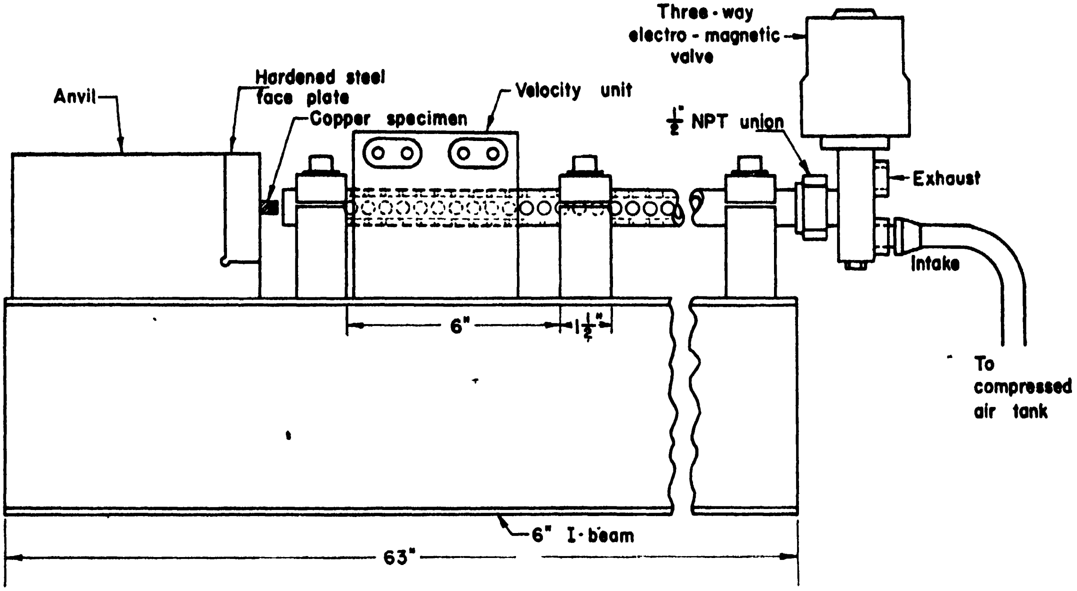

FIG. 1. Air gun for compressing copper cylinders.

that the volume of any element of metal remains unchanged.

## APPARATUS

The test equipment consists of an air gun for blowing a hardened steel piston against the soft copper specimen and auxiliary equipment for measuring the energy of the piston (see Figs. 1 and 2). The gun barrel is a cylindrical tube of steel 55″ long with an outside diameter of $\frac{15}{16}$ inch and an inner diameter of $\frac{1}{2}$ inch. At the muzzle end of the barrel, spaced $\frac{1}{8}$ inch apart, one hundred eighty $\frac{1}{4}$″ holes are drilled in the barrel.

The gun barrel is laid in a V-shaped groove cut into a set of steel supports. Similarly grooved hold-down plates, bolted to the supports, keep the barrel in position. These supports are in turn bolted to a 6-inch I-beam, about 63 inches long. At the muzzle end of the barrel a steel anvil, with a hardened steel face plate, is bolted to the I-beam. The test specimen is placed against this steel plate. The face of the hardened steel plate is very nearly perpendicular to the line of travel of the piston. This insures that the faces of the copper specimen are almost parallel after deformation. The variation in readings at different points on the faces of the specimen is thus kept small.

The propulsive force for the piston is supplied by a compressed air system. Air from a tank at high pressure is led into a smaller tank through a regulating valve. This regulator enables the small tank to be filled to any pressure up to 400 lb. per square inch, although 100 lb./in.$^2$ was the maximum used. A 3-way quick-acting solenoid valve controls the flow of air from the small reservoir to the gun barrel. The time of opening and closing of the valve is determined by a time-delay relay. The sequence of events is the following. A double-pole, double-throw switch is thrown. One side of the switch closes a circuit allowing 220-volt a.c. to flow through the solenoid; thus energized, the solenoid opens the intake valve and allows air to blow against the piston. The piston then moves down the barrel, strikes the specimen and rebounds. Simultaneously with the closure of the first side of the switch the second side closes a circuit in the time-delay unit. After a predetermined time delay a relay is thrown which opens the solenoid circuit. This closes the intake valve and, at the same time, opens the exhaust valve, allowing the rebounding piston to compress and force air out through the exhaust; in so doing, the piston brings itself to a halt.

By actual test, the shortest time for which the time-delay unit could be set to operate properly was about 0.01 second. This setting was used at the fastest velocities and worked very well. In the other direction, the time-delay unit may be set to operate for as much as several seconds. The purpose in keeping the valve open for only a short time is to keep the excess of air flowing through the barrel to a minimum.

The test specimens are made from oxygen-free high conductivity copper rod. Each specimen is made so that the final length is 0.5000 inch ±0.0005 inch and the diameter is 0.3255 inch ±0.0005 inch. They are then annealed in an electrically heated furnace in an atmosphere of hydrogen at a temperature of 950° Fahrenheit. The temperature is maintained for 2½ to 3 hours and the pellets allowed to cool in the furnace. The flow of hydrogen is maintained until the temperature is below 250° Fahrenheit.

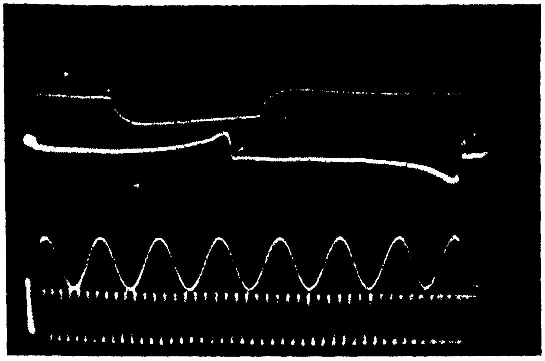

FIG. 3. A typical record obtained by the interruption of the light beam by the moving piston. At (*A*), the piston first enters the light beam; at (*B*), it is leaving the light beam. (*C*) and (*D*) represent a similar situation after the piston has rebounded. The lower oscillogram is the timing calibration for *AB* and *CD*.

The velocity of the piston is measured by noting the time interval between the breaking and making of a narrow beam of light which is incident upon a photo-cell (see Fig. 2). As the piston breaks the first light beam, a voltage change is induced in the photo-cell. This voltage is then amplified and used to trip a sweep generator. The sweep generator controls the horizontal movement of an electron beam across the face of a cathode-ray oscillograph. When the electron spot has completed about a third of its journey, the piston interrupts the second beam of light, producing a voltage impulse

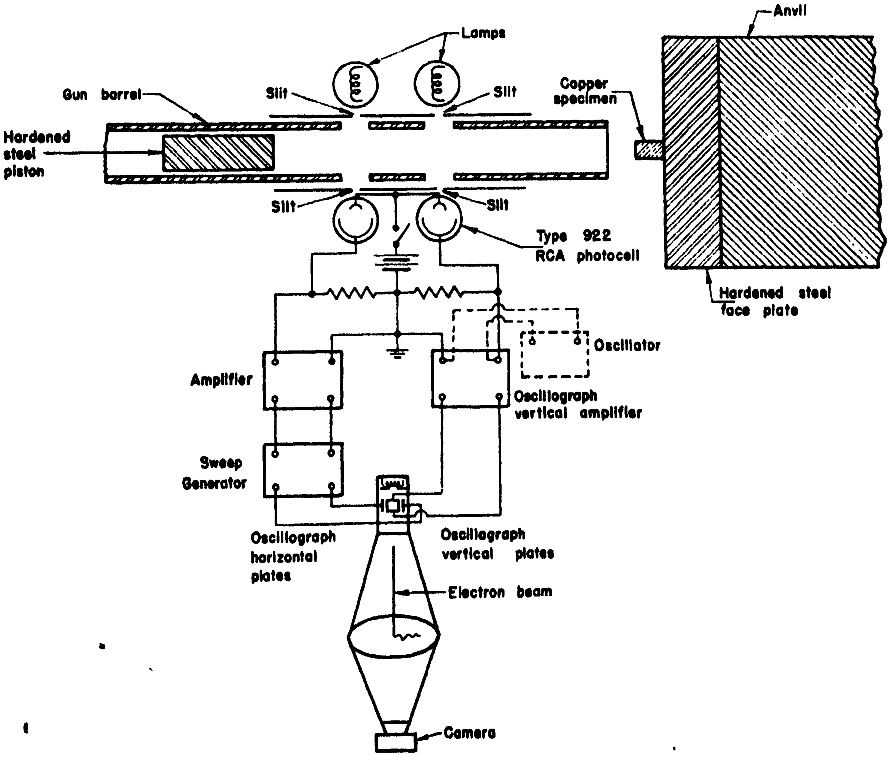

FIG. 2. Apparatus for measuring velocity of piston.

which is led into the vertical amplifier of the oscillograph. The spot then jumps up. When the piston has passed the light beam, the spot jumps back (see Fig. 3). After the piston strikes the copper, it rebounds; this velocity is recorded on the return trace of the electron beam. The distance between jumps is related to time by comparing it with a sine wave of known frequency. This sine wave is taken from an audio-frequency oscillator. To insure accurate time measurements, the output of the oscillator is beat against that of a 1000-cycle tuning-fork oscillator before the timing oscillogram is made. Knowing the piston length and its time to pass by the light beam, the velocity of the piston may be calculated. The energy of deformation is then computed from the relation K.E. $= \frac{1}{2}m(v_1^2 - v_2^2)$ where $m$ is the mass of the piston, $v_1$ is its velocity before striking the specimen, and $v_2$ is its velocity of rebound. The oscilloscope tracings were photographed on 35-mm Super XX film in a camera equipped with an $f$:1.9 lens.

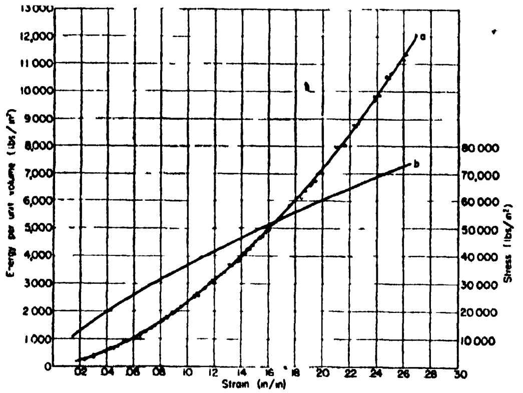

FIG. 4. Energy per unit volume-strain curve and stress-strain curve for copper cylinders in compression. Curve (a) shows dependence of energy absorbed per unit volume on the strain in compression in copper cylinders. Curve (b) is a stress-strain curve for copper derived from curve (a) by numerical differentiation. The rate of strain is approximately 1200 per second.

## PRECISION OF MEASUREMENTS

Before being subjected to impact, each cylinder was measured with a micrometer. One reading was made at the center, four at intervals around the circumference. The average of these was taken as the length of the pellet before deformation. The averages of two sets of reading made in this way repeated to within 0.0001″. After impact, the pellet was again measured at several points around the circumference and an average computed. (The center reading was discarded because it was consistently higher than the average.) The averages of two sets of readings in this case always agreed to within 0.0002″. The maximum error possible from this measurement is then 0.0003″. When the deformation is greater than 0.03″, this error is less than 1 percent.

Measurements on the film are made with a traveling microscope. Measurements with this instrument can be made to a precision of 0.001 millimeter. The line thickness on the film was about 0.1 millimeter. The distance between jumps on the film was of the order of 5 millimeters. Measurements were made to the center of each line. Three or more readings were taken at each point and averaged. The averages could be repeated to within 0.01 millimeter. The maximum error possible in this measurement then is about 0.2 percent.

Measurements on the sine wave were made at the same portion of the film as the velocity record occurred. This was essential because the sweep was not exactly linear, especially at the edges of the scope face. However in the middle half of the oscillogram, the linearity was within 1 percent. The oscillator frequency was always made high enough so that about five cycles covered the same distance as the velocity record (see Fig. 3). Errors due to non-linearity of the sweep were thus reduced. A timing oscillogram was made before and after every few records. Velocities were computed using both timing records and an average taken. Velocities based on different timing oscillograms varied from the average by less than 0.5 percent.

The total maximum random error is thus about 2 percent.

## STRAIN RATE ($\dot{\epsilon}$)

Strain rate is defined as the time rate of change of the strain. Since the difference between the conventional strain and the logarithmic strain is small here, of order 10 percent, and since the dependence of stress on strain rate turns out to be a very slowly changing function (roughly multiplying the strain rate by ten means an increase of 4 or 5 percent in stress), it is sufficiently accurate to use the time rate of change of the conventional strain for the strain rate. For the ½-inch long coppers used here, assuming the average velocity of the striking piston is one-half of the initial velocity with which it strikes the specimen, i.e., uniform deceleration, the average strain rate is numerically equal to the initial velocity expressed in inches/sec.

$$\text{Average } \dot{\epsilon} = \frac{\Delta l}{l_0}\cdot\frac{1}{T} = \frac{\Delta l}{T}\cdot\frac{1}{l_0}$$

$$= \frac{V_a}{l_0} = \frac{V_0}{2l_0} = V_0\frac{\text{in./sec.}}{\text{in.}},$$

where $\Delta l$ = final deformation, $l_0$ = original length = ½ inch, $T$ = total time of deformation-seconds, $v_0$ = initial velocity-inches/second, and $v_a$ = average velocity-inches/second.

The average strain rate is computed by assuming that the velocity with which the specimen contracts, i.e., the velocity of the striking piston, is a decreasing linear function of time. This assumption was checked by making two high speed photographs of the deformation of the copper cylinder. These showed that while the velocity of the striking piston is not linear, the true average velocity exceeded the assumed one by only about 15 percent. Because of the nature of the dependence of the stress on the strain rate, this method of computing the average strain rate is considered adequate.

## DATA

Figure 4, curve (4a), is a plot of energy/unit volume in lb./in.$^2$ against conventional strain in inches/inch. It represents the basic data of the dynamic testing in compression. A smooth curve was drawn through the points in such a manner that as many points lay above the curve as below it. One copper specimen was used for each point and 118 points were obtained. Two hardened steel pistons were employed; one weighed 0.05473 lb., the other 0.1633 lb. Through their use, the average strain rate at the upper and lower ends of the curve was kept within about 50 percent of 1200 l/sec.

Curve (4b) which shows conventional stress *versus* conventional strain was derived from curve (4a) by numerical differentiation. In order to compare these compression data with data in tension, curve (4b) was revised by applying formulas (1) and (2).

Figure 5 shows the revised stress-strain curves. In all cases the ordinate is true stress and the abscissa is logarithmic strain. Curves (a) and (b) in this figure show the relation between stress and strain for copper in compression. All the specimens used in obtaining curves (a) and (b) came from the same lot. The strain rates that apply to these curves are approximately 1200 l/sec. for curve (a) and $1.5\times10^{-3}$ l/sec. for curve (b). The latter curve was obtained by means of an ordinary static compression test. Curve (a) was based on data from the dynamic test and was obtained by the procedure described above. The stress required to produce a given compressional strain dynamically was always greater than that required to produce the same strain statically. This difference in stress increases as the strain increases. Comparison of curves (a) and (b) shows that the percentage difference varies from 17 percent to 29 percent for the interval of strain from 0.10 to 0.30.

It was thought useful to compare these results with those obtained in high speed tension tests of copper at room temperatures. Some work of this kind has been done by Manjoine and Nadai.[1] Curves (c) and (d) in Fig. 5 show the stress-strain curves obtained by them for copper. Their specimens were made of commercially pure copper and were 0.200″ in diameter and 1″ in length. After being machined the specimens were annealed by heating them in dry regenerated gas to 500°C. After that they were cooled to room temperature in 12 hours.

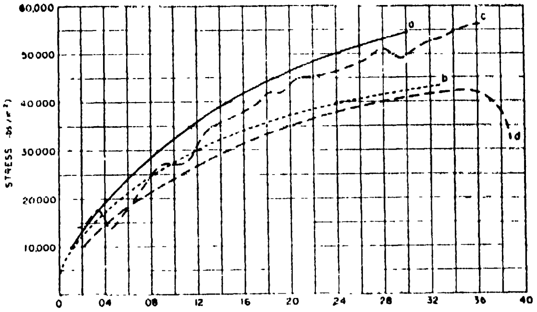

FIG. 5. Stress-strain curves for copper. The ordinate is true stress and the abscissa is logarithmic strain.

Curve (c) in Fig. 5 was obtained in a test of a single specimen subjected to a rate of strain of 900 per second. Curve (d) in Fig. 5 was obtained by means of a static tension test. The difference between the two static curves (b) and (d) is probably due to the fact that the copper used by the writers was not quite the same as that used by Nadai and Manjoine. Comparison of curves (c) and (d) shows that the stress required to produce a given strain in tension dynamically generally exceeds that required to produce the same strain statically. Some of the oscillations in curve (c) are probably not real but may be due to the method of loading the specimen and measuring that load. A more valid curve may possibly be obtained by drawing a smooth average line through the oscillations. If one does this, then the percentage difference between curves (c) and (d) varies from approximately 19 percent to 25 percent for the interval of strain from 0.10 to 0.30. It is interesting to note that the percentage increase in stress required to produce a given strain in copper dynamically rather than statically is much the same for both compression and tension. This comparison should be made when the rates of strain are approximately the same.

---

# $TM_{0,1}$ Mode in Circular Wave Guides with Two Coaxial Dielectrics

SIDNEY FRANKEL
*Federal Telecommunication Laboratories, Inc., New York, New York*

(Received February 3, 1947)

Field components for a transverse magnetic wave in a wave guide with two coaxial dielectrics are computed. A typical example is given to show the calculation of guide dimensions to reduce phase velocity to a preassigned value.

A UNIFORM circular wave guide may be conceived as a device that provides an interaction space between electrons and an electromagnetic field to transfer energy from one to the other. If electrons are injected axially in the guide and the field has an axial electric component, the important interaction is between the electrons and this axial component.

For unimpeded motion, the electrons must travel essentially in a vacuum and with a velocity necessarily less than that of light. On the other hand, the phase velocity of the electromagnetic field in an evacuated circular guide is always greater than the velocity of light. For effective interaction, this field must be slowed down, perhaps to the order of one-tenth or less of the velocity of light. This may be accomplished by surrounding the evacuated axial region of the guide with material of high dielectric constant. For simplicity, circular symmetry may be maintained.

An investigation of the propagation of an electromagnetic field with axial electric component in such a "loaded" guide has been made. Appropriate field equations, which take the necessary boundary conditions into account, are set up and solved. A relationship between the maximum value of axial electric component and transmitted power is given.

## 1. SOLUTION OF FIELD EQUATIONS

### 1.1 Differential Equations

Figure 1 shows a cross section of a wave guide. The section of the axial region is a circle of radius $a$, the constants of the medium being $\mu$ and $\epsilon_2$, the permeability and dielectric constants, respectively. The boundary of the guide is a perfect conductor of radius $b$. In the annular region between these two radii is a material of constants $\mu$ and $\epsilon_1$. It is assumed that $\epsilon_1 > \epsilon_2$ always.

Cylindrical coordinates $r$, $\phi$, and $x$ will be used with the $x$ axis coinciding with the axis of the guide and being positive in the direction toward a sink of power. For a transverse magnetic mode, take $H_x = 0$, and, in accordance with the conventional $TM_{0,1}$ mode for uniform dielectrics, specify additionally that $E_\phi = H_r = 0$. If a field satisfying these requirements exists in the guide under consideration, then the appropriate field equations in m.k.s. units for either dielectric are of the following type.

$$\left.\begin{aligned} -\partial H_\phi/\partial x &= j\omega\epsilon E_r,\\ (1/r)(\partial/\partial r)(rH_\phi) &= j\omega\epsilon E_x,\\ (1/r)(\partial E_x/\partial\phi) &= 0,\\ (\partial E_r/\partial x)-(\partial E_x/\partial r) &= -j\omega\mu H_\phi,\\ (1/r)(\partial E_r/\partial\phi) &= 0. \end{aligned}\right\} \quad (1)$$

The subscript has been omitted from $\epsilon$ to avoid restricting it to either medium.

According to (1), $E_r$ and $E_x$, therefore also $H_\phi$, are independent of $\phi$. The useful equations from (1) are

$$\left.\begin{aligned} \partial H_\phi/\partial x &= -j\omega\epsilon E_r,\\ (1/r)(\partial/\partial r)(rH_\phi) &= j\omega\epsilon E_x,\\ (\partial E_r/\partial x)-(\partial E_x/\partial r) &= -j\omega\mu H_\phi. \end{aligned}\right\} \quad (2)$$

Elimination of $E_r$ and $E_x$ among these equations leads to the following equation in $H_\phi$:

$$\frac{\partial^2 H_\phi}{\partial x^2}+\frac{\partial}{\partial r}\left[\frac{1}{r}\frac{\partial}{\partial r}(rH_\phi)\right]=-\omega^2\mu\epsilon H_\phi=-\frac{\omega^2}{c^2}H_\phi, \quad (3)$$

where $c$ is the velocity of propagation in a medium of unbounded extent with constants $\mu$ and $\epsilon$.

Assume

$$H_\phi=R(r)e^{-\gamma x}, \quad (4)$$

where $\gamma$ is the propagation constant in the $x$ direction and $R$ is a function of $r$ to be determined. Substitution of (4) in (3) yields

$$\frac{d}{dr}\left[\frac{1}{r}\frac{d}{dr}(rR)\right]+\alpha^2 R=0, \quad (5)$$

where

$$\alpha^2=\gamma^2+\omega^2/c^2. \quad (6)$$

Solutions of (5) are of the type

$$R=J_1(\alpha r),\ Y_1(\alpha r), \quad (7)$$

where $J_1$ and $Y_1$ are Bessel functions of the first and second kinds, respectively, and of the first order. If $Z_1(\alpha r)$ represents any linear combination of these functions, then

$$H_\phi=Z_1(\alpha r)e^{-\gamma x}. \quad (8)$$

For unattenuated transmission, $\gamma$ is a pure imaginary; let $\gamma=j\beta$, with $\beta$ real. Then

$$H_\phi=Z_1(\alpha r)e^{-j\beta x}, \quad \alpha=[(\omega/c)^2-\beta^2]^{\frac{1}{2}}. \quad (9)$$

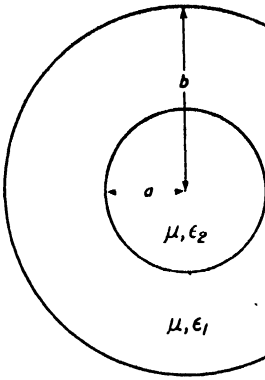

FIG. 1. Cross section of wave guide having two coaxial dielectrics.

From (2), we get immediately

$$\left.\begin{aligned} E_r &= (\beta/\omega\epsilon)Z_1(\alpha r)e^{-j\beta x},\\ E_x &= (\alpha/j\omega\epsilon)Z_0(\alpha r)e^{-j\beta x}, \end{aligned}\right\} \quad (10)$$

where $Z_0$ is a linear combination of Bessel functions of the first and second kind, zeroth order, and we have made use of the relation[1]

$$\frac{d}{dr}[rZ_1(\alpha r)]=\alpha rZ_0(\alpha r). \quad (11)$$

$J_0$ and $J_1$ are finite and continuous everywhere in the complex plane, but $Y_0$ and $Y_1$ have infinite discontinuities at $r=0$. These latter functions are therefore inadmissable in the axial region of Fig. 1. The solutions therefore run as follows.

In medium 1,

$$\left.\begin{aligned} H_{\phi 1} &= [A_1J_1(\alpha_1 r)+B_1Y_1(\alpha_1 r)]e^{-j\beta_1 x},\\ E_{r1} &= \frac{\beta_1}{\omega\epsilon_1}[A_1J_1(\alpha_1 r)+B_1Y_1(\alpha_1 r)]e^{-j\beta_1 x},\\ E_{x1} &= \frac{\alpha_1}{j\omega\epsilon_1}[A_1J_0(\alpha_1 r)+B_1Y_0(\alpha_1 r)]e^{-j\beta_1 x}. \end{aligned}\right\}$$

$$a\leqq r\leqq b. \quad (12a)$$

In medium 2,

$$\left.\begin{aligned} H_{\phi 2} &= A_2J_1(\alpha_2 r)e^{-j\beta_2 x},\\ E_{r2} &= (\beta_2/\omega\epsilon_2)A_2J_1(\alpha_2 r)e^{-j\beta_2 x},\\ E_{x2} &= (\alpha_2/j\omega\epsilon_2)A_2J_0(\alpha_2 r)e^{-j\beta_2 x}, \end{aligned}\right\} 0\leqq r\leqq a. \quad (12b)$$

---

[1] Jahnke and Emde, *Tables of Functions* (B. G. Teubner, Leipzig, 1938), third edition, p. 145.

$A_1$, $B_1$, and $A_2$ are constants to be determined from the boundary and power conditions, $\alpha_1$ and $\alpha_2$ are the propagation constants, and $\beta_1$ and $\beta_2$ are the phase constants, in media 1 and 2, respectively.

### 1.2 Boundary Conditions

Matching of tangential components of the electric field at the dielectric interface requires that

$$E_{x1}=E_{x2} \quad \text{at} \quad r=a$$

for all values of $x$; i.e.,

$$\frac{\alpha_1}{j\omega\epsilon_1}[A_1J_0(\alpha_1a)+B_1Y_0(\alpha_1a)]e^{-j\beta_1x} = -\frac{\alpha_2}{j\omega\epsilon_2}A_2J_0(\alpha_2a)e^{-j\beta_2x}. \tag{13}$$

This can be satisfied for all values of $x$ if, and only if, $\beta_1=\beta_2=\beta$. The phase constant (hence the velocity of propagation) is the same in both media, as might have been expected.

$$\alpha_1^2-\omega^2/c_1^2=-\beta^2=\alpha_2^2-\omega^2/c_2^2. \tag{14}$$

Assume the phase velocity $V_p$ to be intermediate between $c_1$ and $c_2$

$$c_1<V_p<c_2, \quad V_p=\omega/\beta. \tag{15}$$

This leads to the inequality

$$\alpha_2^2<0<\alpha_1^2, \tag{16}$$

whence $\alpha_1$ is real while $\alpha_2$ is a pure imaginary. The field in medium 2 therefore behaves according to Bessel functions of the first kind with pure imaginary argument. Curves for $J_0(jz)$ and $-jJ_1(jz)$, frequently designated as $I_0(z)$ and $I_1(z)$, respectively, have been published.[2] The function $I_0(z)$ is particularly interesting since it shows the radial variation of the axial electric field. This field is fairly uniform for sufficiently small $z$. For $z<0.6$, the variation is less than 10 percent; for $z<2$, the variation is less than about 2:1.

Next, for the tangential component of electric field to vanish at the conductor surface, it is required that $E_{x1}=0$ at $r=b$, i.e.,

$$A_1J_0(\alpha_1b)+B_1Y_0(\alpha_1b)=0. \tag{17}$$

Matching the normal components of dielectric flux at the dielectric interface requires that

$$\epsilon_1E_{r1}=\epsilon_2E_{r2} \quad \text{at} \quad r=a; \text{ i.e.,}$$
$$A_1J_1(\alpha_1a)+B_1Y_1(\alpha_1a)=A_2J_1(\alpha_2a). \tag{18}$$

Matching the tangential magnetic field at the dielectric interface yields no further information. Collecting and rearranging (13), (17), and (18), we have the set of linear homogeneous equations in $A_1$, $B_1$, and $A_2$:

$$\left.\begin{aligned} \frac{\alpha_1}{\epsilon_1}J_0(\alpha_1a)A_1+\frac{\alpha_1}{\epsilon_1}Y_0(\alpha_1a)B_1 -\frac{\alpha_2}{\epsilon_2}J_0(\alpha_2a)A_2&=0,\\ J_0(\alpha_1b)A_1+Y_0(\alpha_1b)B_1&=0,\\ J_1(\alpha_1a)A_1+Y_1(\alpha_1a)B_1-J_1(\alpha_2a)A_2&=0.\end{aligned}\right\} \tag{19}$$

A necessary and sufficient condition that these equations be consistent is that the determinant of the coefficients vanish:

$$\begin{vmatrix} \frac{\alpha_1}{\epsilon_1}J_0(\alpha_1a) & \frac{\alpha_1}{\epsilon_1}Y_0(\alpha_1a) & -\frac{\alpha_2}{\epsilon_2}J_0(\alpha_2a) \\ J_0(\alpha_1b) & Y_0(\alpha_1b) & 0 \\ J_1(\alpha_1a) & Y_1(\alpha_1a) & -J_1(\alpha_2a) \end{vmatrix}=0. \tag{20}$$

If $\beta$ is specified in advance, then $\alpha_1$ and $\alpha_2$ are known from (14), and (20) specifies a necessary and sufficient relationship between $a$ and $b$. The manner of using this information will be illustrated by a later example.

With (20) satisfied, any two of the three relations given in (19) may be used to solve for the ratios of the constants $A_1$, $B_1$, and $A_2$. By using the first and the third,

$$A_1=K_AA_2, \quad B_1=K_BA_2, \tag{21}$$

where

$$\left.\begin{aligned} K_A&=-\frac{\pi\epsilon_1a}{2}\begin{vmatrix} \frac{\alpha_2}{\epsilon_2}J_0(\alpha_2a), & \frac{\alpha_1}{\epsilon_1}Y_0(\alpha_1a) \\ J_1(\alpha_2a), & Y_1(\alpha_1a) \end{vmatrix}\\ K_B&=-\frac{\pi\epsilon_1a}{2}\begin{vmatrix} \frac{\alpha_1}{\epsilon_1}J_0(\alpha_1a), & \frac{\alpha_2}{\epsilon_2}J_0(\alpha_2a) \\ J_1(\alpha_1a), & J_1(\alpha_2a) \end{vmatrix}\end{aligned}\right\} \tag{22}$$

and we have made use of the standard identity

$$Y_0(s)J_1(s)-Y_1(s)J_0(s)=2/\pi s.$$

---

[2] Page 224 of reference 1.

The field components are then given as follows:

Medium 1: $a \leqq r \leqq b$.

$$\left.\begin{aligned} E_{z1} &= A_2 \frac{\alpha_1}{j\omega\epsilon_1}[K_A J_0(\alpha_1 r) + K_B Y_0(\alpha_1 r)]e^{-j\beta z}, \\ E_{r1} &= A_2 \frac{\beta}{\omega\epsilon_1}[K_A J_1(\alpha_1 r) + K_B Y_1(\alpha_1 r)]e^{-j\beta z}, \\ H_{\phi 1} &= A_2[K_A J_1(\alpha_1 r) + K_B Y_1(\alpha_1 r)]e^{-j\beta z}, \end{aligned}\right\}. \tag{23a}$$

Medium 2: $0 \leqq r \leqq a$.

$$\left.\begin{aligned} E_{z2} &= A_2 \frac{\alpha_2}{j\omega\epsilon_2} J_0(\alpha_2 r)e^{-j\beta z}, \\ E_{r2} &= A_2 \frac{\beta}{\omega\epsilon_2} J_1(\alpha_2 r)e^{-j\beta z}, \\ H_{\phi 2} &= A_2 J_1(\alpha_2 r)e^{-j\beta z}. \end{aligned}\right\} \tag{23b}$$

In (23), the constant $A_2$ remains to be determined.

### 1.3 Axial Field as a Function of Transmitted Power

The constant $A_2$ may be evaluated in terms of the peak transmitted power $P_M$ or twice the average power $P$. For this purpose, the complex Poynting vector is integrated over a convenient cross section of the guide. This reduces to

$$P_M = \int_0^b \int_0^{2\pi} E_r H_\phi^* \cdot r d\phi dr,$$

where $H_\phi^*$ is the complex conjugate of $H_\phi$. By (22), $K_A$ and $K_B$ both contain the factor $\alpha_2$ and are therefore pure imaginaries. If $E_r$ and $H_\phi$ are specified to have zero phase angle at $z=0$, then $A_2$ is also a pure imaginary, and $j$ appears only in the exponential factor. The integration then runs

$$P_M = 2\pi A_2^2 \frac{\beta}{\omega\epsilon_1} F(a,b;\epsilon_1,\epsilon_2),$$

where

$$F = \frac{\epsilon_1}{\epsilon_2}\int_0^a r J_1^2(\alpha_2 r)dr + \int_a^b r[K_A J_1(\alpha_1 r) + K_B Y_1(\alpha_1 r)]^2 dr \tag{24}$$

or

$$A_2 = ((P_M/2\pi)(\omega\epsilon_1/\beta F))^{\frac{1}{2}}. \tag{25}$$

At the center of the tube, the maximum value of the axial field $E_{z2}$ is

$$E_{z0} = \left| A_2 \frac{\alpha_2}{\omega\epsilon_2} \right| = \left| \frac{\alpha_2}{\omega\epsilon_2}\left(\frac{P_M}{2\pi}\frac{\omega\epsilon_1}{\beta F}\right)^{\frac{1}{2}} \right|. \tag{26}$$

### 1.4 Further Discussion of the Solution

The determinant (20) may be considered to yield a solution for $b$ when $\alpha_1$ and $\alpha_2$ are known. After defining a set of functions

$$Q_1(s) = \frac{J_0(s)}{Y_0(s)}, \quad Q_2(s) = -j\frac{J_1(js)}{J_0(js)}, \quad Q_3(s) = \frac{J_0(s)}{J_1(s)}, \quad Q_4(s) = \frac{Y_1(s)}{J_1(s)}, \tag{27}$$

we can reduce (20) to the form

$$Q_1(\alpha_1 b) = \frac{1 - j\frac{\alpha_1}{\alpha_2}\frac{\epsilon_2}{\epsilon_1}Q_2(\alpha_2 a)Q_3(\alpha_1 a)}{Q_4(\alpha_1 a) - j\frac{\alpha_1}{\alpha_2}\frac{\epsilon_2}{\epsilon_1}Q_2(\alpha_2 a)\frac{Q_3(\alpha_1 a)}{Q_1(\alpha_1 a)}}. \tag{28}$$

All of these $Q$ functions, with the exception of $Q_2(s)$ have been plotted.[3] $Q_2(s)$ is plotted in Fig. 2 of this paper. The use of these curves simplifies the calculation of $b$.

The chief remaining problem is an evaluation of the function $F(a, b; \epsilon_1, \epsilon_2)$ in (24). The function is integrable in known Bessel functions. By reference to a standard treatise on Bessel functions,[4] it can be shown that

$$F = \frac{1}{\alpha_2^2}F_1(\alpha_2 a) + \frac{K_A^2}{\alpha_1^2}[F_1(\alpha_1 b) - F_1(\alpha_1 a)] + \frac{2K_AK_B}{\alpha_1^2}[F_3(\alpha_1 b) - F_3(\alpha_1 a)] + \frac{K_B^2}{\alpha_1^2}[F_2(\alpha_1 b) - F_2(\alpha_1 a)], \tag{29}$$

where

$$\left.\begin{aligned} F_1(s) &= \frac{s^2}{2}\{[J_1(s)]^2 - J_0(s)J_2(s)\}, \\ F_2(s) - F_2(u) &= \frac{s^2}{2}\{[Y_1(s)]^2 - Y_0(s)Y_2(s)\} - \frac{u^2}{2}\{[Y_1(u)]^2 - Y_0(u)Y_2(u)\}, \\ F_3(s) &= \tfrac{1}{2}\{s^2[Y_1(s)J_1(s) + Y_2(s)J_2(s)] - s[Y_1(s)J_2(s) + Y_2(s)J_1(s)]\}. \end{aligned}\right\} \tag{30}$$

Future work may indicate whether or not these results can be simplified.

## 2. TYPICAL EXAMPLE

Suppose a $TM_{0,1}$ wave is to be set up at $\omega = 3\cdot 10^{10}$ per second traveling at one-tenth the velocity of light in vacuum, so that $V_p = 3\cdot 10^7$ meters per second, whence $\beta = (10)^3$ per meter. Assume the dielectric material is such that

$\mu = 4\pi 10^{-7}$ henry per meter,
$\epsilon_1 = (10^{-7}/18\pi)$ farad per meter
(relative dielectric constant $= 200$),
$\epsilon_2 = (10^{-9}/36\pi)$ farad per meter.

Then $\alpha_1 = 10^3$, $\alpha_2 = j10^3$ by (14). Next, let us try using a radius $a = 2$ millimeters $= 2\cdot 10^{-3}$ meter. Then

$$\begin{aligned} \alpha_1 a &= 2, \\ \alpha_2 a &= j2, \\ \alpha_1/\epsilon_1 &= 5.55\cdot 10^{11}, \\ \alpha_2/\epsilon_2 &= j1.11\cdot 10^{14}. \end{aligned}$$

From Fig. 2, $Q_2(j2) = 0.70$, and from reference 1 and (27)

$$\begin{aligned} Q_1(2) &= 0.45, \\ Q_3(2) &= 0.39, \\ Q_4(2) &= -0.19. \end{aligned}$$

Then by (28), $Q_1(\alpha_1 b) = -5.2$ whence

$$\alpha_1 b = 0.73,\ 3.78,\ 6.89,\ \cdots$$

and

$$b = 0.7,\ 3.8,\ 6.9,\ \cdots,\ \text{millimeters}.$$

We take $b = 3.8$ millimeters as the smallest available value of $b > a$. A more careful calculation using tables rather than curves shows that $b = 3.6$ millimeters.

Next, compute $K_A$ and $K_B$ using (22).

$$\begin{aligned} K_A &= j153.3, \\ K_B &= j812.5. \end{aligned}$$

The expressions for the field components (23)

---

[3] Pages 200–203 of reference 1.

[4] G. N. Watson, *A Treatise on the Theory of Bessel Functions* (Macmillan Company, New York, 1944), second edition.

then become

$$E_{z1}=A_2 2842[J_0(\alpha_1 r)+5.30\,Y_0(\alpha_1 r)]e^{-j\beta z},$$
$$E_{r1}=jA_2 2892[J_1(\alpha_1 r)+5.30\,Y_1(\alpha_1 r)]e^{-j\beta z},$$
$$H_{\phi 1}=A_2 153.3[J_1(\alpha_1 r)+5.30\,Y_1(\alpha_1 r)]e^{-j\beta z},$$
$$E_{z2}=A_2 3703 J_0(\alpha_2 r)e^{-j\beta z},$$
$$E_{r2}=A_2 3774 J_1(\alpha_2 r)e^{-j\beta z},$$
$$H_{\phi 2}=A_2 J_1(\alpha_2 r)e^{-j\beta z}.$$

These quantities are plotted as functions of $r$ in Figs. 3 and 4. Here it is plain that the electric vectors have the same orders of magnitude in both dielectrics, while the magnetic vector is practically negligible in the central dielectric. This fact, combined with the small cross-sectional area of the inner dielectric, results in most of the transmitted power being propagated in the outer dielectric.

The factor $F$ in (24) may be evaluated by numerical integration, whence it turns out that $F=-0.00037-0.3475=-0.3479$, the smaller term being the contribution of the inner dielectric. Since by (26) the transmitted power is related linearly to $F$, it can be seen that only about 0.1 percent of the power is propagated in the central region.

By substitution in (26) we now have immediately $E_{z0}=5.77(P_M)^{\frac{1}{2}}$, volts per centimeter, at the axis of the guide.

# Graphical Methods for Evaluating Fourier Integrals

W. J. Cunningham
*Cruft Laboratory, Harvard University, Cambridge, Massachusetts**

(Received March 12, 1947)

The Fourier transform method of determining the response of a linear system to an arbitrary input signal often has its practical usefulness impaired because of difficulties in evaluating the necessary integrals. One possibility of overcoming these difficulties lies in the application of graphical methods to the transformations. Three such graphical procedures are described, all based upon fundamental properties of the transforms. Each method involves an analysis of the curves of the function to be transformed as a sum of curves of simpler functions whose transforms are known. The methods are useful in cases where the problem is too complicated for a simple analytic solution, or where part of the necessary data is available only in the form of a curve obtained, say, from experimental measurements of transmission characteristics or wave shapes. The accuracy of the methods is restricted only by that of the graphical plotting and curve fitting. If only approximate results are required, they may be obtained relatively quickly by these methods.

## I. INTRODUCTION

One of the standard mathematical methods for determining the response of a linear transmission system to an input disturbance of arbitrary shape is based upon the Fourier integral.[1,2] In the application of this method it is necessary first to express the input function of time as a corresponding function of frequency by means of the appropriate Fourier integral. The resulting frequency function, or transform, is multiplied by the steady-state transmission characteristics of the system to give the frequency function at the output of the system. The time function, or inverse transform, at the output is obtained from the output frequency function by means of the inverse form of the Fourier integral. The integrals needed in these transformations may be written in a number of ways, a convenient form being as follows:

$$g(f)=\int_{-\infty}^{\infty} e(t)\exp(-j\omega t)dt, \qquad (1)$$

$$e(t)=\int_{-\infty}^{\infty} g(f)\exp(+j\omega t)df, \qquad (2)$$

$$\omega=2\pi f,\quad j=+(-1)^{\frac{1}{2}},$$

where $g(f)$ and $e(t)$ are corresponding transforms of frequency and of time. In Fourier integrals of this form, the entire frequency and time scales, both positive and negative values, must be considered.

Several difficulties may arise when an effort is made to apply this method to the solution of practical problems. Often the input signal is known in the form of a curve, but a mathematical expression for it is not available. The same thing may be true (perhaps more often so) for the transmission characteristics of the system. Even if these mathematical expressions were known, it might not be possible to carry out the integrations needed in the evaluation of the Fourier transforms. A number of standard forms of these integrals are available,[3] but if the unknown system does not fit one of these transforms, solution may be very difficult.

## II. GRAPHICAL METHODS

A possible way of obviating these difficulties is to resort to a graphical analysis which will replace the integrations normally required. Furthermore, such graphical methods allow the use of data known only as a curve found from experimental measurements. If extremely accurate results are not required, approximations may be introduced in such a way that the graphical method may yield a useful result more quickly than other rigorous methods. The graphical method is particularly useful when such

[3] G. A. Campbell and R. M. Foster, "Fourier integrals for practical applications," Bell Telephone Monograph, B-584, (1931).

approximations are being made, since it is relatively easy to visualize their effect upon the final results. When the system is complicated, the graphical solution likewise becomes complicated, as does any other means of transient analysis. At least two graphical methods for determining the response of a system to an arbitrary input signal have already been described.[4, 5] However, the procedures of the present discussion differ from these two and may have certain advantages in their application.

These methods are based upon fundamental properties of the Fourier integrals.[3] Perhaps the most important property is the superposition principle for linear systems. This principle states that if a function is made up of any linear combination of other functions, the Fourier transform of the first function is equal to the same linear combination of the Fourier transforms of the other functions. Therefore, it is possible to collect as geometric curves a number of mathematically simple functions and their transforms. A function in the form of a complicated curve may be broken into some linear combination of these simple curves. The transform of the complicated curve is then the same linear combination of the transforms of the simple curves. The whole process may be carried out by graphical methods.

In physical problems the input function of time and the output function of time are generally both real. Their corresponding transforms are usually complex functions, each having both a real and an imaginary part. The real parts of these complex functions have even symmetry; their inverse transforms are also real and have even symmetry. The imaginary parts of the complex functions have odd symmetry; their inverse transforms are real and have odd symmetry. Thus, the inverse transform of a complex function is real, and consists of the sum of an even function and an odd function.

An important type of problem is that in which the input to the system is zero until zero time, when the input function begins to have a finite value. If the physically realizable system is passive, its output must also be zero for times less than zero. This fact, plus the discussion of the preceding paragraph, leads to an important conclusion. The real time function at the output of the system must be zero for negative times and will generally have a non-zero value for positive times. Therefore, the even and odd real functions which compose it must have identical geometric shape at positive times and be mirror images of one another at negative times.[6] If this property is utilized, it is often necessary to consider only one of these component functions, and not both simultaneously.

The solution of a typical problem might proceed as shown in Fig. 1, where both positive and negative scales of time and frequency are shown. The input function of time, Fig. 1(a), is applied at zero time and is assumed to be sufficiently simple mathematically so that its transform, Fig. 1(b), may be found as a complex function of frequency from Eq. (1). If this is not true, the problem is more involved, but still may be solved by the methods to be described. It will also be assumed that the steady-state transmission characteristics of the system, Fig. 1(c), are known as a complex function of frequency. These characteristics may be found by the usual steady-state analysis methods, or in the case of actual systems, may be determined experimentally. It is necessary now to find the product, Fig. 1(d), at each frequency, of the complex functions of frequency representing the

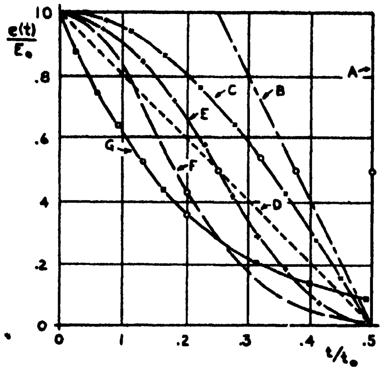

FIG. 2. Real even functions of time; only positive half of each is shown. The maximum value of the function is $E_0$; its total duration is approximately $t_0$. Circles indicate the nominal duration, $t_n$. Corresponding transforms are shown in Fig. 3. A. Rectangle. B. Trapezoid. C. Half cosine. D. Triangle. E. Cosine squared. F. Gaussian. G. Exponential.

input signal and the transmission characteristics of the system. If these two functions are available in algebraic form (magnitude and angle are most convenient), they may be multiplied directly. If one or both of them is available only as a curve, the multiplication of ordinates must be done on a point by point basis. The product obtained in this way will generally be a complex function of frequency and should be expressed as a real part, Fig. 1(e), and an imaginary part, Fig. 1(f). The inverse transform of each part, Fig. 1(g) and (h), is the contribution of that part to the real function of time at the output of the system. As previously pointed out, each contribution must be the same for positive values of time. Because of their even and odd symmetry, their sum at negative times is zero. In order to obtain the output signal, Fig. 1(i), the two contributions may be added, or more simply, only one contribution (either (g) or (h)) need be considered at positive times only, and its value doubled.

The last step of transforming the function of frequency at the output of the system into the corresponding function of time is usually the step producing the greatest mathematical difficulty. It is for this purpose that the methods described here will be found useful.

## III. CORRESPONDING FUNCTIONS

A number of corresponding simple functions of time and of frequency are given in Fig. 2 and Fig. 3. A collection of curves of this sort is useful, either in the direct graphical solution of more complicated wave shapes, or in providing the investigator with a qualitative picture of the relation between typical functions. All of these functions of time and frequency are real and, therefore, must have even symmetry. Only one half of each curve is plotted, for the sake of convenience, but it must be remembered that each of these curves is symmetrical about the vertical axis and has the same values for negative as for positive abscissas. The curves are obtained by assuming relatively simple mathematical functions of time and finding the corresponding functions of frequency with the aid of Eq. (1). For convenience, the curves are plotted with dimensionless ratios as coordinates, and the time functions (Fig. 2) are adjusted so that the approximate total duration of each is the time $t_0$. Also indicated on the curves, with small circles, are the points corresponding to the nominal duration, $t_n$, and the nominal cut-off frequency, $f_n$, for each curve.[5] The nominal duration and nominal cut-off may be defined for real even functions in the following way,

$$\left.\begin{aligned} t_n &= 1/e(0)\int_0^\infty e(t)dt, \\ f_n &= 1/g(0)\int_0^\infty g(f)df, \end{aligned}\right\} \qquad (3)$$

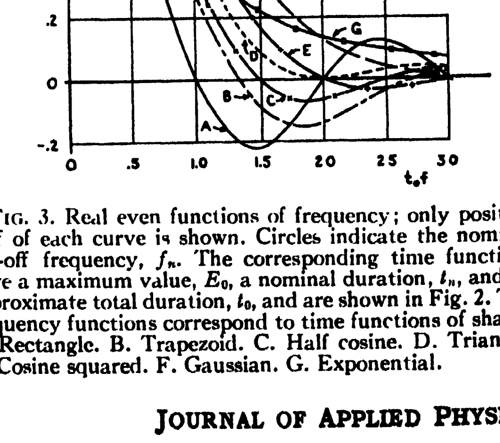

FIG. 3. Real even functions of frequency; only positive half of each curve is shown. Circles indicate the nominal cut-off frequency, $f_n$. The corresponding time functions have a maximum value, $E_0$, a nominal duration, $t_n$, and an approximate total duration, $t_0$, and are shown in Fig. 2. The frequency functions correspond to time functions of shape: A. Rectangle. B. Trapezoid. C. Half cosine. D. Triangle. E. Cosine squared. F. Gaussian. G. Exponential.

where $e(0)$ is $e(t)$ evaluated at zero time, and $g(0)$ is $g(f)$ evaluated at zero frequency, and both $e(0)$ and $g(0)$ are finite. In geometrical terms, the nominal duration, $t_n$, is the base of a rectangle which has an altitude, $e(0)$, and an area equal to the total area under the curve of $e(t)$, taken for positive times only. A similar relation applies to $f_n$. For zero values of the arguments, the quantities are

$$e(0)=\int_{-\infty}^{\infty} g(f)df=2f_n g(0),$$

$$g(0)=\int_{-\infty}^{\infty} e(t)dt=2t_n e(0),$$

and their product gives the fundamental relation,

$$4f_n t_n=1.$$

If this relation is observed and the parameters, $E_0$, $t_0$, and $t_n$, are chosen properly, the scales of Figs. 2 and 3 may be made to fit any desired conditions or systems of units. The maximum value of the time function, occurring here at zero time, is $E_0$.

One further important property of the transforms may be found from inspection of the Fourier integrals. If the arguments of the time function and the frequency function are interchanged, the functions will still correspond provided the sign of one argument is changed. With real even functions, such as Fig. 1(e) and (g), this sign change produces no visible change in the functions. Therefore, the real even functions of Fig. 2 may be taken as functions of frequency, if desired, whereupon the real even functions of Fig. 3 become functions of time. It is sufficient merely to interchange the $t$ and $f$ symbols of these curves.

Another group of corresponding functions which is of interest is shown in Fig. 4. Here, the functions of time, Fig. 4(a) and (c), are cosine functions in which an integral number, $n$, of quarter cycles occurs within the arbitrary time, $t_a$. Since the cosines are even functions the total duration of the functions of time is $2t_a$. Again, the frequency functions, Fig. 4(b) and (d), corresponding to the assumed time functions, may be found with the help of Eq. (1). The form of the result is slightly different depending upon whether $n$ is chosen odd or even. Two families of curves are plotted in Fig. 4 for this reason. These frequency functions are the frequency spectra of a.c. pulses containing a total of $n$ half-cycles, and occurring within the time $2t_a$. As the value of $n$ is made larger, the apparent frequency of the time function is increased, and the main hump of the corresponding frequency spectrum is moved to a point higher on the frequency scale. All of these functions are real and even, although only the positive half of each curve is shown, and once more it is possible to interchange time and frequency if desired.

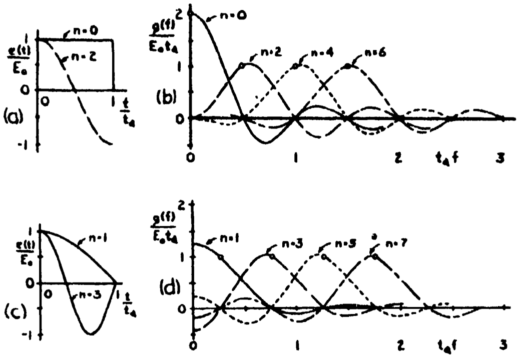

FIG. 4. Corresponding real even functions of time and frequency; only positive half of each curve is shown. Time functions have $n$ quarter cycles in the interval, $t_a$. The parameter, $n$, is even at (a) and odd at (c). Corresponding frequency functions are shown at (b) and (d), respectively. Circles indicate points where only a single curve is not zero.

An important feature of these frequency functions, which is used to simplify later analyses, becomes apparent after a study of Fig. 4. If $n$ is chosen either odd or even, there is a certain frequency at which the frequency function for a single value of $n$ is not zero, while the functions for all other values of $n$ are zero. The function which is not zero at this particular frequency has a value which is a constant, regardless of $n$. In mathematical terms, if $n$ is an integer, either odd or even as the case may be, and $m$ is an integer odd or even to match $n$, then

$$\left.\begin{aligned}&\text{at } f=m/(4t_a), && g(f)=0, && \text{if } m\neq n\\ &\text{at } f=n/(4t_a), && g(f)=E_0t_a, && \text{if } n\neq 0\\ &\text{at } f=0, && g(f)=2E_0t_a, && \text{if } n=0.\end{aligned}\right\}\quad(4)$$

The points where $m=n$ are shown by circles on Fig. 4(b) and (d). In one of the uses of these functions it is necessary to sum a number of

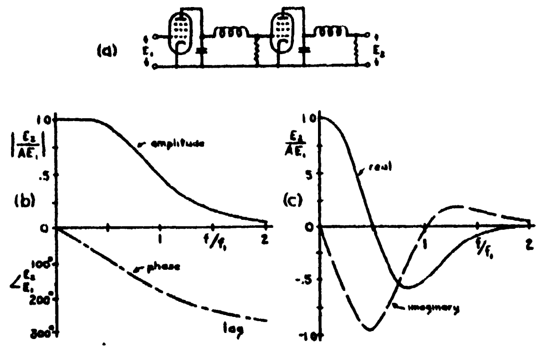

FIG. 5. (a) Low-pass amplifier circuit for use in examples. $E_1$ and $E_2$ are r.m.s. voltages of a single frequency. $A$ is the zero-frequency voltage amplification. $f_1$ is a reference frequency. (b) Steady-state transmission characteristics of (a), amplitude and phase. (c) Steady-state transmission characteristics of (a), real and imaginary parts.

curves having different values of $n$. These points, where $m=n$, are uniquely determined by a single curve and, therefore, may be easily located.

## IV. EXAMPLE FOR TYPICAL SOLUTIONS

As an example to illustrate the application of the graphical methods, the circuit of Fig. 5(a) will be used. This circuit consists of two identical sections of a low-pass network, coupled by pentode vacuum tubes. The r.m.s. voltage of a given frequency applied at the input of the system is $E_1$, and the resulting r.m.s. voltage at the output is $E_2$. For a particular choice of the component element values, the steady-state transmission characteristics of the system are shown in Fig. 5(b) and (c). Figure 5(b) gives these characteristics in terms of amplitude and phase, while Fig. 5(c) represents the same characteristics expressed as a real and an imaginary part. These parts are the products of the amplitude by the cosine and sine, respectively, of the phase angle. At a given frequency, the real part of the transmission characteristics is the ratio between the r.m.s. value of that component of the output voltage, which is in phase with the input voltage, and the r.m.s. value of the input voltage. Similarly, the imaginary part of the transmission characteristics is the corresponding ratio involving that component of the output voltage which leads the input voltage by ninety degrees. In the figure only positive frequencies are shown, although the shapes of the curves for negative frequencies must be understood. The amplitude curve and the real curve have even symmetry; the angle curve and the imaginary curve have odd symmetry. The scales of these curves are given as dimensionless ratios. The factor, $A$, is the voltage amplification of the system at zero frequency, and the reference frequency, $f_1$, is the frequency at which the inductor and capacitor of the circuits are in series resonance.

A non-sinusoidal input voltage, which has an instantaneous value, $e_1(t)$, is now applied to the system. In order not to complicate the example too much, this voltage is assumed to be an impulse function, having an infinite amplitude, zero duration, but a finite area equal to $E_0t_0$. The transform, $g_1(f)$, of such an impulse is easily shown to be a constant, $E_0t_0$, at all frequencies. This fact might be obtained from the curves of Fig. 2 and Fig. 3 for the rectangular wave shape, by allowing the duration, $t_0$, to approach zero as the amplitude, $E_0$, becomes infinite, like $E_0/t_0$. The product of this constant value multiplied by the steady-state transmission characteristics of the system therefore has the shape of these characteristics, with the ordinates merely changed by the constant factor, $E_0t_0$. This product is the frequency function, $g_2(f)$, at the output of the system. Its real part appears in Figs. 6(a), 7(a), and 8(a).

## V. DIRECT CURVE-FITTING METHOD

Perhaps the most direct graphical method of obtaining the output signal, $e_2(t)$, is to make use of the curves of Figs. 2 and 3, combining them graphically so as to fit the frequency function in

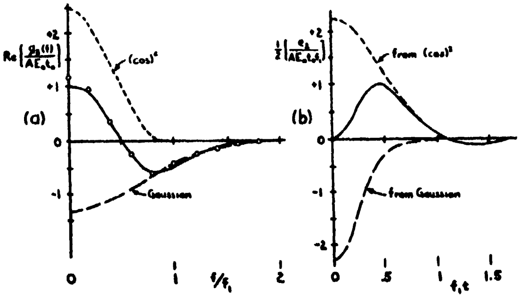

FIG. 6. Solution by direct curve fitting. (a) Real part of frequency function at output of system, as sum of simple curves. Circles indicate sum of dotted curves. (b) Output signal from system, as sum of inverse transforms of simple curves.

question. This procedure is illustrated in Fig. 6. The solid curve in Fig. 6(a) is the real part of the frequency function at the output of the system of Fig. 5(a), when an impulse of area $E_0t_0$ is applied at the input. Again, dimensionless ratios are used on the coordinate axes, and only the positive half of each curve is shown. This curve may be approximated by the sum of the cosine-squared curve and the (negative) Gaussian curve of Fig. 2, with their scales suitably adjusted. Although the curves of Fig. 2 are given as functions of time, it has already been pointed out that their arguments may be changed to frequency if desired. It is convenient to make the change for the present purpose. This curve-fitting is a trial and error process, but is not too difficult. The sum of the two curves is indicated by the circles in Fig. 6(a) and is seen to fit the given curve fairly well.

In Fig. 6(b) the transforms of the two standard frequency functions are plotted, having been obtained with the help of Fig. 3, and with careful observance of the coordinates. Again, only the positive half of each curve is shown. The solid curve of Fig. 6(b) is the sum of the two standard transforms. It has the proper shape for the output signal from the system, but the ordinates have just half the correct value. If the ordinates are doubled, this curve represents the desired output signal.

Where the shape of the frequency function is not too complicated, as is true here, it may be fitted reasonably well by a simple combination of two or three of the standard curves. After some practice this may be done with a minimum of trial and error. Obviously, the more closely the sum of the standard curves approximates the unknown curve, the more accurate will be the final results.

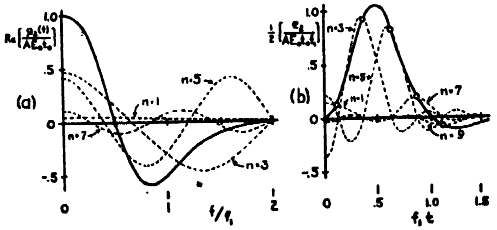

FIG. 7. Solution by cosine analysis of frequency function. (a) Real part of frequency function at output of system, as sum of cosines. (b) Output signal from system, as sum of transforms of cosines.

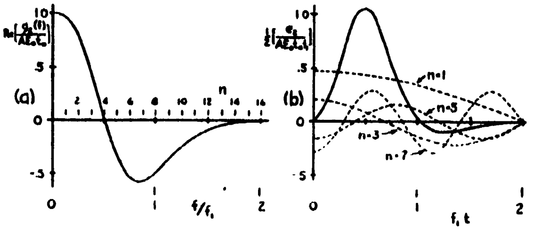

FIG. 8. Solution by cosine synthesis of time function. (a) Real part of frequency function at output of system, with selected points indicated. (b) Output signal from system, as sum of cosines.

## VI. COSINE ANALYSIS OF THE FREQUENCY FUNCTION

In order to eliminate the trial and error of the type of curve-fitting just described, the cosine functions of Fig. 4 and their transforms may be used. It is necessary to interchange time and frequency in these curves, but since they are real even functions, the interchange may be made with no other modifications. The frequency function at the output of the system may be analyzed as a sum of cosine functions by any of a number of standard graphical methods. For example, the Fischer-Hinnen method[7] is well suited for this purpose. The transforms of the cosine functions may then be found from Fig. 4 and summed.

This process is illustrated in Fig. 7. The solid curve in Fig. 7(a) represents the real part of the frequency function at the output of the system, just as before, and is plotted in the same way. This curve is analyzed as the sum of cosines having odd numbers of quarter cycles in the frequency interval, $f_a = 2f_1$. This choice of this interval must be such that the given curve has essentially zero value for frequencies outside of the interval. The cosine functions thus obtained are plotted in Fig. 7(a) with the parameter, $n$, indicating the number of quarter cycles executed in the interval. Only values of $n$ up to seven are plotted, although higher values are actually required to represent the curve well.

The transforms of each of these cosine functions may be found with the help of Fig. 4. The transforms are plotted in Fig. 7(b), showing only values of $n$ up to nine, and are summed. Once

---

[7] F. A. Laws, *Electrical Measurements* (McGraw-Hill Book Company, Inc., New York, 1938), second edition, pp. 687–695.

again, if the ordinates of this sum are doubled, the output signal from the system is obtained. The larger the number of cosines used in the original analysis, the more accurately they will approximate the frequency function, and the more accurate will be the final result.

This analysis of Fig. 7 was carried out with $n$ chosen odd, and the curves of Fig. 4(c) and (d) were used. Exactly the same results will be obtained if $n$ is chosen even, although the analysis is different and the curves of Fig. 4(a) and (b) would be employed. There is usually little basis for choosing between these two analyses since either will produce the same result with about the same amount of effort.

The shape of the transforms in Fig. 4(b) and (d) is relatively complicated, and their plotting and summing as in Fig. 7(b) is tedious. However, if it is sufficient to obtain only a few discrete points on the curve of the output signal, the properties of these functions are such that their plotting may be eliminated. It was pointed out earlier, in connection with Eq. (4), that there are certain times at which only the curve for a single value of $n$ contributes to the final sum. These points are shown by circles in Fig. 7(b). The times at which these points occur are $n/(4f_a)$, and the values at these times are $a_n f_a$, where $a_n$ is the amplitude of the $n$th cosine function of the analysis, and $n$ is not zero. If $n$ is zero, the value at $t=0$ is $2a_0 f_a$. These points are located by data from the cosine analysis, and plotting of the transforms is not required. Evidently, if it is desired to obtain a large number of points closely spaced along the curve of the output function, the frequency interval, $f_a$, must be chosen relatively large and the cosine analysis carried to large values of $n$.

## VII. COSINE SYNTHESIS OF TIME FUNCTION

A further simplification in the analysis results if the foregoing procedure is applied in reverse order. The unknown frequency function is analyzed as the sum of functions having the shape of those of Fig. 4(b) and (d), and their transforms then found as cosine functions. In this case, the frequency and time scales are left as in Fig. 4. This type of analysis is simpler than the analysis into cosines, since it involves only a direct reading of the value of the curve at certain points. It is not necessary to plot the curves into which the frequency function is analyzed.

This process is illustrated in Fig. 8, where once more Fig. 8(a) represents the real part of the frequency function at the output of the system. The abscissa of this curve is divided into frequency intervals, $f_b$, chosen in this case as $f_1/8$. These intervals are numbered consecutively as shown, with $n$ equal to zero at zero frequency. The value of the curve at points corresponding to the various values of $n$ may then be read directly. The transform of the curve is the sum of the ordinates of a number of cosine curves which execute $n$ quarter cycles in the time interval, $t_b = 1/(4f_b) = 2/f_1$, where $n$ is chosen either odd or even. The amplitude of the $n$th cosine is $p_n/t_b$ where $p_n$ is the value of the frequency function at $nf_b$, and $n$ is not zero. If $n$ is zero, the amplitude of the zeroth cosine (i.e., constant term) is $p_0/(2t_b)$. Cosine time functions, with $n$ odd and values only up to seven, are plotted in Fig. 8(b) and summed. Their sum, with its ordinates doubled, is the output signal from the system. The same result would have been obtained had $n$ been chosen even instead of odd, and once more there is little basis for choice in the matter. If the final time function is to be relatively accurate, the frequency interval, $f_b$, must be chosen small enough so that information is obtained from each important part of the frequency function.

## VIII. INPUT SIGNAL IN THE FORM OF A STEP FUNCTION

In the preceding examples, the input signal to the system has been chosen as an impulse function, since this function has the simplest possible transform. For many applications, in the analysis of the behavior of servomechanisms[8] for instance, the step function is often used for test purposes. The step function, $e_s(t)$, is defined as

$$\begin{cases} e_s(t)=0 & \text{for} \quad t<0 \\ e_s(t)=E_0 & \text{for} \quad t>0. \end{cases}$$

The step function may also be written $e_s(t)$

---

[8] H. Lauer, R. Lesnick, L. E. Matson, *Servomechanism Fundamentals* (McGraw-Hill Book Company, Inc., New York, 1947), Chap. IV.

$=E_0/2+e_s''(t)$ where $e_s''(t)$ is defined as

$$\begin{cases} e_s''(t) = -E_0/2 & \text{for} \quad t<0 \\ e_s''(t) = +E_0/2 & \text{for} \quad t>0 \end{cases}$$

and is a real odd function of time. The usual step function, $e_s(t)$, is thus replaced by a constant, $E_0/2$, and the symmetrical step, $e_s''(t)$. The transform of $e_s''(t)$ may be found from Eq. (1) as $g_s''(f) = -jE_0/\omega$, and is an imaginary odd function of frequency. This result is obtained by multiplying the time function by factors of the form $\exp(\pm ct)$, where $c$ is a real constant, the sign of which is chosen so as to make the product vanish at plus and minus infinity. After completing the integration of Eq. (1), $c$ is allowed to become zero, whereupon the transform given above is found.

The response of a system to the symmetrical step function, $e_s''(t)$, may be determined by any of the methods already described in connection with the impulse function. The response to the constant, $E_0/2$, is simply the product of $A$ (the amplification of the system at zero frequency) and $E_0/2$. Finally, the sum of the responses to the symmetrical step, $e_s''(t)$, and to the constant, $E_0/2$, is the response of the system to the step function, $e_s(t)$. If only the real part of the frequency function at the output is used in the solution, the ordinates of the result must be doubled. For a passive system, at rest at $t=0$, the response must also be zero at $t=0$. After a long time the response must be $AE_0$.

## IX. FINAL REMARKS

In each of the three graphical methods described here only the real part of the frequency function at the output of the system was utilized. It would be possible, of course, to make the analysis in terms of the imaginary part alone. There are occasions when both the real and the imaginary parts of the function must be considered. This is true, for example, if a real time function having no symmetry is to be transformed into its corresponding frequency function. In such a case, the frequency function will be complex, and both real and imaginary parts must be found. The necessary transformations may follow any of the procedures already described, since the same methods allow transformation from frequency to time, or *vice versa*.

The imaginary part may be handled most easily by a procedure analogous to the third method described, in which the real part was treated in terms of a sum of cosine functions. Inasmuch as the imaginary part must have odd symmetry, it must be treated in terms of a sum of sine functions. It is not difficult to set up families of sine functions and their transforms analogous to the cosine functions of Fig. 4. A negative sine curve has as a transform a curve similar in shape to those of Fig. 4(b) and (d), with the main hump positive. The curves necessarily have odd symmetry, and one function is imaginary while the other is real. The most important fact so far as an analysis in sine functions is concerned, is that the relations expressed in Eq. (4) for the transforms of cosine functions are also valid for the transforms of sine functions. Therefore, the analysis in terms of sines proceeds in the same way as has been discussed here in terms of cosines. The only differences are the opposite type of symmetry and the negative algebraic sign which must appear in such a ratio as $-p_n/t_b$, giving the amplitude of the $n$th sine for synthesis by the third method.

Only the very simple cases of an impulse function and a step function at the input of the system were considered here. If the input signal is more complicated so that its transform is not readily calculable, a graphical analysis of the type already described may be used to find this transform. If the input signal is real, but has no symmetry, steps (d) through (i) of Fig. 1 must be carried out, in reverse order, of course, to yield the frequency function, $g_1(f)$, corresponding to the input signal. With this function known, the remainder of the analysis proceeds as already described.

Of the three graphical methods discussed here, the third one in which the output signal is synthesized as a sum of cosine (or sine) functions is probably the most useful. However, if the curves are relatively simple, the first method, involving an experimental fitting of the curves, may lead more quickly to a result. As in all graphical methods, the accuracy of the results obtained from any of the procedures depends largely upon the skill with which the plotting is carried out. If only the approximate shape of the output signal is required, the graphical curve-fitting may be simplified so that it may be done in a short time. If accurate results are needed then more careful analysis is required.

Finally, it should be pointed out that the third method is in many problems essentially the same as that used by Bedford and Fredendall.[4] However, the bases for the two methods are somewhat different, and only in certain cases do the two become identical. In the present method, the frequency function at the output of the system is considered in terms of its real or imaginary parts, leading to the synthesis of the output signal as a sum of cosines or sines, all of which have zero relative phase displacement. In the method used by Bedford and Fredendall, the output signal is synthesized as a sum of cosines which have phase displacements determined by the problem. For a given number of components, a better representation may be obtained by the latter method, since an additional variable is allowed. On the other hand, the manipulation required to obtain the result may be simpler in the method described here.

### X. ACKNOWLEDGMENT

The original work reported here was done under the able guidance of Professor E. L. Chaffee and his helpful comments and suggestions are gratefully acknowledged.

# Two Calculating Machines for X-Ray Crystal Structure Analysis

A. D. Booth
*Institute for Advanced Study, Princeton, New Jersey, and Birkbeck College, England*

(Received July 2, 1946)

The calculation of structure factors in x-ray structure analysis is one of the most laborious operations. Two mechanisms are described which have proved of great service in several analyses. The simpler of the devices is of general application and can be constructed with comparatively limited workshop facilities.

## INTRODUCTION

APART from large and expensive machines for performing automatically the whole range of crystallographic calculation, there remains a need for simple *ad hoc* devices to deal with particular aspects of the problem. If the current schemes for centralizing the latter stages of Fourier refinement come to fruition, this demand for the "home made" and simple type of calculator is likely to be increased.

It is the purpose of this paper to describe two such arrangements which the author designed and found useful in practical structure analysis. The first is especially valuable in the case of tetragonal space groups and found extensive application during the determination of the structure of pentaerythritol tetranitrate.[1] The second is considerably simpler in principle and in design and has been in constant and satisfactory use in structure analysis[2,3] for the past four years.

## THE TETRAGONAL CALCULATOR

In tetragonal space groups it is necessary to obtain the value of expressions of the type:

$$F(hkl)=\sum_r f_r\left[\cos 2\pi\frac{hx_r}{a}\cdot\cos 2\pi\frac{ky_r}{b}-\cos 2\pi\frac{kx_r}{a}\cdot\cos 2\pi\frac{hy_r}{b}\right]\cos 2\pi\frac{lz_r}{c} \quad (1)$$

for a range of values of $(h, k, l)$. The information given being the values of $(hx_r/a,\ ky_r/b,\ lz_r/c)$ and $f_r$.

This calculation is performed by the mechanism shown in Fig. 1.

$L_1N_1$ and $L_2N_2$ are two bars of $\frac{3}{8}''$ diam. steel

---

[1] Booth and Llewellyn, Proc. Roy. Soc. (to be published).

[2] G. A. Jeffrey, Proc. Roy. Soc. A183, 388 (1945).

[3] G. A. Jeffrey, Proc. Roy. Soc. A188, 222 (1947).

rod which are capable of rotation in a horizontal plane about vertical axes through their centers, $O_1$ and $O_2$, respectively. Sliding along these bars are riders $P_1$ and $P_2$, so arranged as to be capable of fixation at any given radii $OP_1$ and $OP_2$ (positive or negative). Attached to the riders is a link mechanism $VP_1RP_2$; this has the bars $P_1RP_2$, $VR$ rigidly fixed at right angles, and the links $VP_1$, $VP_2$ of equal length. The bar $P_1RP_2$ can slide freely through the rider points $P_1P_2$, whilst the links $P_1V$, $P_2V$ can rotate about $P_1$, $P_2$, and $V$ with the latter freely sliding on $RV$.

The effect of this mechanism is seen to be the maintenance of $R$ at the mid point of $P_1$ and $P_2$.

If now the bars $L_1N_1$, $L_2N_2$ are rotated through angles $\theta_1$ and $\theta_2$ from the horizontal line $O_1O_2$, as shown, the displacement of $R$, parallel to $O_1O_2$, is simply:

$$\tfrac{1}{2}(O_2P_2\cos\theta_2 - O_1P_1\cos\theta_1). \tag{2}$$

This component of the motion of $R$ is separated by means of the framework $ABCD$ which can move, on rollers, in a horizontal line parallel to $O_1O_2$, $R$ moving in a groove in $AB$.

The motion of $CD$ is communicated, *via* a silk string $S$, to a disk $E$ which rotates about a vertical axis through its center $M$. The top surface of $E$ is covered with fine calico and has applied to it a planimeter assembly $P$. If the axis of the planimeter makes an angle $\theta_3$ with the radius $Mp$ through its point of contact $p$, the resultant rotation is

$$\Theta\cdot Mp\cdot\cos\theta_3, \tag{3}$$

where $\Theta$ is the angle of rotation of $E$.

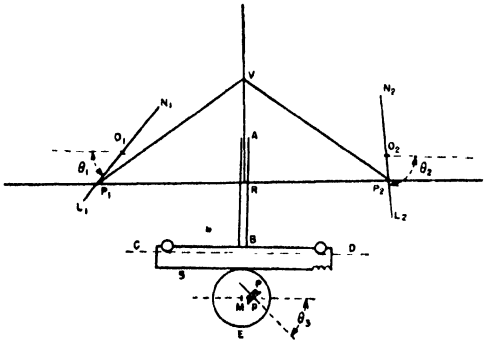

FIG. 1.

Thus, if scale factors are properly adjusted, the motion recorded on the planimeter is:

$$Mp(O_2P_2\cos\theta_2 - O_1P_1\cos\theta_1)\cos\theta_3. \tag{4}$$

The planimeter assembly is provided with a clutch so that it can be removed from contact with $E$.

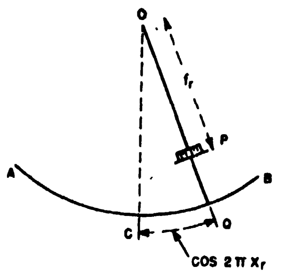

FIG. 2.

It follows, that by making:

$$Mp = f_r$$

$$O_2P_2 = \cos 2\pi\frac{hx_r}{a},$$

$$\theta_2 = \cos 2\pi\frac{ky_r}{b},$$

$$O_1P_1 = \cos 2\pi\frac{kx_r}{a},$$

$$\theta_1 = \cos 2\pi\frac{hy_r}{b},$$

$$\theta_3 = 2\pi\frac{lz_r}{c},$$

and resetting between operations, the summation (1) can be computed. The bars $L_1N_1$, $L_2N_2$ bear upon their upper surfaces scales directly calibrated in $\cos 2\pi(hx/a)$.

The machine proved most effective when two operators were available, one for each turntable, $L_1N_1$, $L_2N_2$, and reduced the time of computing the complicated expression (1) by a factor of approximately 4.

Unfortunately no photographs of the machine were taken and it has now, with the ending of the war, been dismantled.

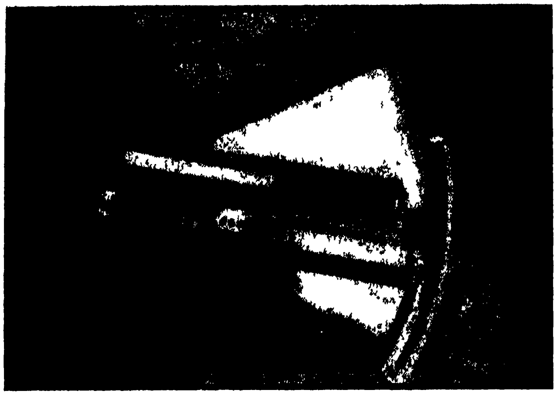

FIG. 3.

### THE COSINE ADDING MACHINE

This is considerably simpler in principle than the machine just described and has the advantage of not requiring any delicate mechanism of the planimeter type.

Although not always the most mathematically elegant method, it is easily shown that any structure factor formula can be reduced to a set of summations of the type:

$$\sum_r f_r \begin{Bmatrix} \sin \\ \cos \end{Bmatrix} 2\pi\left(\frac{hx_r}{a} \pm \frac{ky_r}{b} \pm \frac{lz_r}{c}\right). \quad (5)$$

A table of the functions $hx_r/a \pm ky_r/b + lz_r/c$ is readily computed using a "Facit" or other multiplying machine so that it is desirable to have a simple and rapid means of effecting the summation:

$$\sum_r f_r \begin{Bmatrix} \sin \\ \cos \end{Bmatrix} 2\pi X_r. \quad (6)$$

This is found in the mechanism shown in Fig. 2. A planimeter wheel $P$ is mounted on a bar $OQ$ pivoted at $O$: if the bar is turned through an angle $CQ = K\cos 2\pi X_r$, where $K$ is constant, the motion recorded by $P$ is simply:

$$K' \cdot OP \cdot \cos 2\pi X_r.$$

The constants are so arranged that $OP \propto f_r$ so that:

$$f_r \cos 2\pi X_r$$

is recorded.

By removing $P$ from contact with the plane $OABC$ during the return of $Q$ to its zero, $C$, and resetting $OP$, the complete summation (6) can be rapidly effected.

The machine is particularly advantageous in organic structure analysis where $f_r$ is constant for a large number of atoms.

Practical details are shown in Fig. 3. The planimeter wheel has a vulcanized rubber tire, the outside diameter being 1.625″. The counter mechanism was extracted from an old electricity meter with a step up ratio between wheel and counter of 1:7. The angle scale of $\cos 2\pi X_r$ is in the form of a circular segment and is attached to the planimeter on rail assemblies as shown. A simple spring push type clutch is provided so that the planimeter is normally out of contact with the friction plate, the latter being of sand blasted brass. An audible "click" is given on the return of the setting to zero.

This machine proves not much inferior in speed to a normal key driven adding machine.

### DISCUSSION

The second, and simpler of these machines, has been and is of constant utility and is sufficiently versatile to be worth making a permanent fixture in a crystallographic laboratory. The first is of more ephemeral application, but is worthy of description as containing a number of mechanical elements which can be incorporated in other special purpose machines, and which may consequently be of service to other workers in the field.

The author wishes to record his thanks to Mr. H. W. Giles for his care and numerous helpful suggestions while constructing the second machine, and to the Board of the British Rubber Producers' Research Association under whose auspices the machine was constructed. For the first machine valuable mechanical help was given by Mr. W. H. Small, B.Sc.

# The Field of a Microwave Dipole Antenna in the Vicinity of the Horizon*

C. L. Pekeris**
*Columbia University Mathematical Physics Group, New York, New York*

(Received April 8, 1947)

In this paper a method is developed for determining the electromagnetic field produced by a microwave antenna at points on the horizon, and on either side of it, where neither the ray theory nor the normal mode theory can be used conveniently. The theory is developed for a condition of standard atmospheric refraction, by use of a space in which the earth is flattened and the rays are curved. This allows us to make a simple derivation of the ray theory, valid in the optical region, and of the normal mode theory, suited for the shadow zone. For the intermediate region centered around the horizon we use the original integral for the potential to obtain expressions for the field under the restriction of maximum absorption, which for typical ground conditions applies to wave-lengths less than about a meter. Three cases are treated in which the transmitter, or receiver, are either situated on the ground or are elevated several natural units of height. For an elevated transmitter and receiver the Hertzian potential $\Psi$ due to a point source at the origin is in the vicinity of the horizon given by

$$|\Psi| = [1/2(r\hat{r})^{\frac{1}{2}}]\left|(2/\pi^{\frac{1}{2}})e^{i\pi/4}\int_0^{\infty} \exp[-i(2\tau^{\frac{1}{2}}t+t^2)]dt - [(2/3)^{\frac{1}{2}}\Omega/\pi^{\frac{1}{2}}]e^{-i\pi/12}F(p)\right|, \quad \text{(A)}$$

with

$$p=(3/2)^{\frac{2}{3}}(x-\mathfrak{x}),\ \Omega^2=(z_1^{-\frac{1}{2}}+z_2^{-\frac{1}{2}}),$$
$$\tau=(x-\mathfrak{x})^2/\Omega^2,\ \mathfrak{x}=z_1^{\frac{1}{2}}+z_2^{\frac{1}{2}},$$

where $x$ denotes the horizontal distance $r$ expressed in natural units, $z_1$ and $z_2$ the heights of transmitter and receiver in natural units, $\hat{r}$ the distance of receiver from transmitter when the former is on the horizon. $F(p)$ (see Eq. (68) below) has been evaluated, and is given in Table IV, while the integral in (A) can be expressed in terms of the tabulated Fresnel integrals. In the limit of very short wave-lengths the field *on* the horizon approaches the value $1/(2\hat{r})$ which would result from the diffraction of the *direct ray only* by a straight edge placed at the point of tangency of the horizon with the earth. A comparison of the field obtained from (A) with exact values computed by van d. Pol and Bremmer, using the ray theory and the normal mode theory, is shown in Figs. 6 and 7.

When the transmitter is at zero elevation and the receiver is elevated several units of height, the potential in the vicinity of the horizon is given by

$$|\Psi_v| = \frac{(3/2\pi a_e)^{\frac{1}{3}}\lambda^{\frac{1}{3}}}{\pi(r\hat{r})^{\frac{1}{2}}}\left|\frac{G(p)\epsilon_1}{(\epsilon_1-1)^{\frac{1}{2}}}\right|, \quad \text{(B)}$$

$$|\Psi_h| = \frac{(3/2\pi a_e)^{\frac{1}{3}}\lambda^{\frac{1}{3}}}{\pi(r\hat{r})^{\frac{1}{2}}}\left|\frac{G(p)}{(\epsilon_1-1)^{\frac{1}{2}}}\right| \quad \text{(C)}$$

for vertical polarization and horizontal polarization, respectively. Here $\epsilon_1$ denotes the complex dielectric constant, $a_e$ the effective radius of the earth, and $\lambda$ the wave-length. $G(p)$ is given in Eq. (78) and is shown in Fig. 4. A comparison of (B) with exact values obtained by van d. Pol and Bremmer is shown in Fig. 8.

When both the transmitter and receiver are at zero elevation, it is found that the potential can be expressed as the *sum* of the surface wave appropriate for a *flat* ground and an integral depending on the radius of the earth. At great distances, the two terms tend to cancel out. Under conditions of maximum absorption this leads to

$$|\Psi_v| = \frac{2}{r^2k_0}\left|\frac{\epsilon_1^2 g(p')}{(\epsilon_1-1)}\right|; \quad |\Psi_h| = \frac{2}{r^2k_0}\left|\frac{g(p')}{(\epsilon_1-1)}\right|, \quad \text{(D)}$$

$$p'=(3/2)^{\frac{2}{3}}x, \quad g(p')=1-(2e^{i\pi/4}/3\pi^{\frac{1}{2}})(p')^{\frac{3}{2}}H(p').$$

$H(p')$ is given in (84) and $g(p')$ is shown in Fig. 5, where it is compared with results obtained previously by van d. Pol and Bremmer using the normal mode theory.

For points *on* the horizon Eq. (A) reduces to

$$|\Psi| = (1/2\hat{r})|1-(0.684-0.183i)\Omega|, \quad \text{(E)}$$

while in (B) and (C) we put $|G(0)| = 2.13$.

## 1. INTRODUCTION

In the treatment of the problem of diffraction of radio waves around the earth[1] there are available at present the ray method, which is valid only in the lit region, and the method of normal modes, which is suited for the shadow region beyond the horizon. On the horizon and beyond the ray method breaks down completely, while the method of normal modes requires an increasing number of modes to be used as one recedes from the horizon into the lit

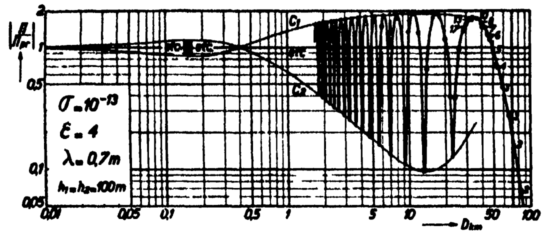

FIG. 1. Black circle points were calculated by the ray theory. The numbers placed near the open circles represent the number of modes that had to be included in order to obtain an accuracy of one percent. The horizon is at the dashed line (van d. Pol and Bremmer, Phil. Mag. 27, 270 (1939)).

region. This is illustrated in Fig. 1 which is taken from the work of van d. Pol and Bremmer.[2] The purpose of this investigation is to develop a theory of diffraction of microwaves which is intrinsically most accurate in the vicinity of the horizon, and which becomes less accurate as one recedes from the horizon either far into the lit zone or far into the shadow zone, thus bridging the gap between the ray theory and the normal mode theory. The horizon is the locus of coalescence of the direct ray with the reflected ray, and for this reason our work displays some points of similarity with Airy's theory of diffraction near a caustic. Expression (A) for the Hertzian potential given above reduces to an interference pattern between the direct and reflected rays for points inside the lit zone (Figs. 6 and 7), while inside the shadow zone it is a monotone decreasing function caused by cancellation of the two terms.

The propagation of microwaves around the earth presents a peculiar diffraction problem, in that the distance of the source from the sphere, as well as the wave-length, is small in comparison with the radius of the sphere. Furthermore, we are interested in the diffracted field at points which are within a range of only a fraction of the radius from the sphere. The question has often been raised to what extent an object of finite curvature diffracts like a straight edge placed at the point of tangency of the horizon line. In this connection our analysis shows that, within ranges of the order of a fraction of the radius from the sphere, the field *on the horizon* approaches the value for a straight edge in the limit of short wave-lengths, provided we neglect the contribution from the reflected ray. The latter is justified because of the divergence of the reflected ray near the horizon.

Our treatment differs from Watson's, and its later extensions by van d. Pol and Bremmer,[1] in that the problem of diffraction around the spherical earth is transformed into one of diffraction over a flat earth through an atmosphere with a suitably variable index of refraction. This device was first introduced by Schelleng, Burrows and Ferrell,[3] and it is known to be valid[4] out to ranges of the order of the radius of the earth and for wave-lengths greater than a centimeter up to heights of the order of a thousand feet. By this method one obviates the synthesis of an original solution expressed as a series of spherical harmonics, and, furthermore, arrives directly at an integral for the potential containing Bessel functions of the order $\frac{1}{3}$, which are intrinsic to the problem.

The effect of the curvature of the earth is introduced by replacing the actual index of refraction $\mu$ by a modified index $N$ defined by

$$N(r) = r\mu(r)/a\mu(a), \qquad (1)$$

$a$ denoting the radius of the earth and $r$ the distance from the center of the earth. In a free atmosphere $N(r)$ increases with height $h$ above the surface at the rate of $h/a$, while under conditions of standard atmospheric refraction this rate is changed to $h/a_e$, with[3] $a_e \simeq 4a/3$. Our problem reduces therefore to finding a solution for the Hertzian potential $\Psi$ satisfying the wave equation:

$$\nabla^2\Psi + k_0{}^2\mu^2\Psi = 0, \quad k_0 = 2\pi/\lambda, \qquad (2)$$

$$\mu^2 = (1+qh), \quad q = 2/a_e, \quad \text{in air}, \qquad (3)$$

$$\mu^2 = (1+qh)\epsilon_1, \quad \epsilon_1 = \epsilon - i\sigma/\omega, \quad \text{in the ground}, \qquad (4)$$

where $\epsilon$ denotes the dielectric constant and $\sigma$ the conductivity of the ground, and a time factor $e^{i\omega t}$ has been assumed. It will be noted that it is necessary to distort the space inside the earth as well. The fact that the expression for $\mu^2$ in (4) becomes formally negative inside the earth (where $h$ is negative) at a depth of about half $a_e$

need not concern us, since the earth-flattening approximation is to be applied only under conditions where the energy inside the earth is confined to a thin surface layer.

It should be noted that the problem treated here finds an application in underwater acoustics,[5] where the index of refraction $\mu$ for sound propagation sometimes varies with depth $h$ according to Eq. (3). In that problem of a real flat boundary and a variable $\mu$, the parameter $q$ in (3), which is a measure of the curvature of the rays, need not be small. On the other hand, in the application to propagation of microwaves around the earth, the earth-flattening approximation is valid only insofar as powers of $qh$ higher than the first can be neglected, so that in the sequel, the expression for the field should be relied on only as far as the first power in $qh$.

## 2. FORMAL SOLUTION

The solution of (2) must reduce to the form $e^{-ikR}/R$ at small distances $R$ from the source, it must represent an outgoing wave at great distances from the source, and the tangential components of the electric and magnetic fields must be continuous at the surface of the earth. The formal solution of (2), satisfying the above mentioned boundary conditions, can be obtained by a method given by H. Lamb.[5,6] The solution is built up from elementary solutions of the form

$$\psi = e^{i\omega t} J_0(kr) F(h) G(k), \tag{5}$$

$r$ now denoting horizontal distance, and $k$ a variable over which one eventually integrates in the complex $k$-plane. $F(h)$ satisfies the equations

$$(d^2F/dh^2) + [k_0^2(1+qh) - k^2]F = 0, \quad \text{in the air } (h>0), \tag{6}$$

$$(d^2F/dh^2) + [k_1^2(1+qh) - k^2]F = 0; \quad k_1^2 = k_0^2\epsilon_1, \quad \text{in the ground } (h<0). \tag{7}$$

The fundamental solutions of (6) are

$$M(u) = u^{\frac{1}{2}} H_{1/3}{}^{(1)}(2u^{\frac{3}{2}}/3), \quad N(u) = u^{\frac{1}{2}} H_{1/3}{}^{(2)}(2u^{\frac{3}{2}}/3), \quad u = (k_0/q)^{\frac{2}{3}}[1+qh-(k^2/k_0^2)], \tag{8}$$

while the solution of (7), which does not become infinite at great depth, is

$$P(v) = v^{\frac{1}{2}}[J_{1/3}(2v^{\frac{3}{2}}/3) + J_{-1/3}(2v^{\frac{3}{2}}/3)] = [(3v)^{\frac{1}{2}}/2][H_{1/3}{}^{(1)}(2v^{\frac{3}{2}}/3)e^{i\pi/6} + e^{-i\pi/6}H_{1/3}{}^{(2)}(2v^{\frac{3}{2}}/3)],$$
$$v = (k_1/q)^{\frac{2}{3}}[1+qh-(k^2/k_1^2)]. \tag{9}$$

Here the phase of $u$ is zero when positive, and $-i\pi$ when negative, and similarly for $v$. Let the transmitter's height above the ground be denoted by $h_1$, then we have

$$\begin{aligned} &F_1(h) = C(k)N(u), \quad h>h_1, \\ &F_2(h) = A(k)M(u) + B(k)N(u), \quad 0<h<h_1, \\ &F_3(h) = E(k)P(v), \quad h<0, \end{aligned} \tag{10}$$

where the functions of $k$, $A$, $B$, $C$, and $E$ are determined by the boundary conditions. These are, for a point source at $h_1$,

$$F_1 = F_2, \quad (\partial F_2/\partial h) - (\partial F_1/\partial h) = 2k, \quad \text{at } h = h_1, \tag{11}$$

$$\partial F_2/\partial h = \partial F_3/\partial h, \quad k_0^2 F_2 = k_1^2 F_3 \quad \text{at } h=0, \text{ for vertical polarization}, \tag{12}$$

$$\partial F_2/\partial h = \partial F_3/\partial h, \quad F_2 = F_3 \quad \text{at } h=0, \text{ for horizontal polarization}. \tag{13}$$

Using the relations

$$dM/du = uH_{-2/3}{}^{(1)}(2u^{\frac{3}{2}}/3), \quad dN/du = uH_{-2/3}{}^{(2)}(2u^{\frac{3}{2}}/3), \tag{14}$$

$$H_\nu{}^{(1)}(z) \cdot H_{\nu+1}{}^{(2)}(z) - H_{\nu+1}{}^{(1)}(z) \cdot H_\nu{}^{(2)}(z) = 4i/\pi z, \tag{15}$$

in solving for $A$, $B$, $C$, and $E$ from (11) and (12), or from (11) and (13), we obtain

$$\Psi_1=-[i\pi e^{\omega t}/3(qk_0^2)^{1/3}]\int_0^\infty J_0(kr)kdk(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)[H_{1/3}^{(1)}(2u_1^{3/2}/3)+$$
$$+(B/A)H_{1/3}^{(2)}(2u_1^{3/2}/3)],\quad h>h_1, \tag{16}$$

$$\Psi_2=-[i\pi e^{\omega t}/3(qk_0^2)^{1/3}]\int_0^\infty J_0(kr)kdk(u_1u)^{1/2}H_{1/3}^{(2)}(2u_1^{3/2}/3)[H_{1/3}^{(1)}(2u^{3/2}/3)$$
$$+(B/A)H_{1/3}^{(2)}(2u^{3/2}/3)],\quad 0<h<h_1, \tag{17}$$

$$\Psi_3=-[i\pi\gamma e^{\omega t}/3(qk_0^2)^{1/3}]\int_0^\infty J_0(kr)kdk[P(v)/P(v_0)]H_{1/3}^{(2)}(2u^{3/2}/3)[H_{1/3}^{(1)}(2u_0^{3/2}/3)+$$
$$+(B/A)H_{1/3}^{(2)}(2u_0^{3/2}/3)],\quad h<0, \tag{18}$$

$$u_0=(k_0/q)^{2/3}[1-(k^2/k_0^2)],\quad u_1=(k_0/q)^{2/3}[1+qh_1-(k^2/k_0^2)],\quad v_0=(k_1/q)^{2/3}[1-(k^2/k_1^2)], \tag{19}$$

$$B/A=-[\beta u_0^{1/2}H_{1/3}^{(1)}(2u_0^{3/2}/3)-u_0H_{-2/3}^{(1)}(2u_0^{3/2}/3)]/[\beta u_0^{1/2}H_{1/3}^{(2)}(2u_0^{3/2}/3)-u_0H_{-2/3}^{(2)}(2u_0^{3/2}/3)], \tag{20}$$

$$\beta=(1/\epsilon_1^{2/3})[\dot{P}(v_0)/P(v_0)]\simeq(iv_0^{1/2}/\epsilon_1^{2/3});\quad \gamma=1/\epsilon_1,\ \text{for vertical polarization}, \tag{21}$$

$$\beta=\epsilon_1^{1/3}[\dot{P}(v_0)/P(v_0)]\simeq iv_0^{1/2}\cdot\epsilon_1^{1/3};\quad \gamma=1,\ \text{for horizontal polarization}. \tag{22}$$

The only assumption made in deriving this solution, aside from the one involved in the earth-flattening approximation, was in writing $iv_0^{1/2}$ for $\dot{P}(v_0)/P(v_0)$. This approximation holds with increasing accuracy the more absorptive the ground is; even for dry soil the error introduced by this approximation is less than one part in 10[7].

We shall now show that in the limit of an infinite radius of the sphere ($q\to0$) our solution reduces to Sommerfeld's solution[6] for the potential of a dipole over a *flat* earth. As $q\to0$, $u_0$ defined in (19) becomes very large, and

$$u_1^{3/2}\to u_0^{3/2}+(3h_1/2)(k_0^2-k^2)^{1/2}+\cdots;\quad u\to u_0^{3/2}+(3h/2)(k_0^2-k^2)^{1/2}+\cdots. \tag{23}$$

We can therefore replace the Hankel functions in (16) and (17) by their asymptotic expansions:

$$H_{1/3}^{(1)}(z)\to(2/\pi z)^{1/2}\exp[i(z-5\pi/12)],\quad H_{1/3}^{(2)}(z)\to(2/\pi z)^{1/2}\exp[i(-z+5\pi/12)], \tag{24}$$

$$B/A\to\exp[-i5\pi/6+4iu_0^{3/2}/3]R(k),\quad k<k_0, \tag{25}$$

$$R(k)=\left[\frac{k_1^2(k_0^2-k^2)^{1/2}-k_0^2(k_1^2-k^2)^{1/2}}{k_1^2(k_0^2-k^2)^{1/2}+k_0^2(k_1^2-k^2)^{1/2}}\right],\ \text{for vertical polarization,}$$
$$=\left[\frac{(k_0^2-k^2)^{1/2}-(k_1^2-k^2)^{1/2}}{(k_0^2-k^2)^{1/2}+(k_1^2-k^2)^{1/2}}\right],\ \text{for horizontal polarization,} \tag{26}$$

$$(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)[H_{1/3}^{(1)}(2u_1^{3/2}/3)+(B/A)H_{1/3}^{(2)}(2u_1^{3/2}/3)]$$
$$\to\frac{3(qk_0^2)^{1/3}}{\pi(k_0^2-k^2)^{1/2}}\{\exp[-i(h-h_1)(k_0^2-k^2)^{1/2}]+R(k)\exp[-i(h_1+h)(k_0^2-k^2)^{1/2}]\}, \tag{27}$$

$$\Psi_1\to-i\int_0^\infty\frac{J_0(kr)kdk}{(k_0^2-k^2)^{1/2}}\{\exp[-i(h-h_1)(k_0^2-k^2)^{1/2}]+R(k)\ \exp[-i(h_1+h)(k_0^2-k^2)^{1/2}]\},\quad h>h_1. \tag{28}$$

This agrees with Sommerfeld's solution for a flat earth in which $h_1\to0$, since $(k_0^2-k^2)^{1/2}\to-i(k^2-k_0^2)^{1/2}$ for $k>k_0$.

b. $h < h_1$

FIG. 2. $h_1$ = height of transmitter, $h$ = height of receiver.

### 3. RAY THEORY

In this section we shall show briefly how one can derive from our solution given in (16) and (17) the geometric-optical approximation, which is valid for short wave-lengths inside the lit region. No detailed discussion of this subject will be attempted here, since this has been done adequately originally by van d. Pol and Bremmer and later by Burrows and Norton,[1] and since, furthermore, our main interest in this investigation lies in determining the field in the vicinity of the horizon. Now, according to Fermat's principle, a ray is a curve connecting the transmitter and receiver such that along it the travel-time is stationary. Such a curve is characterized by a definite angle $\theta$ which it makes with the vertical at the transmitter, and this value of $\theta$ is associated with a particular value of $k$ ($<k_0$) in the integrals (16) and (17), through the relation[7] $k = k_0\mu(h_1)\sin\theta$. Hence our task is to find the values of $k$ in the path of integration for which the travel-time is stationary. This travel-time is equal to the limit approached by the phase of the wave as the frequency (or $k_0$) is increased indefinitely, because the *beginning* of a pulse starting from quiescence is controlled by the high frequency components. It follows that our procedure is first to obtain asymptotic expressions for the integrands valid for large wave numbers $k_0$, then find the values of $k$ for which the phase is stationary (if such points exist), and finally to evaluate the integrals around the points of stationary phase.

To begin with, the integrals in (16) and (17) can, under certain conditions[8] which are met in our case, be transformed by the use of the relation

$$\int_0^\infty J_0(kr)\psi(k)kdk = \tfrac{1}{2}\int_{-i\infty}^{\infty} H_0^{(2)}(kr)\psi(k)kdk. \quad (29)$$

In the limit of large $r$ (in comparison with $\lambda$) we have

$$H_0^{(2)}(kr) \rightarrow (2/\pi kr)^{\frac{1}{2}} \exp[i\pi/4 - ikr], \quad (30)$$

and (29) reduces to

$$\int_0^\infty J_0(kr)\psi(k)kdk$$
$$\rightarrow [e^{i\pi/4}/(2\pi r)^{\frac{1}{2}}]\int_{-i\infty}^{\infty} e^{-ikr}\psi(k)k^{\frac{1}{2}}dk. \quad (31)$$

Taking now the integral in (16) we write it in the form

$$\Psi_1 \simeq \frac{\pi \exp[i\omega t - i\pi/4]}{3(qk_0^2)^{\frac{1}{3}}(2\pi r)^{\frac{1}{2}}}$$
$$\times \int_{-i\infty}^{\infty} e^{-ikr}[V(k) + W(k)]k^{\frac{1}{2}}dk, \quad h > h_1, \quad (32)$$

$$V(k) \equiv (u_1u)^{\frac{1}{2}}H_{1/3}^{(2)}(2u^{\frac{3}{2}}/3)H_{1/3}^{(1)}(2u_1^{\frac{3}{2}}/3),$$
$$(33)$$
$$W(k) \equiv (u_1u)^{\frac{1}{2}}(B/A)H_{1/3}^{(2)}(2u^{\frac{3}{2}}/3)H_{1/3}^{(2)}(2u_1^{\frac{3}{2}}/3).$$

For large wave numbers $k_0$, and as long as $k$ is less than $k_0(1+qh_1)^{\frac{1}{2}}$ (and therefore also less than $k_0(1+qh)^{\frac{1}{2}}$), both $u_1$ and $u$ are large, so that we obtain from (24)

$$e^{-ikr}V(k) \rightarrow (3/\pi)(uu_1)^{-\frac{1}{4}} \exp[-ip_1(k)],$$
$$p_1(k) = kr + (2u^{\frac{3}{2}}/3) - (2u_1^{\frac{3}{2}}/3). \quad (34)$$

The point $k$ of stationary phase is determined from

$$\partial p_1(k)/\partial k = r - (2x/q)[(1+qh-x^2)^{\frac{1}{2}}$$
$$-(1+qh_1-x^2)^{\frac{1}{2}}] = 0, \quad (35)$$
$$x \equiv (k/k_0) = (1+qh_1)^{\frac{1}{2}}\sin\theta.$$

As $x$ varies from *zero* to its maximum possible value of $(1+qh_1)^{\frac{1}{2}}$, $r$ changes from *zero* to $\bar{r}_0$, where

$$q\bar{r}_0 = 2[1+qh_1]^{\frac{1}{2}} \cdot [q(h-h_1)]^{\frac{1}{2}} \quad (36)$$

defines the ray which starts out horizontally at the source. In real space the rays defined by (35) are the direct rays emitted above the transmitter's horizon.[9]

---

[8] Reference 5, pp. 305 to 307.

[9] Above line $AB$ in Fig. 2.

If the receiver is located above $h_1$ but below the transmitter's horizon ($r > \bar{r}_0$), the phase of the term $e^{-ikr}V(k)$ in (32) does not have a stationary point, so that this term's contribution becomes small relative to the second term's, on account of its highly oscillatory nature. The direct ray reaching the receiver in this case arises from a stationary point $k$ of $e^{-ikr}W(k)$, where $k_0 < k < k_0(1+qh_1)^{\frac{1}{2}}$. This term has also another stationary point at $k < k_0$, which gives the reflected ray for any position of the receiver in the lit zone. When $k_0 < k < k_0(1+qh_1)^{\frac{1}{2}}$ we put

$$w = (2/3)(k_0/q)[(k^2/k_0^2)-1]^{\frac{3}{2}}, \quad (2u_0^{\frac{3}{2}}/3) = e^{-i3\pi/2}w, \tag{37}$$

and obtain from (20)

$$\frac{B}{A} = \left\{ \frac{\beta[I_{-1/3}(w) + e^{-i\pi/3}I_{1/3}(w)] + (3w/2)^{\frac{1}{3}}[I_{2/3}(w) + e^{-i\pi/3}I_{-2/3}(w)]}{\beta[I_{-1/3}(w) + e^{i\pi/3}I_{1/3}(w)] + (3w/2)^{\frac{1}{3}}[I_{2/3}(w) + e^{i\pi/3}I_{-2/3}(w)]} \right\}. \tag{38}$$

For large $w$

$$I_\nu(w) \rightarrow [e^w/(2\pi w)^{\frac{1}{2}}][1 - \{(4\nu^2-1)/8w\} + \cdots], \quad B/A \rightarrow e^{-i\pi/3}, \tag{39}$$

and

$$e^{-ikr}W(k) \rightarrow (3/\pi)(uu_1)^{-\frac{1}{4}} \exp[(i\pi/2) - ip_2(k)], \quad p_2(k) = kr + (2u^{\frac{3}{2}}/3) + (2u_1^{\frac{3}{2}}/3), \tag{40}$$

$$\partial p_2(k)/\partial k = r - (2x/q)[(1+qh_1-x^2)^{\frac{1}{2}} + (1+qh-x^2)^{\frac{1}{2}}] = 0. \tag{41}$$

As $x$ varies from its minimum value of 1 to its maximum value of $(1+qh_1)^{\frac{1}{2}}$, $r$, as given by (41), changes from $\bar{r}$ to $\bar{r}_0$, where $\bar{r}$ denotes the horizontal distance from transmitter when the receiver is on the horizon, and is given by

$$q\bar{r} = 2(qh_1)^{\frac{1}{2}} + 2(qh)^{\frac{1}{2}}. \tag{42}$$

These are the direct rays emitted below the transmitter's horizon, thus complementing the direct rays not included in $p_1(k)$.

For $k < k_0$ we have, on using (25),

$$e^{-ikr}W(k) \rightarrow R(k)(3/\pi)(uu_1)^{-\frac{1}{4}} \exp[-ip_3(k)], \quad p_3(k) = kr - (4u_0^{\frac{3}{2}}/3) + (2u^{\frac{3}{2}}/3) + (2u_1^{\frac{3}{2}}/3), \tag{43}$$

$$\partial p_3(k)/\partial k = r - (2x/q)[(1+qh_1-x^2)^{\frac{1}{2}} + (1+qh-x^2)^{\frac{1}{2}} - 2(1-x^2)^{\frac{1}{2}}] = 0. \tag{44}$$

Here, as $x$ varies from 0 to 1, $r$ changes from *zero* to $\bar{r}$. These are the rays *reflected* at the surface of the earth, $R(k)$ representing the reflection coefficient for a plane earth, with the divergence factor arising from the integration around the stationary point, as is shown in the Appendix.

When the elevation of the receiver is less than that of the transmitter ($h < h_1$) we have to use $\Psi_2$ given in (17). Here the second term is identical with $W(k)$ in (32), and therefore leads to the phases $p_2(k)$ and $p_3(k)$, which are symmetrical in $h_1$ and $h$. In the case of $p_2(k)$

$$k_0 < k < k_0(1+qh)^{\frac{1}{2}}, \quad q\bar{r} > qr > qr_0 = 2[1+qh]^{\frac{1}{2}} \cdot [q(h_1-h)]^{\frac{1}{2}}, \tag{45}$$

where $r_0$ denotes the horizontal distance when the transmitter is on the horizon of the receiver (see

TABLE I. Location of the points $x(=k^*/k_0)$ of stationary phase, and the rays associated with them.

| | | | Limits of $x$ | | Limits of $r$ | | | Sign of $\frac{\partial^2 p[k^*]}{\partial k^2}$ |
|---|---|---|---|---|---|---|---|---|
| | Phase | Eq. | $x_1$ | $x_2$ | $r(x_1)$ | $r(x_2)$ | Nature of ray | |
| $h > h_1$ | $p_1(k)$ | 35 | 0 | $(1+qh_1)^{\frac{1}{2}}$ | 0 | $\bar{r}_0$ | Direct | $-$ |
| | $p_2(k)$ | 41 | 1 | $(1+qh_1)^{\frac{1}{2}}$ | $\bar{r}$ | $\bar{r}_0$ | Direct | $+$ |
| | $p_3(k)$ | 44 | 0 | 1 | 0 | $\bar{r}$ | Reflected | $-$ |
| $h < h_1$ | $p_4(k)$ | 47 | 0 | $(1+qh)^{\frac{1}{2}}$ | 0 | $r_0$ | Direct | $-$ |

| | $p_3(k)$ | 44 | 0 | 1 | 0 | $\bar{r}$ | Reflected | $-$ |

Fig. 2). When the receiver is closer to the transmitter ($r<r_0$), the direct ray arises from a stationary point of the first term in the integrand of (17):

$$e^{-ikr}(u_1u)^{\frac{1}{2}}H_{1/8}{}^{(2)}(2u_1{}^{\frac{3}{2}}/3)H_{1/3}{}^{(1)}(2u^{\frac{3}{2}}/3)\rightarrow(3/\pi)(uu_1)^{-\frac{1}{4}}\exp[-ip_4(k)]. \tag{46}$$

$$p_4(k)\equiv kr+(2u_1{}^{\frac{3}{2}}/3)-(2u^{\frac{3}{2}}/3),\quad \partial p_4(k)/\partial k=r-(2x/q)[(1+qh_1-x^2)^{\frac{1}{2}}-(1+qh-x^2)^{\frac{1}{2}}]=0. \tag{47}$$

As $x$ varies from *zero* to $(1+qh)^{\frac{1}{2}}$, $r$ changes from *zero* to $r_0$, thus complementing the rays arising from the stationary point in the second term. The reflected ray in the case $h<h_1$ arises from the second term, and is given by (43) and (44). The location of the points of stationary phase is summarized in Table I. Figure 2 illustrates the geometry of the problem.

We shall now indicate how one obtains the amplitudes of the rays by integrating around the points of stationary phase. It will suffice to illustrate the procedure in the case of the first term of $\Psi_2$ in (17), which yields the direct ray given in (47). We have first, on using (31) and then (46),

$$\begin{aligned}\Psi_2'\equiv-\frac{i\pi\exp[i\omega t]}{3(qk_0{}^2)^{\frac{1}{3}}}&\int_0^\infty J_0(kr)kdk(u_1u)^{\frac{1}{2}}H_{1/3}{}^{(2)}(2u_1{}^{\frac{3}{2}}/3)H_{1/3}{}^{(1)}(2u^{\frac{3}{2}}/3)\\ &\simeq\frac{\pi\exp[i\omega t-i\pi/4]}{3(qk_0{}^2)^{\frac{1}{3}}(2\pi r)^{\frac{1}{2}}}\int_{-i\infty}^\infty e^{-ikr}(u_1u)^{\frac{1}{2}}H_{1/3}{}^{(2)}(2u_1{}^{\frac{3}{2}}/3)H_{1/3}{}^{(1)}(2u^{\frac{3}{2}}/3)(k)^{\frac{1}{2}}dk\\ &\simeq\frac{\exp[i\omega t-i\pi/4]}{(qk_0{}^2)^{\frac{1}{3}}(2\pi r)^{\frac{1}{2}}}\int_{-i\infty}^\infty(uu_1)^{-\frac{1}{4}}\exp[-ip_4(k)]k^{\frac{1}{2}}dk.\end{aligned} \tag{48}$$

Let the point $k$ at which $p_4(k)$ is stationary be denoted by $k^*$; then we have in the neighborhood of $k^*$

$$p_4(k)=p_4(k^*)+\tfrac{1}{2}[\partial^2p_4(k^*)/\partial k^2]t^2+\cdots,\quad t=k-k^*. \tag{49}$$

Using this expansion in (48) we obtain

$$\begin{aligned}\int_{-i\infty}^\infty(uu_1)^{-\frac{1}{4}}\exp[-ip_4(k)]k^{\frac{1}{2}}dk&\simeq\exp[-ip_4(k^*)][(uu_1)^{-\frac{1}{4}}k^{\frac{1}{2}}]_{k=k^*}\cdot\int_{-\infty}^\infty\exp[-(i\partial^2p_4/2\partial k^2)t^2]dt\\ &=(k^*)^{\frac{1}{2}}(q/k_0)^{\frac{1}{2}}(1+qh_1-x^2)^{-\frac{1}{4}}(1+qh-x^2)^{-\frac{1}{4}}\exp[i\pi/4-ip_4(k^*)]\left|\frac{2\pi}{\partial^2p_4/\partial k^2}\right|^{\frac{1}{2}}\end{aligned} \tag{50}$$

where we have written $x$ for $k^*/k_0$. Hence, the direct ray is given by

$$\Psi_2'\simeq\frac{\exp[i\omega t-ip_4(k^*)]x^{\frac{1}{2}}}{[k_0r|\partial^2p_4/\partial k^2|]^{\frac{1}{2}}(1+qh_1-x^2)^{\frac{1}{4}}(1+qh-x^2)^{\frac{1}{4}}}. \tag{51}$$

This can now be expressed explicitly in terms of $r$, $h_1$, and $h$ by using (47). It follows from the latter that

$$x^2=[r^2/4R^2]\cdot[a+b+(4ab-q^2r^2)^{\frac{1}{2}}],\quad a\equiv1+qh_1,\quad b\equiv1+qh,\quad R\equiv[r^2+(h-h_1)^2]^{\frac{1}{2}}, \tag{52}$$

$$\partial^2p_4/\partial k^2=-[r(4ab-q^2r^2)^{\frac{1}{2}}/2k_0x(a-x^2)^{\frac{1}{2}}(b-x^2)^{\frac{1}{2}}],$$

$$\Psi_2'\simeq\frac{\exp[i\omega t-ip_4(k^*)]x2^{\frac{1}{2}}}{r(4ab-q^2r^2)^{\frac{1}{4}}}=\frac{\exp[i\omega t-ip_4(k^*)][a+b+(4ab-q^2r^2)^{\frac{1}{2}}]^{\frac{1}{2}}}{2^{\frac{1}{2}}R(4ab-q^2r^2)^{\frac{1}{4}}}, \tag{53}$$

$$p_4(k^*)=[k_0/(3\cdot2^{\frac{1}{2}}R)]\cdot[(a+b+qR)^{\frac{1}{2}}+(a+b-qR)^{\frac{1}{2}}]\cdot[q^2r^2+2a^2+2b^2-(a+b)(4ab-q^2r^2)^{\frac{1}{2}}]. \tag{54}$$

The amplitude of the direct ray reduces to $R^{-1}$ if powers of $q$ higher than the first are neglected.

As to the normal mode theory, which is useful in the shadow zone, we shall merely mention here that it can be obtained by evaluating the integral in (32) at the residues of $(B/A)$ defined in (20). For details of this calculation in the case of strong absorption ($\beta\gg1$) the reader is referred to reference 5, pages 307 and 308.

TABLE II.

## 4. THE FIELD IN THE VICINITY OF THE HORIZON IN CASE THE TRANSMITTER AND RECEIVER ARE ELEVATED SEVERAL NATURAL UNITS OF HEIGHT ABOVE THE GROUND

We now turn to our principal task, which is the determination of the field in the vicinity of the horizon. It will be noted from Table I that as $r\rightarrow\bar{r}$ (the horizon) the stationary point of $p_2(k)$ approaches $k_0$ from above, while the stationary point of $p_3(k)$ approaches the same limit from below. This corresponds to the coalescence of the direct ray with the reflected ray on the horizon. Since both of these stationary points arise from the second terms (containing the $B/A$ factor) in the integrands of (16) and (17), and since the principal contribution to the integrals occurs near the stationary points, it follows that, except for the case when the transmitter or receiver are on the ground, the field in the neighborhood of the horizon can be determined approximately by integrating the second terms in the integrands of (16) and (17) over a small range of $k$ on either side of $k_0$. When the transmitter or receiver, or both, are on the ground, both terms in the integrands of (16) or (17) need to be considered.

In the sequel it will be convenient to define a natural unit of height, $H$, and a natural unit of horizontal distance, $L$, through

$$H=(k_0^2q)^{-\frac{1}{3}},\quad L=2(kq^2)^{-\frac{1}{3}},\quad z_1=h_1/H,$$
$$z_2=h/H,\quad x=r/L,\quad p=(3/2)^{\frac{1}{3}}(x-\bar{x}).\qquad(55)$$

If λ is expressed in centimeters then, for a mean radius of the earth of 6371 km and $a_e=(4/3)a$, we have

$$H(m)=2.208\lambda^{\frac{2}{3}},\quad L(\text{km})=6.124\lambda^{\frac{1}{3}}.\qquad(56)$$

Further, we write

$$(k^2/k_0^2)-1=(3qw/2k_0)^{\frac{2}{3}},\quad k>k_0;\qquad k_0,\qquad(57)$$
$$1-(k^2/k_0^2)=(3vq/2k_0)^{\frac{2}{3}},\quad k<$$

and tabulate the expansions of some relevant quantities in Table II. $(B/A)$ is given in terms of $w$ for $k>k_0$ in (38), while for $k<k_0$ we have

$$\frac{B}{A}=\left\{\frac{\beta[J_{-1/3}(v)-e^{-i\pi/3}J_{1/3}(v)]+(3v/2)^{\frac{1}{3}}[J_{2/3}(v)+e^{-i\pi/3}J_{-2/3}(v)]}{\beta[J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)]+(3v/2)^{\frac{1}{3}}[J_{2/3}(v)+e^{i\pi/3}J_{-2/3}(v)]}\right\}.\qquad(58)$$

We shall limit the discussion to the case of strong absorption when $\beta$ is large, so that

$$\frac{B}{A}\longrightarrow-\left[\frac{H_{1/3}^{(1)}(2u_0^{\frac{3}{2}}/3)}{H_{1/3}^{(2)}(2u_0^{\frac{3}{2}}/3)}\right]=\frac{[J_{-1/3}(v)-e^{-i\pi/3}J_{1/3}(v)]}{[J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)]}=\frac{[I_{-1/3}(w)+e^{-i\pi/3}I_{1/3}(w)]}{[I_{-1/3}(w)+e^{i\pi/3}I_{1/3}(w)]}.\qquad(59)$$

Now

$$\beta_v=(iv_0^{\frac{1}{2}}/\epsilon_1^{\frac{1}{2}})\sim i[(k_0/q)^{\frac{1}{3}}]\cdot[(\epsilon_1-1)^{\frac{1}{2}}/\epsilon_1];\quad \beta_h=\beta_v\epsilon_1,\qquad(60)$$

where the subscripts $v$ and $h$ signify vertical and horizontal polarization, respectively. Table III shows in four typical cases of ground constants that for wave-lengths less than a meter $|\beta_v|\gg1$, and that this is true at all frequencies for $|\beta_h|$. Relation (59) is strictly true when the ground is a perfect reflector,[8] i.e., when the boundary condition at the ground is $\Psi=0$.

It follows from the preceding discussion that in the vicinity of the horizon

$$\Psi\simeq\frac{i\pi\exp[i\omega t]}{3(qk_0^2)^{1/3}}\int_0^\infty J_0(kr)kdk(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)H_{1/3}^{(2)}(2u_1^{3/2}/3)\frac{H_{1/3}^{(1)}(2u_0^{3/2}/3)}{H_{1/3}^{(2)}(2u_0^{3/2}/3)}$$

$$\simeq-\frac{\pi\exp[i\omega t-i\pi/4]}{3(qk_0^2)^{1/3}(2\pi r)^{1/2}}\int_{-i\infty}^\infty e^{-ikr}(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)H_{1/3}^{(2)}(2u_1^{3/2}/3)\frac{H_{1/3}^{(1)}(2u_0^{3/2}/3)}{H_{1/3}^{(2)}(2u_0^{3/2}/3)}k^{1/2}dk \quad (61)$$

$$\simeq\frac{\pi^{1/2}\exp[i\omega t-i\pi/4]}{3(12)^{1/3}(rL)^{1/2}}\left\{\int_0^\infty e^{-ikr}(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)H_{1/3}^{(2)}(2u_1^{3/2}/3)\left[\frac{I_{-1/3}(w)+e^{-i\pi/3}I_{1/3}(w)}{I_{-1/3}(w)+e^{i\pi/3}I_{1/3}(w)}\right]\frac{dw}{w^{1/3}}\right.$$

$$\left.+\int_0^\infty e^{-ikr}(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)H_{1/3}^{(2)}(2u_1^{3/2}/3)\left[\frac{J_{-1/3}(v)-e^{-i\pi/3}J_{1/3}(v)}{J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)}\right]\frac{dv}{v^{1/3}}\right\}, \quad (62)$$

where $u$, $u_1$, and $k$ take on their respective expressions in terms of $w$ and $v$, as shown in Table II. The only approximation made in going from (61) to (62) was in writing $k_0^{1/2}$ for $k^{1/2}$, which is justified because $H^2/L^2$ $(=1.3\times10^{-7}\lambda^{2/3}{}_{\text{cm}})$ is extremely small in the microwave region.

We shall evaluate the integral in (62) for the case when $z_1$ and $z$ are several units. We can then write

$$e^{-ikr}(u_1u)^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)H_{1/3}^{(2)}(2u_1^{3/2}/3)\rightarrow(3/\pi)(uu_1)^{-1/4}\exp[i5\pi/6-ip_2(k)], \quad (63)$$

$$\Psi\simeq\frac{\exp[i7\pi/12+i\omega t-ip_2(k_0)]}{(12)^{1/3}(\pi rL)^{1/2}(z_1z_2)^{1/4}}\left\{\int_0^\infty\exp[-ipw^{2/3}-isw^{1/3}]\left(e^{-i\pi/3}+\frac{e^{i\pi/3}[I_{-1/3}(w)-I_{1/3}(w)]}{[I_{-1/3}(w)+e^{i\pi/3}I_{1/3}(w)]}\right)\frac{dw}{w^{1/3}}\right.$$

$$\left.+\int_0^\infty\exp[ipv^{2/3}-isv^{4/3}]\left(\frac{J_{-1/3}(v)-e^{-i\pi/3}J_{1/3}(v)}{J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)}\right)\frac{dv}{v^{1/3}}\right\}, \quad (64)$$

$$\int_0^\infty\exp[-ipw^{2/3}-isw^{4/3}](dw/w^{1/3})=[(12)^{1/3}/\Omega]\int_0^\infty\exp[-i(2\tau^{1/2}t+t^2)]dt, \quad (65)$$

$$\Omega^2=[(1/z_1^{1/2})+(1/z_2^{1/2})],\quad \tau=(x-\bar{x})^2/\Omega^2,\quad s=(3/2)^{4/3}\bar{x}/4(z_1z_2)^{1/2}=(3/2)^{1/3}\Omega^2/4;$$

$$\int_0^\infty\exp[ipv^{2/3}]\left[\frac{J_{-1/3}(v)-e^{-i\pi/3}J_{1/3}(v)}{J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)}\right]\frac{dv}{v^{1/3}}$$

$$=e^{i\pi/3}\int_0^\infty\exp\{[(-3^{1/2}/2)+(i/2)]px^{2/3}\}\left[\frac{I_{-1/3}(x)-I_{1/3}(x)}{I_{-1/3}(x)+e^{-i\pi/3}I_{1/3}(x)}\right], \quad (66)$$

$$\Psi=\frac{\exp[i\omega t-ip_2(k_0)]}{2(r\bar{r})^{1/2}}\left\{\frac{2e^{i\pi/4}}{\pi^{1/2}}\int_0^\infty\exp[-i(2\tau^{1/2}t+t^2)]dt-\frac{(2/3)^{1/3}\Omega e^{-i\pi/12}}{\pi^{1/2}}F(p)\right\}, \quad (67)$$

TABLE III. Values of $|\beta_v|$ and $|\beta_h|$ for four typical ground constants.

TABLE IV. Values of $F(p)$ and $G(p)$ defined in (68) and (78), respectively; $R$ and $I$ denote real and imaginary parts.

| $p$ | −4.0 | −3.5 | −3.0 | −2.5 | −2.0 | −1.5 | −1.0 | −0.5 | 0 | 0.5 | 1.0 | 1.5 | 2.0 | 2.5 | 3.0 | 3.5 | 4.0 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $RF(p)$ | −2.35 | .18 | 1.70 | 2.21 | 2.21 | 2.04 | 1.84 | 1.64 | 1.44 | 1.23 | 1.03 | .84 | .68 | .55 | .45 | .38 | .33 |
| $IF(p)$ | −2.79 | −3.15 | −2.18 | −1.10 | −.36 | .02 | .14 | .10 | 0 | −.11 | −.20 | −.26 | −.27 | −.26 | −.24 | −.21 | −.19 |
| $RG(p)$ | | | | | 8.38 | 5.96 | 3.62 | 2.49 | 1.84 | 1.24 | .67 | .27 | .07 | | | | |
| $IG(p)$ | | | | | −1.63 | 2.89 | 3.24 | 2.22 | 1.06 | .23 | −.16 | −.23 | −.16 | | | | |

$$F(p)=\int_0^\infty \exp[-ipx^{\frac{2}{3}}]\frac{dx}{x^{\frac{1}{3}}}\left[\frac{I_{-1/3}(x)-I_{1/3}(x)}{I_{-1/3}(x)+e^{i\pi/3}I_{1/3}(x)}\right]$$

$$+\int_0^\infty \exp\{[(-3^{\frac{1}{2}}/2)+(i/2)]px^{\frac{2}{3}}\}\frac{dx}{x^{\frac{1}{3}}}\left[\frac{I_{-1/3}(x)-I_{1/3}(x)}{I_{-1/3}(x)+e^{-i\pi/3}I_{1/3}(x)}\right]. \quad (68)$$

In deriving (67) we have neglected the contribution from the $v^{4/3}$ and $w^{4/3}$ terms in the exponents of the *second* and *third* terms in the integrand of (64). This is justified if the principal contribution to $F(p)$ arises from a small range in $x$ near the origin, or if $s\ll 1$. In any case, the error involved can be estimated by using instead of $F(p)$ in (67) the quantity $[F(p)+is(d^2F/dp^2)]$. If $s(d^2F/dp^2)$ is small, it can be added to $F(p)$ to improve the accuracy; if it is not small, (67) cannot be relied upon.

Values of $F(p)$ at intervals of 0.5 obtained from (68) are shown[10] in Table IV. From the second differences, approximate values of $d^2F/dp^2$ were obtained, and are plotted in Fig. 3.

The integral in (67) can be expressed in terms of the tabulated Fresnel[11] integrals, as follows:

$$(2/\pi^{\frac{1}{2}})(e^{i\pi/4})\int_0^\infty \exp[-i(2\tau^{\frac{1}{2}}t+t^2)]dt=e^{i\tau}\{1-(1+i)[C(\tau)-iS(\tau)]\},\quad \tau^{\frac{1}{2}}>0,$$

$$=e^{i\tau}\{1+(1+i)[C(\tau)-iS(\tau)]\},\quad \tau^{\frac{1}{2}}<0, \quad (69)$$

where $\tau^{\frac{1}{2}}[=(x-\bar{x})/\Omega]$ is positive for $r>\bar{r}$, and negative for $r<\bar{r}$. For large positive $p$ (in the shadow zone)

$$F(p)\rightarrow(3/2p)e^{-i\pi/6},\quad \int_0^\infty \exp[-i(2\tau^{\frac{1}{2}}t+t^2)]dt\rightarrow -i/2\tau^{\frac{1}{2}}, \quad (70)$$

and these leading terms just cancel each other in (67).

## 5. THE FIELD IN THE VICINITY OF THE HORIZON WHEN THE TRANSMITTER IS ON THE GROUND AND THE RECEIVER IS ELEVATED SEVERAL NATURAL UNITS OF HEIGHT ABOVE THE GROUND

When $h_1=0$, but $h>0$, we have $u_1=u_0$, and Eqs. (16), (15), and (20) yield

$$\Psi=[2e^{i\omega t}/(qk_0^2)^{\frac{1}{2}}]\int_0^\infty J_0(kr)kdku^{\frac{1}{2}}H_{1/3}^{(2)}(2u^{\frac{3}{2}}/3)/Q(k), \quad (71)$$

$$Q(k)\equiv[\beta u_0^{\frac{1}{2}}H_{1/3}^{(2)}(2u_0^{\frac{3}{2}}/3)-u_0H_{-2/3}^{(2)}(2u_0^{\frac{3}{2}}/3)]. \quad (72)$$

Proceeding now as in the previous section we obtain, in the case of strong absorption and a value of $z_2$ of several units,

$$\Psi\simeq\frac{2^{\frac{1}{2}}\exp[i\omega t+i\pi/4]}{(qk_0^2)^{\frac{1}{2}}(\pi r)^{\frac{1}{2}}}\int_{-i\infty}^\infty e^{-ikr}k^{\frac{1}{2}}dku^{\frac{1}{2}}H_{1/3}^{(2)}(2u^{\frac{3}{2}}/3)/Q(k), \quad (73)$$

---

[10] We are indebted to the Mathematical Tables Project for the use of their manuscript of Bessel functions of order ⅓.

[11] Jahnke-Emde, *Tables of Functions* (Dover Publications, New York, 1933), p. 35.

$$Q \simeq \beta u_0^{1/2} H_{1/3}^{(2)}(2u^{3/2}/3) = [(2/3^{1/2})\cdot(3v/2)^{1/3}]\cdot[iJ_{-1/3}(v)+e^{-i\pi/6}J_{1/3}(v)]\beta, \quad k<k_0,$$

$$= [(2/3^{1/2})\cdot(3w/2)^{1/3}]\cdot[iI_{-1/3}(w)-e^{-i\pi/6}I_{1/3}(w)]\beta, \quad k>k_0, \tag{74}$$

$$e^{-ikr}u^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3) \rightarrow (3/\pi^{1/2})u^{-1/4}\exp[i5\pi/12-ip_5(k)], \quad p_5(k)=kr+(2u^{3/2}/3), \tag{75}$$

$$p_5(k)=p_5(k_0)-pv^{2/3}+s'v^{4/3}+\cdots=p_5(k_0)+pw^{2/3}+s'w^{4/3}+\cdots, \quad s'=(3/2)^{4/3}/4z_2^{1/2}, \tag{76}$$

$$\Psi \simeq \frac{\exp\{i[\omega t-(\pi/3)-k_0r-(2z_2^{3/2}/3)]\}(3\lambda/2\pi a_e)^{1/3}}{\pi(r\bar{r})^{1/2}\gamma(\epsilon_1-1)^{1/2}}G(p), \tag{77}$$

$$G(p)=\int_0^\infty \frac{\exp[-ipw^{2/3}]dw}{w^{1/3}[I_{-1/3}(w)+e^{i\pi/3}I_{1/3}(w)]}+\int_0^\infty \frac{\exp[ipv^{2/3}]dv}{v^{1/3}[J_{-1/3}(v)-e^{i\pi/3}J_{1/3}(v)]}$$

$$=\int_0^\infty \frac{\exp[-ipx^{2/3}]dx}{x^{1/3}[I_{-1/3}(x)+e^{i\pi/3}I_{1/3}(x)]}+e^{i\pi/3}\int_0^\infty \frac{\exp\{[(-3^{1/2}/2)+(i/2)]px^{2/3}\}dx}{x^{1/3}[I_{-1/3}(x)+e^{-i\pi/3}I_{1/3}(x)]}. \tag{78}$$

As before, the contribution from the $s'$ terms in the exponents can be estimated by using instead of $G(p)$, $[G(p)+is'(d^2G/dp^2)]$.

Values of $G(p)$ are given in Table IV, and $|G(p)|$ is plotted in Fig. 4. Figure 3 gives approximate values of $d^2G/dp^2$, which may be used for the purpose of estimating the correction due to the $s'$ term.

## 6. THE FIELD WHEN BOTH TRANSMITTER AND RECEIVER ARE ON THE GROUND (SURFACE WAVE)

The expression for the potential is obtained in this case by putting $u=u_0$ in (72):

$$\Psi=[2e^{i\omega t}/(qk_0^2)^{1/3}]\int_0^\infty J_0(kr)kdku_0^{1/2}H_{1/3}^{(2)}(2u^{3/2}/3)/Q(k). \tag{79}$$

Making use of the identity

$$\frac{u_0^{1/2}H_{1/3}^{(2)}(2u_0^{3/2}/3)}{Q}=\frac{(qk_0^2)^{1/3}}{[(k_0^2-k^2)^{1/2}+\gamma(k_1^2-k^2)^{1/2}]}\cdot\{-i+[u_0H_{1/3}^{(2)}(2u^{3/2}/3)-iu_0H_{-2/3}^{(2)}(2u_0^{3/2}/3)]/Q\}, \tag{80}$$

we can write

$$\Psi=\phi+\psi, \quad \phi=-2ie^{i\omega t}\int_0^\infty \frac{J_0(kr)kdk}{[(k_0^2-k^2)^{1/2}+\gamma(k_1^2-k^2)^{1/2}]}, \tag{81}$$

$$\psi=2e^{i\omega t}\int_0^\infty \frac{J_0(kr)kdk[u_0H_{1/3}^{(2)}(2u_0^{3/2}/3)-iu_0H_{-2/3}^{(2)}(2u_0^{3/2}/3)]}{[(k_0^2-k^2)^{1/2}+\gamma(k_1^2-k^2)^{1/2}]Q(k)}. \tag{82}$$

Here $\phi$ is Sommerfeld's potential of the surface wave for a *flat* earth, as can be seen by putting $h_1=h=0$ in (28). $\psi$ is an *additive* potential which represents the effect of the curvature of the earth; it vanishes in the limit of an infinite radius.

Using the same methods as in the preceding two sections we obtain, for the case of strong absorption,

$$\Psi \simeq \frac{\exp[i(3\pi/4)-irk_0]q}{(2\pi rk_0)^{1/2}(\epsilon_1-1)\gamma^2}H(p'), \quad p'=(3/2)^{2/3}(r/L), \tag{83}$$

$$H(p')=\int_0^\infty \exp[-ip'x^{2/3}]\cdot[E(x)-iF(x)]dx+\int_0^\infty \exp\{p'[(-3^{1/2}/2)+(i/2)]x^{2/3}\}\cdot[E(x)+iF(x)]dx, \tag{84}$$

$$E(x)-iF(x)=\frac{e^{-i\pi/6}[I_{-2/3}(x)-I_{1/3}(x)]+i[I_{-1/3}(x)-I_{2/3}(x)]}{[I_{-1/3}(x)+e^{i\pi/3}I_{1/3}(x)]}. \tag{85}$$

In the microwave region we may use for $\phi$ the leading term in the asymptotic expansion

$$\phi \rightarrow -\frac{2i\exp[-ik_0r]}{\gamma^2(\epsilon_1-1)k_0r^2}\left[1+\frac{i(3\epsilon_1+2)}{k_0r}+\cdots\right], \tag{86}$$

which follows by partial integration of van d. Pol's integral for $\phi$.[12] Combining (83) with (86) we obtain for the surface wave in a spherical earth

$$\Psi \simeq \frac{\exp[-i(\pi/2)+ik_0r]}{\gamma^2(\epsilon_1-1)k_0r^2}g(p'), \quad g(p')=1-\frac{2e^{i\pi/4}}{3\pi^{\frac{1}{2}}}(p')^{\frac{3}{2}}H(p'). \tag{87}$$

The function $H(p')$ has been computed from (84), and $|g(p')|$ is shown by the dashed curve in Fig. 5, where it is compared with a corresponding function $G(\eta)$ ($\eta=0.521p'$) computed by van d. Pol and Bremmer,[13] who used the normal mode theory.

## 7. DISCUSSION OF RESULTS

In this section we shall apply our theory to several cases which have been computed exactly by van d. Pol and Bremmer,[1] using the normal mode theory. The theory developed here is best suited for computing the field on the horizon and its immediate proximity. It becomes increasingly inaccurate as one recedes either far into the lit zone or far into the shadow zone. In addition, we also restricted ourselves to the case of strong absorption through the assumption that the quantity $\beta$ given in (21), (22), and (60) is large compared with unity. In the case of an elevated transmitter or receiver we have also assumed that the elevation is several units of natural height ($z_1$ or $z_2 \gg 1$), and that the quantities $s$, or $s'$ defined in (66) and (76) are small. All these assumptions become valid as the wave-length is decreased.

Figures 6 and 7 show a comparison of our results with exact values obtained by van d. Pol and Bremmer for an elevated transmitter and receiver. The case of a grounded transmitter is

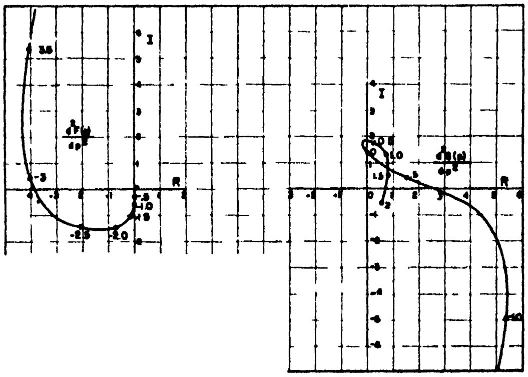

FIG. 3. Approximate values of $[d^2F(p)/dp^2]$ and $[d^2G(p)/dp^2]$. The numbers on the curves denote values of $p$.

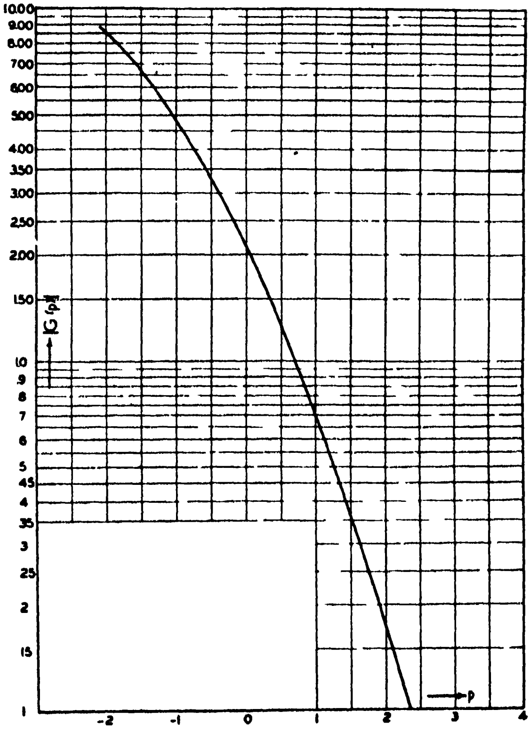

FIG. 4. The modulus of $G(p)$ defined in Eq. (78) and tabulated in Table IV.

[12] B. van d. Pol, Zeits. f. Hochfreqenztech. 37, 152 (1931).

[13] B. van d. Pol and H. Bremmer, Phil. Mag. 24, 173 (1937).

shown in Fig. 8. Some relevant quantities are tabulated in Table V, where the actual radius of the earth was used so as to conform to the calculations of van d. Pol and Bremmer. It is seen that in the cases treated the agreement near the horizon is sufficient for practical purposes for microwaves. Good agreement is also shown by Fig. 5 for the surface wave. Here our results do not go beyond those obtained by van d. Pol and Bremmer.

In a subsequent communication it will be shown that when the transmitter's height $z_1$ is small, equations (B) and (C) are to be multiplied by a factor $|(1+\beta z_1|$. When both $z_1$ and $z_2$ are small the potential $|\Psi|$ in (D) is to be multiplied by $|(1+\beta z_1)(1+\beta z_2)|$. Burrows and Gray[1] have computed a function $F(L)=(3^{\frac{1}{2}}/2\pi)\times|G[(8/9)^{\frac{1}{3}}p]|$, using the normal mode theory. These authors also give $F(L)$ for the case of a perfectly conducting earth.

## APPENDIX

## The Amplitude of the Reflected Wave

If we integrate the second term in (32) around the stationary point $k^*$ of $p_3(k)$ defined in (44) we obtain, in a manner similar to the derivation of (51), for the amplitude $\Psi_1'$ of the reflected wave

$$\Psi_1'=\frac{\exp[i\omega t-ip_3(k^*)]R(k^*)(qx)^{\frac{1}{2}}}{(rP)^{\frac{1}{2}}(1+qh_1-x^2)^{\frac{1}{4}}\cdot(1+qh_2-x^2)^{\frac{1}{4}}}. \tag{a}$$

$$\begin{aligned}P\equiv 2(1+qh_1-x^2)^{\frac{1}{2}}-[2x^2/(1+qh_1-x^2)^{\frac{1}{2}}]\\+2(1+qh_2-x^2)^{\frac{1}{2}}-[2x^2/(1+qh_2-x^2)^{\frac{1}{2}}]\\-4(1-x^2)^{\frac{1}{2}}+[4x^2/(1-x^2)^{\frac{1}{2}}];\quad x=k^*/k_0.\end{aligned} \tag{b}$$

Here $R(k)$, the reflection coefficient for a plane earth, is given in (26). In deriving it we used the asymptotic expression (25), which is valid only if $u_0$ is large. This is

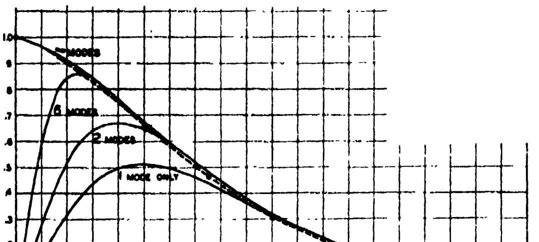

FIG. 5. Comparison of our results for the surface wave with those of van d. Pol and Bremmer (Phil. Mag. 24, 173, 1937). ------ $|g(p')|$, Eq. (87); ——— the corresponding function from normal mode theory using various modes.

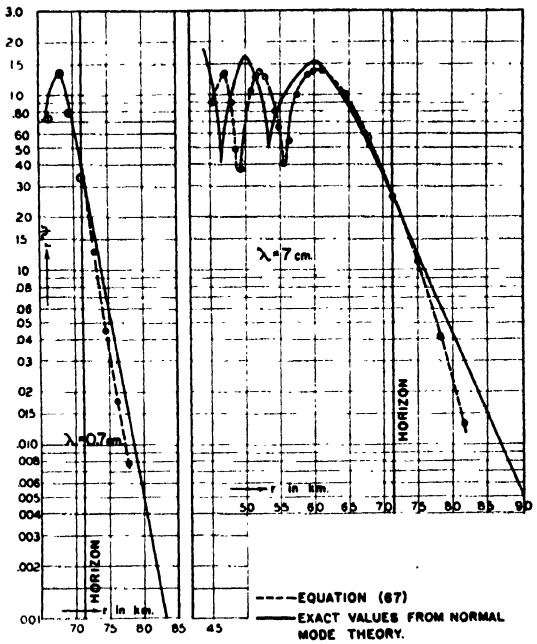

FIG. 6. Comparison of our results with those of van d. Pol and Bremmer.[2] Transmitter and receiver at a height of 100 m. $\epsilon=4$, $\sigma=10^{-13}$ e.m.u.

|---|---|---|---|---|
| 0.7 cm | 63 | .11 | .054 | 614 |
| 7 cm | 14 | .23 | .12 | 285 |
| 70 cm | 2.9 | .50 | .25 | 132 |
| 700 cm | .63 | 1.08 | .54 | 56 |

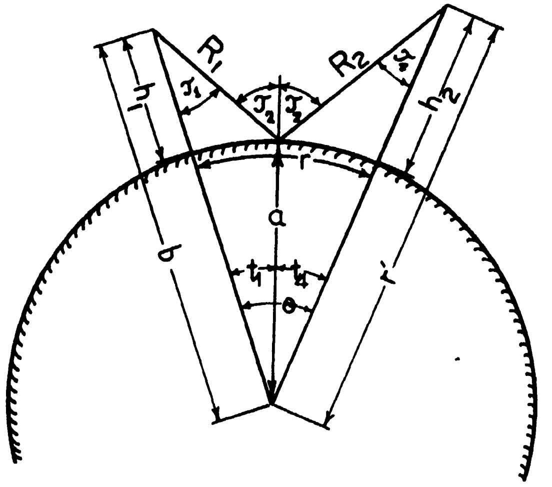

FIG. 9. The ray reflected from the surface of the earth

We shall now compare (a) with the expression for the reflected wave derived by van d. Pol and Bremmer,[15] and which includes the so-called divergence factor:

$$\Psi_1'=\frac{\exp[\imath\omega t-\imath p_3(k^*)]R(k^*)a(\sin\tau_2\cos\tau_2)^{\frac{1}{2}}}{[br'\sin\theta(R_1r'\cos\tau_4+R_2b\cos\tau_1)]^{\frac{1}{2}}},\tag{c}$$

where the quantities are defined in Fig. 9. We have, to within terms of the order $q^2h^2$,

$$\begin{gathered}1+qh_1=b^2/a^2;\quad 1+qh_2=r^2/a^2,\quad q=2/a,\\ (1+qh_1-x^2)^{\frac{1}{2}}=(b/a)\cos\tau_1,\quad (1+qh_2-x^2)^{\frac{1}{2}}=(r'/a)\cos\tau_4,\\ x=\sin\tau_2,\ R_1=b\cos\tau_1-a\cos\tau_2,\ R_2=r'\cos\tau_4-a\cos\tau_2,\end{gathered}\tag{d}$$

$$P=2(R_1\cos\tau_4\cos t_1+R_2\cos\tau_1\cos t_4)/(a\cos\tau_1\cos\tau_2\cos\tau_4).\tag{e}$$

Substituting in (a) we get

$$\Psi_1=\frac{\exp[\imath\omega t-\imath p_3(k^*)]a(\sin\tau_2\cos\tau_2)^{\frac{1}{2}}}{[br'r(R_1\cos\tau_4\cos t_1+R_2\cos\tau_1\cos t_4)]^{\frac{1}{2}}}.\tag{f}$$

Since $\sin\theta\simeq r/a$, and $\cos t_1$ and $\cos t_4$ are close to unity, expressions (c) and (f) agree within the region of validity of the earth-flattening approximation.

## Linearized Supersonic Flow through Ducts

H. F. Ludloff and F. Reiche
*College of Engineering, New York University, New York, New York*

April 22, 1947

In various aerodynamical problems, it is desirable to be able to compute the supersonic field of flow through ducted bodies by an analytic, approximate method, which yields quick insight into essential flow features as related to the shape of the nozzle wall. The linearized theory of supersonic flow suggests solutions that can be produced by spreading "supersonic sources" of various intensities over the surface of a hollow skeleton cylinder. If the source density is assumed constant over this surface, the wall contour of a converging diverging nozzle results. With a source intensity which increases linearly along the generatrices of the cylinder, one obtains ducts of gradually decreasing cross section. In the first case, one obtains a duct with a dull rim, and at the entrance a compression shock which has the shape of a double Mach cone, subtended over the rim as the base. This shock is weak near the rim, but becomes stronger toward the vertex and remains particularly strong over the whole surface of the second Mach cone. The linear source distribution produces a knife-sharp rim, as a consequence of which the shocks can be shown to disappear. A certain combination of these two source distributions hinders the formation of shocks, and produces a converging diverging nozzle, whose inside diameter increases at the exit section to the same magnitude as it had at the entrance section. In this way no wave drag results.

Derivation of these results is based on computing the velocity potential from which the velocity and stream function can be derived:

$$\varphi=-2d\cdot\int_0^{\omega^*}d\omega\int_0^{x-\beta R}d\xi\cdot\frac{f(\xi)}{[(x-\xi)^2-\beta^2R^2]^{\frac{1}{2}}}.$$

Here $f(\xi)$ is intensity of source layer at point with coordinates $\xi$ (along generatrix) and $\omega$ (azimuth) on surface of cylinder; $x-\xi$ and $R$, axial and radial components of pseudo-distance between source point and point under consideration. $R^2=d^2+r^2-2d\cdot r\cdot\cos\omega$; $d$ radius of cylinder, $r$ radial distance between axis and point under consideration.

$$\omega^*=\cos^{-1}\frac{d^2+r^2-x^2/\beta^2}{2d\cdot r};\quad \beta^2=M^2-1.$$

(I). For constant source density ($f(\xi)=A$), we get:

$$\varphi=-2d\cdot A\cdot\int_0^{\omega^*}d\omega\cdot\log\frac{\beta R/x}{1-[1-(\beta R/x)^2]^{\frac{1}{2}}}.\tag{1}$$

Differentiating and introducing $R^2=\rho$ instead $\omega$ as integration variable:

$$v_r=\frac{\partial\varphi}{\partial r}=\frac{xd\cdot A}{\beta r}\int_b^c\frac{d\rho}{\rho}\cdot\frac{(\rho-(a\cdot b)^{\frac{1}{2}})}{[(c-\rho)(a-\rho)(\rho-b)]^{\frac{1}{2}}},\tag{2}$$

where

$$a=(d+r)^2,\quad b=(d-r)^2,\quad c=x^2/\beta^2.$$

The expression for $v_r$ can be discussed.

(a) at $x/\beta=d-r$, i.e. at front cone, by expansion:

$$v_r=-\pi\cdot A\cdot\left(\frac{d}{r}\right)^{\frac{1}{2}}\left\{1-\frac{3d+r}{4d}\left[\frac{x/\beta-(d-r)}{2r}\right]\cdots\right\},\tag{2a}$$

which shows discontinuity, $-\pi\cdot A\cdot(d/r)^{\frac{1}{2}}$, of $v_r$ at front cone.

(b) at $x/\beta=d+r$, i.e. at second Mach cone, by forming:

$$\lim_{c\to a}v_r\sim\lim_{c\to a}\frac{xd\cdot A}{\beta r}\int_b^c\frac{d\rho}{\rho}$$
$$\times\frac{\rho-(a\cdot b)^{\frac{1}{2}}}{[(c-\rho)(a-\rho)(\rho-b)]^{\frac{1}{2}}}\to\log[(x/\beta)^2-(d+r)^2],\tag{2b}$$

which shows coalescence of singularities and logarithmic infinity of $v_r$, at second Mach cone.

(c) in the far rear region, by expanding after $\beta R/x$:

$$v_r=\frac{\pi\beta^2r\cdot d\cdot A}{x^2}\left\{1+\frac{3}{4}\frac{\beta^2}{x^2}(r^2+2d^2)\cdots\right\},\tag{2c}$$

which shows that disturbance velocity vanishes asymptotically.

The stream function can be obtained by means of Stokes three-dimensional representation:

$$\psi=-\rho_0\int_{(d-r)\cdot\beta}^{x}r\cdot\frac{\partial\varphi}{\partial r}\cdot dx'.\tag{3}$$

Upon inserting (2) into (3), we can discuss $\psi$, upon integrating (2a), (2b), and (2c) with respect to $x$. In this way one can see that $\psi$

(a) has no discontinuity at front cone, since it is proportional to $[x/\beta-(d-r)]$,

(b) is regular and finite at second Mach cone, since it is an integral over a logarithmic infinity,

(c) vanishes asymptotically as $1/x$.

The streamtubes are computed from the relation $U\cdot\rho_0\cdot(r^2/2)+\psi(x,r)=U\cdot\rho_0\cdot(d^2/2)$; they show a constriction between first and second Mach cone near the entrance, and at infinity an inside diameter of the same magnitude as at the entrance.

(II). For linearly increasing source distribution ($f(\xi)=\bar{A}\cdot\xi$), we get:

$$\varphi=2\bar{A}\cdot d\int_0^{\omega^*}d\omega\left\{-x\cdot\cosh^{-1}\frac{x}{\beta\cdot R}+(x^2-\beta^2\cdot R^2)^{\frac{1}{2}}\right\}\tag{1}$$

and

$$\frac{\partial\varphi}{\partial r}=v_r=\frac{\bar{A}\cdot\beta\cdot d}{r}\int_b^c\frac{d\rho}{\rho}\frac{(c-\rho)^{\frac{1}{2}}(\rho-(a\cdot b)^{\frac{1}{2}})}{[(a-\rho)(\rho-b)]^{\frac{1}{2}}}.\tag{2}$$

Therefore, (a) at $x/\beta=d-r$, i.e. at front cone:

$$v_r\sim\frac{x/\beta-(d-r)}{(d\cdot r)^{\frac{1}{2}}}\xrightarrow{\pi}0,\tag{2a}$$

which means that there is no discontinuity of $v_r$ at entrance, i.e. knife-edged rim.

(b) at $x/\beta=d+r$, i.e. at second Mach cone: $v_r$ remains finite; in (II), (2) $(c-\rho)^{\frac{1}{2}}$ appears now in numerator; therefore for $c\to a$ $(c-\rho)^{\frac{1}{2}}$ and $(a-\rho)^{\frac{1}{2}}$ cancel, rather than forming a cumulative singularity.

(c) at far rear, expansion after $\beta R/x$ yields:

$$v_r=-\frac{\bar{A}\pi\cdot\beta^2r\cdot d}{x}\left\{1+\frac{1}{4}\frac{\beta^2}{x^2}(r^2+2d^2)+\cdots\right\}.\tag{2c}$$

As before, the stream function is obtained by integration with regard to $x$, so that at far rear:

$$\psi=\rho_0\bar{A}\pi\beta^2r^2\cdot d\cdot[\log x+\cdots].\tag{3c}$$

Asymptotically, $\psi$ becomes logarithmic infinite; the cross section of the duct decreases as $(r/d)^2 \sim 1/(1+c\cdot\log x)$. For practical purposes, the flow remains parallel within a wide range of $x$, but a considerable wave drag results.

The advantages of both source distributions (absence of shocks; wide exit section) can be combined, by assuming linearly increasing source intensity $\bar{A}\cdot\xi$ from the rim to a distance $\xi=B$, from where a constant source intensity $\bar{A}\cdot B$ continues. Such a source combination can be resolved into a linear source distribution, starting at the rim, and a linear sink distribution, starting a distance $B$ behind. It is easy to see that the source layer produces a conical compression shock, while the sink layer starts a subsequent expansion wave of equal strength, so that no strong shock will develop anywhere and no wave drag result.

# Rigorous Solution of Linearized Supersonic Flow Through Ducts

C. E. Mack, Jr., *Grumman Aircraft Engineering Corporation*
AND
H. F. Ludloff and F. Reiche, *College of Engineering, New York University, New York*

April 22, 1947

In the case of constant source strength along a skeleton cylinder, a rigorous solution of the linearized problem of flow through ducted bodies may be obtained in closed form. The method of approach is such that complete elliptic integrals of the first, second, and third kind arise; however, complete integrals of the third kind may be expressed in terms of elliptic integrals of the first and second kinds so that existing tables suffice for numerical computation.

As in the case of the series expansions, the solution assumes different forms depending upon the location of the test point $P(x, r)$. If $P$ is so located that its fore cone cuts some but not all of the generatrices of the skeleton cylinder, then $P$ is said to lie in the front district. If the fore cone of $P$ cuts all the generatrices of the skeleton cylinder, then $P$ lies in the rear district. Each region will be considered separately.

### FRONT DISTRICT $\beta(d-r)<x<\beta(d+r)$

If the value of $v_r$ as given by Eq. (I, 2) above is substituted into Eq. (I, 3) for the disturbed stream function, the latter is given by

$$\psi=-\frac{\rho_0 d\cdot A\beta}{2}\int_{c'=b}^{c'=c}dc'\int_{\rho=b}^{\rho=c'}\frac{d\rho}{\rho}\frac{(\rho-(ab)^{1/2})}{[(c'-\rho)(a-\rho)(\rho-b)]^{1/2}} \quad (1)$$

where the symbols have the same meaning as previously. This integral may best be handled by reversing the order of integration, *viz:*

$$\psi=-\frac{\rho_0 d\cdot A\beta}{2}\int_{\rho=b}^{\rho=c}\frac{d\rho(\rho-(ab)^{1/2})}{\rho((a-\rho)(\rho-b))^{1/2}}\int_{c'=\rho}^{c'=c}\frac{dc'}{(c'-\rho)^{1/2}}. \quad (2)$$

Carrying out the integration with respect to $dc'$,

$$\psi=-\rho_0 d\cdot A\beta\left[\int_{\rho=b}^{\rho=c}\frac{(c-\rho)^{1/2}d\rho}{((a-\rho)(\rho-b))^{1/2}}\right.$$
$$\left.-(ab)^{1/2}\int_{\rho=b}^{\rho=c}\frac{(c-\rho)^{1/2}d\rho}{\rho[(a-\rho)(\rho-b)]^{1/2}}\right]. \quad (3)$$

If now the substitution $\rho=b+(c-b)\sin^2\theta$ is made, then after a short reduction the value of $\psi$ is easily seen to be

$$\psi=-2\frac{\rho_0 d\cdot A\beta}{(a-b)^{1/2}}[(a-b)E_1(k)-(a-c-(ab)^{1/2})F_1(k)$$
$$-c(a/b)^{1/2}\Pi_1(n,k)], \quad (4)$$

where $F_1$, $E_1$, and $\Pi_1$ are complete elliptic integrals of the first, second, and third kinds, the parameters $k$ and $n$ being given by

$$k^2=(c-b)/(a-b),\quad 0\leq k<1;\quad n=(c-b)/b,\quad 0\leq n<\infty.$$

It has been shown by Cayley that the complete elliptic integral of the third kind may be written, in our notation, as

$$\left[\frac{(n+1)(n+k^2)}{n}\right]^{1/2}\Pi_1(n,k)=\frac{\pi}{2}+\left[\frac{n+k^2}{n(n+1)}\right]^{1/2}F_1(k)$$
$$+F_1(k)F(k',\theta)-F_1(k)E(k',\theta)-E_1(k)F(k',\theta), \quad (5)$$

where $F(k',\theta)$, $E(k',\theta)$ are incomplete elliptic integrals the parameters of which are

$$k'^2=1-k^2,\quad \cot^2\theta=n.$$

When the value of $\Pi_1$ from Eq. (5) is substituted into Eq. (4) and the dimensionless ratio $Y=(r/d)(0\leq Y<1)$ introduced, it follows at once that

$$\psi=-\rho_0 d^2\cdot A\beta\{4Y^{1/2}[E_1(k)-k'^2F_1(k)]$$
$$-[(1-Y)^2+4k^2Y]^{1/2}[\pi+2\{F_1(k)-E_1(k)\}F(k',\theta)$$
$$-2F_1(k)E(k',\theta)]\}. \quad (6)$$

The stream lines may be obtained from this by evaluating the right-hand side for a suitable range of parameters, combining the results with the stream function for the undisturbed stream and interpolating to find the curves along which the total $\psi$ is constant.

In a similar way to that used above and by the same substitution $\rho=b+(c-b)\sin^2\theta$ it is easy to find the velocity components $v_x=\partial\varphi/\partial x$ and $v_r=\partial\varphi/\partial r$. The results are

$$v_x=-\frac{4Ad}{\beta(a-b)^{1/2}}F_1(k), \quad (7)$$

$$v_r=\frac{2d\cdot A(c)^{1/2}}{r(a-b)^{1/2}}\left[F_1(k)-\left(\frac{a}{b}\right)^{1/2}\Pi_1(n,k)\right]. \quad (8)$$

The elliptic integral of the third kind may be removed as before.

### REAR DISTRICT $\beta(d+r)<x<\infty$

The determination of the disturbed stream function for the rear region is very similar to that of the front region, so only the final result need be stated. The value of $\psi$ is given by

$$\psi=-\rho_0 d^2\cdot A\beta\left\{\frac{4}{k}Y^{1/2}\left[E_1(k)-\frac{1-Y}{1+Y}k'^2F_1(k)\right]\right.$$
$$-\left[(1-Y)^2+\frac{4Y}{k^2}\right]^{1/2}[\pi+2\{F_1(k)-E_1(k)\}F(k',\theta)$$
$$\left.-2F_1(k)E(k',\theta)]-4Y^{1/2}+2(1+Y)\tan^{-1}\frac{2Y^{1/2}}{1-Y}\right\}, \quad (9)$$

where now the parameters $k$, $k'$, $\theta$ are different than for the front region. We have here

$$k^2=(a-b)/(c-b),\quad 0\leq k<1;\quad \cot^2\theta=(a-b)/b$$

and of course $k'^2 = 1 - k^2$. The velocity components are essentially the same as before and need not be reproduced.

Although the solution above is for the case of constant source strength, it may be shown that for polynomial source distributions, the stream lines may be obtained by repeated integration of the stream lines for the constant source. For example, the stream lines for a linear source distribution may be obtained by a single graphical or numerical integration from the constant source stream lines.

---

## The Mechanism of Cutting Fluid Action

MILTON C. SHAW
*Mechanical Engineering Department, Massachusetts Institute of Technology, Cambridge, Massachusetts*

April 23, 1947

IN a recent letter to the editor,[1] Mr. G. P. Brewington questioned the observation of Ernst and Merchant[2] concerning the lack of correlation between the efficiency of a metal cutting fluid and its physical properties. In support of his contention that some relationship does exist between the cutting ratio and the physical properties of the fluid, Mr. Brewington cites the fact that materials having certain end groups present in their chemical structure (such as $-SH$ or $-Cl$) give a high cutting ratio. It is not clear how this observation substantiates Mr. Brewington's point of view. While it is true that the nature of the end group present on a molecule has an influence on its tendency to become adsorbed on a metal surface, the possibility of the cutting fluid reacting chemically with the metal cut should not be overlooked.

Considerable experimental data have been collected in recent years which indicate that certain effective metal cutting fluids do act by reacting chemically with the metal during the cutting operation. These observations support a rather simple theory of cutting fluid action in which the fluid reacts chemically in the neighborhood of the tool point to form a low shear strength solid lubricant which, in turn, prevents metal-to-metal contact between chip and tool. This mechanism of cutting fluid operation has been described[3] as being a chemico-physical action inasmuch as the fluid first reacts to form chemical products which, in turn, prevent metal-to-metal contact by a physical separation of the surfaces.

The afore-mentioned correlation between chemical structure and cutting performance is, from the writer's point of view, evidence of the correctness of the chemico-physical mechanism of cutting fluid action. Direct chemical analysis has established the presence of solid chemical products of low shear strength on the surface of metal cut in the presence of effective cutting fluids. The fact that certain good cutting fluids are also effective when applied to the tool in their vapor form, the tool and work piece being maintained at a temperature in excess of the boiling point of the fluid, is further evidence of the importance of the chemical rather than physical nature of the fluid. Other observations such as the dependence of the effectiveness of a cutting fluid upon the nature of the metal cut and the fact that benzene is a poorer cutting fluid than air can be explained in terms of the chemical aspects of the problem.

Probably the strongest argument in favor of the chemico-physical theory of cutting fluid action is offered by the discovery that metal cutting processes may be used in the manufacture of chemical products. In this case the product is a chemical rather than a finished machine part. Certain conditions which are found to exist at the point of a cutting tool appear to have an important bearing upon the initiation of a chemical reaction. Three such conditions are:

1. high local pressure—a pressure which will approach the hardness of the metal cut;
2. high local temperature—a temperature which will locally approach the melting point of the metal cut;
3. a nascent highly reactive and highly stressed clean metal surface.

These three conditions may be used to advantage in many organo-metallic reactions particularly those reactions which are difficult to start. In such a case the work piece becomes the metal reactant while the cutting fluid takes the form of the liquid reactant. This method of carrying out a chemical reaction has been termed "mechanical activation."[4] While mechanical activation represents an example of cutting fluid action in which the chemical products formed at the interface between the chip and the tool are present on a macroscopic scale, and, indeed, in some instances represent the entire quantity of metal cut, it should be evident that this technique is in reality a limiting case of cutting fluid action.

The writer concurs in Mr. Brewington's belief that the normal primary monohydric alcohols derive their limited effectiveness as cutting fluids for aluminum from chemical action, and has previously published[5] some substantiating data.

The physical properties of a cutting fluid which control the rate and quantity of fluid which can find its way to the cutting point might well influence the over-all performance of a metal cutting fluid. There thus appear to be two distinct phases of the general problem. First, the physical properties of a useful fluid must be such as to insure sufficient mobility that a satisfactory quantity of fluid reach the cutting point. Second, after the fluid has reached the tool point it is necessary that its chemical nature be such as to enable it to react chemically with the metal cut to form a low shear strength solid lubricant. The required mobility of a cutting fluid will depend largely upon the cutting speed, becoming of negligible significance at very low speed. The afore-mentioned tests of Ernst and Merchant were carried out at a very low cutting speed (5.5 inches per minute) and hence no correlation between cutting efficiency and the physical properties of the cutting fluid should be expected. However, if high speed cutting data were to be examined with regard to the physical properties influencing the mobility of the fluid (viscosity and surface tension), some correlation might be found.

# New Books

## A Chronological History of Electrical Development

NATIONAL ELECTRICAL MANUFACTURERS ASSOCIATION, 155 East 44 Street, New York, 1946. 106 pp. Price $2.

This is an historical record of electricity and the devices and equipment created by the electrical manufacturing industry to utilize it; of a long line of men of science, their initiative, theories, research, experiments, and discoveries, and their contributions to the present age of electricity, electronics, and atomic energy. The book is designed as a reference work for editors, writers, commentators, libraries, and schools, as well as for industry.

While the book touches on such modern electrical applications as television, fluorescent and ultraviolet light, the giant turbo-generator, and the electron micro-analyzer for atomic research, its accent is on the early-day men of science and industry and the steps they took to make electrical living possible. Other contributing factors are recorded, among them electrical expositions and congresses, the birth of electrical publications, engineering and trade associations, societies, foundations, and institutes.

## Methods of Mathematical Physics

BY HAROLD JEFFREYS AND BERTHA SWIRLES JEFFREYS. Pp. 679+VII. Cambridge, at the University Press; The Macmillan Company, New York, 1947. Price $15.00.

As the authors state in their preface, this book is intended to provide an account of those parts of pure mathematics that are most frequently needed in physics. The manner in which they propose to carry out their treatment is revealed by a statement in the preface that careful analysis is more important in science than in pure mathematics, not less, and that the easiest way to make a statement reasonably plausible is to give a rigorous proof. It is this reviewer's feeling that that intention has been carried out in ample measure and in most adequate style.

Chapter 1 treats the real variable and includes such topics as the Bolzano-Weierstrass (without so naming it) and Heine-Borel theorems, Riemann and Stieltjes integrals, uniform continuity and uniform convergence, and infinite integrals. Chapters 2 and 3 deal with vectors and tensors, respectively, the treatment throughout bearing in mind the student of physics and emphasizing such topics as the strain and stress tensors, Euler's dynamical equations, parallax, and the motion of a top. Chapter 4 is on matrices and contains a treatment of quadratic and Hermitian forms, the Pauli spin matrices, the Eddington and Dirac 4×4 matrices, crystal structure, and electromagnetic theory. In Chapter 5, we find multiple integrals, including line and surface integrals, Green's and Stokes' theorems, flux and circulation. A careful analysis is made of the notions of area and of length. Potential theory is the content of Chapter 6. Poisson's and Laplace's equations, minimal theorems, the Rayleigh-Ritz method of numerical solution are treated in detail. Operational methods and physical applications of the operational method occupy Chapters 7 and 8, respectively. The applications deal with charging of a condenser, the seismograph, resonance, dissipative and gyroscopic systems, and radioactive disintegration. Chapter 9 (numerical methods) includes such topics as Lagrange's interpolation formula, divided differences, the central difference formula, formulas for the value of a definite integral, numerical solution of algebraic and differential equations. A note on graphical methods recommends that they be honored in the breach rather than in observance. They are best avoided entirely, the authors advise us. Chapter 10 treats the calculus of variations and leads up to the Hamilton equations, principle of least action, and Routh's modified Lagrangian function. Chapters 11, 12, and 13 deal with functions of a complex variable and their application to contour integration and conformal representation. The Joukowsky transformations are treated in detail. Fourier series are the subject matter of Chapter 14. Approximation by polynomials, as well as by trigonometric series, is discussed, also the Laplace transform. Chapter 15 is given over to the factorial and related functions. Our authors frown on the gamma-function as a matter of notation and prefer to label it the factorial function. Wallis's formula for the value of $\pi$ and Stirling's formula for the value of $\log Z!$ are derived. Chapter 16 is devoted to second-order linear differential equations. These are studied as regards ordinary and singular points and are solved in series and by complex integrals. Infinite determinants are touched on in this connection. Asymptotic expansions occupy Chapter 17, with application to such matters as wave velocity, dispersion of water waves, and refraction of a pulse. Potential waves and heat conduction, waves in one dimension and spherical symmetry, conduction of heat in one and three dimensions, and allied physical ideas are treated in Chapters 18, 19, and 20. The many important systems of coordinates are treated in detail. Bessel functions in Chapter 21 and applications of Bessel functions in Chapter 22 are a logical continuation of the subject matter in the three preceding chapters. In Chapter 23 are found the confluent hypergeometric function, its representation in series and by complex integrals, Whittaker's transformation, Hermite and Laguerre polynomials, and Schrödinger's equation for the hydrogen-like atom. Chapter 24 is given over to Legendre and associated functions and their application to potential theory. Chapter 25, on elliptic functions, closes the text.

Thirteen pages of notes follow, numbered according to the sections of the text to which they refer and designed to clarify or amplify such sections. For example, the Heine-Borel theorem, alluded to in Section 1.072 of the text, is proved in the corresponding section of the notes.

The appendix on notation, which completes the book, embodies recommendations on standardizing certain bits of notation—particularly those with regards to $\nu$ and $\varphi$—which, as is well known, have not been used with uniformity of meaning in the literature.

The legends posted below the chapter headings are often delightful and illuminating. To quote a few: "one by one, or all at once" (multiple integrals), "but all that moveth doth mutation love" (potential theory), "even Cambridge mathematicians deserve justice" (operational methods), "I have no satisfaction in formulas unless I feel their numerical magnitude" (numerical methods).

Each chapter is followed by a list of problems, in all—if the reviewer's count is correct—230, and culled, in a large measure, from the British collections such as the Mathematical Tripos.

A high degree of thoroughness, such as will satisfy the pure mathematician, with the entire work set in a frame of physical applications, which enliven and give meaning to the mathematics treated, make this book a welcome addition to the literature of mathematical physics.

## Photography by Infrared. Its Principles and Applications

BY WALTER CLARK. Second Edition. Pp. 472+xvii, Figs. 93, 21½×14 cm. John Wiley and Sons, Inc., New York, 1946.

The London air raids destroyed the printing plates for the first edition of this book, which was published in England in 1939. The author has taken full advantage of this opportunity to revise thoroughly and modernize the presentation. Included are not only many wartime developments both here and abroad, but also more fundamental advances such as the improvement of infra-red sensitizing dyes.

The result is a comprehensive and authoritative account of the subject, and one that will appeal particularly to the amateur photographer, to the scientific research worker, and to the technician interested in possible application of infra-red. The author states that some acquaintance with photographic practice is assumed, although a fair amount of space is devoted to ordinary photographic procedures, with only occasional reference to the modifications required for work in the infra-red.

This material, including a chapter on darkroom practice, one on the characteristics of films, and an appendix on developers, etc., was presumably included to enhance the value of the book as a laboratory guide. However, it also furnishes a good background for discussion of the problems peculiar to the infra-red, and the general reader with little experience in photography will appreciate the complete and logical way in which the subject as a whole is presented.

The introductory chapter is mostly historical, and the inclusion of direct quotations and illustrations from the early publications, both here and elsewhere in the book, is an attractive feature. Incidentally, it is unfortunate that the very first figure, depicting Newton's experiment on the dispersion of white light, is incorrectly drawn. The reviewer was pleasantly surprised to find due credit given to the physicists and astronomers who did the pioneer work in infra-red photography, because all too often this work has been overlooked. The second chapter contains a useful summary of the general practice of infra-red photography, with references to later chapters where the various matters are treated in more detail. This ingenious arrangement, while very suitable for the purpose in hand, leads to a considerable amount of repetition.

In keeping with the objective of discussing principles as well as applications, further chapters deal with the sensitometric characteristics of photographic materials, sensitization for the infra-red, indirect methods on infra-red photography, and sources of infra-red. These subjects are well presented, and embody a wealth of valuable information. The only criticism that might be made is the failure to distinguish clearly at the outset between the effects of the intensity of the light and of the exposure time. Thus "exposure" is used as abscissas for the characteristic curves without stating that it is the product of intensity and time, and the situation is not improved by giving the wrong units in the first place in which they appear. A very good discussion of the failure of the reciprocity law is given later, but the author has followed the almost universal tendency of writers in this field first to give the impression that the two variables are equivalent, and afterwards to correct this impression.

The remainder of the book is devoted to the various applications of infra-red photography, chief among which are differentiation of materials (textiles, printer's inks, paintings, documents), medicine, botany and paleontology, photo-micrography, landscape photography, forest and other surveys, special effects photography, photography in the dark, spectrographic and astronomical photography, and camouflage detection. Penetration of haze and fog is covered both from the theoretical and observational standpoints, and here the author rightly emphasizes that, contrary to the popular impression, infra-red has little advantage where the large particles of natural fogs are concerned. A final chapter deals with the optical properties of materials in the infra-red. It includes data on the transmission and reflection of common materials, on infra-red filters, and an especially valuable discussion of the infra-red focus of lenses.

Rarely does one find a book as well documented as this one. The bibliographies following each chapter frequently contain over one hundred titles, in many languages. Although a few of the latest developments, such as the concentrated arc and the interference filter, are not included, the coverage of the subject is remarkably complete. This, together with the abundance of valuable data and the many fine illustrations, should justify the prediction that the book will be the standard reference work in infra-red photography for some time to come.

## Introduction to Electron Optics. The Production, Propagation and Focusing of Electron Beams

BY V. E. COSSLETT. Pp. 272, Figs. 155, 16½×25 cm. The Clarendon Press, Oxford, England. 1946.

*Introduction to Electron Optics* is primarily a textbook based on a series of lectures delivered by the author, at Oxford, as part of a course in electron optics. The book maintains a reasonably good balance between mathematical manipulation, physical ideas, and experimental results. The treatments of the various topics are not so long or detailed as to result in a ponderous book but still include sufficient material to serve as a good introduction to the general subject.

The subject matter is presented in the following order, with the first five topics taking up about two-thirds of the total space:

1. Electrostatic fields
2. Electrostatic focusing
3. Magnetic focusing
4. Aberrations
5. Production of electron beams
6. Cathode-ray tubes
7. Electron diffraction and electron microscopes
8. Miscellaneous application.

The mathematical treatments of lenses can be readily followed by students with training in mathematics through differential equations and vector analysis. The presentation is clear and no difficulty with the meanings or symbols should be encountered. (A list of mathematical symbols is appended.) The discussions are well illustrated by line drawings and graphs, as well as numerical data.

The book is intended for students of electron optics, although those doing research in this field will likely find it useful. Each chapter contains a list of references for further reading along the lines of the material of the particular chapter. The use of a general bibliography of a few carefully chosen references for each phase of the subject is to be commended.

The section dealing with electron diffraction is very brief as is that concerned with electron microscopy. In these two instances the reference might have been somewhat more extensive, but it is very likely that those who are interested in applied electron optics will have access to other sources. The emphasis is on fundamentals rather than design and use.

In the opinion of the reviewer, this book should serve exceedingly well as a basis for courses in electron optics in American universities.

## Relaxation Methods in Theoretical Physics

BY R. V. SOUTHWELL. Pp. 248. Figs. 117, 16×24½ cm. Oxford, at the Clarendon Press, Oxford, England, 1946.

The technique of solving numerically the Laplace equation in one dimension, by reduction to a difference equation and subsequent application of "relaxation" networks, has become a well-known procedure in advanced problems in engineering. Professor R. V. Southwell and his colleagues have contributed notably to this advance in applied mathematics. Their work has been summarized in exceedingly useful form in Professor Southwell's book, *Relaxation Methods in Engineering Science*, published in 1940. It is highly gratifying, therefore, to have at hand a companion volume which treats in a similar way the two-dimensional problems of mathematical physics.

The book under review, *Relaxation Methods in Theoretical Physics*, is devoted to the solution of the partial differential equation $\frac{\partial}{\partial x}\left[\chi\frac{\partial\psi}{\partial x}\right]+\frac{\partial}{\partial y}\left[\chi\frac{\partial\psi}{\partial y}\right]+Z=0$, where $\chi$ and $Z$ may be functions of $x$ and $y$, and $\psi(x, y)$ is the function sought, subject to prescribed boundary conditions. The arrangement of the book is excellent, and presents enough detail so that the interested reader may understand the background theory and carry through the computational techniques to a useful end.

Two chapters are devoted to the development of the approximating difference equations for the case $\chi=$ constant in a form for numerical solution and to the relaxation techniques for square, triangular, and hexagonal networks. Practical hints for the beginner are included. As pointed out by the author, one can gain a clear insight into the method only by doing the examples in detail.

Irregular networks applied to various boundary conditions are considered in Chapter III. Three types of boundary conditions are treated, *viz.*, (1) $\psi$ has a given value on the boundary, (2) $\partial\psi/\partial\nu$, the normal derivative of $\psi$, has specified values on the boundary, and (3), a combination of these two conditions. In many cases boundaries of complex shape may be reduced to circular or square boundaries by conformal transformation so that computation by simple nets is more readily effected.

Problems of more complexity, in which $\chi$ is a function of $x$ and $y$, are discussed in detail in Chapter V. While problems of this type are more difficult to solve by orthodox methods than those of the plane harmonic type ($\chi=$constant), they may be solved numerically with only slight modification in the relaxation technique.

The power of the relaxation method becomes fully apparent in its application to problems in which different equations govern the wanted function or in which some part of the boundary conditions must be determined by computation. Such problems are next to insoluble by orthodox methods. The last chapter of the book treats in detail physical problems of the above type.

An appendix contains formulae for numerical integration and differentiation, a bibliography of papers relating to relaxation methods, a list of the problems solved as examples in the text, and large charts illustrating the solutions. These include torsion problems, conformal transformations, oil pressure distributions in bearings, temperature distribution in a piston, percolation of liquids through walls or strata of various types, etc.

In conclusion one may mention that the basic aim of the numerical approach to physical problems, so admirably treated in this book, is to provide a flexible solution commensurate with the accuracy of the experimental data involved. The wide utility of the relaxation method should be made known to all serious students of physics and engineering who are concerned with more than a "handbook" solution to physical problems. In providing these two basic books, Professor Southwell has performed a major service for the advancement of mathematics in engineering.

## The Mathematical Tables Project

Sponsored by the National Bureau of Standards. Columbia University Press, New York.

In a recently published book, *An Index of Mathematical Tables*, three British authors have erected a monument to those scientists, who from 1596 on, have published the tables reviewed in the index, an estimated one thousand tables. While it is not possible to contemplate this vast array of published tables without experiencing a feeling of gratitude to the many computers whose work is represented, at the same time it is to be observed that the tables reviewed are published in a bewildering assortment of ways. Some are actually unavailable, and many are practically so. Some are to be found buried in periodical literature, and others constitute a few pages in scattered books. Some of the tables appear as isolated volumes, and still others appear in series of volumes.

The fact that the publications of the New York Project appear as a sequence of tables of similar size and binding, and are sold at nominal prices, makes the series of incalculable value to the modern scientist. As the volumes appear, the set becomes more and more the first source to be consulted when a mathematical table is wanted. The writer of this review looks forward to the day when any table of general usefulness will be found among these volumes.

The care that is exercised in the preparation of these tables, in order to prevent the printing of wrong values, can neither be briefly described nor readily appreciated by any but the professional computer.

The writer of this review regrets that the bound volumes of this table have not been imprinted with distinguishing numbers. In the back of each volume is placed a complete list of all of the volumes prepared prior to the date on which that volume was published. In this list each title bears a reference number. These numbers make better references to a particular volume than do the rather long and similar titles. It seems unfortunate that this number does not appear on the outside cover nor even on the title page. A complete list of titles follows in which those titles which have been recently received are starred.

(1) Table of the First Ten Powers of the Integers from 1 to 1000. 80 pp. (1939). Out of print.
(2) Tables of the Exponential Function $e^x$. XV+535 pp. (1939).
(3) Tables of Sines and Cosines for Radian Arguments. XIX+275 pp. (1940).
(4) Tables of Circular and Hyperbolic Sines and Cosines for Radian Arguments. XVII+405 pp. (1939).
(5) Tables of Sine, Cosine, and Exponential Integrals, Vol. I. XXVII+444 pp. (1940).
(6) Tables of Sine, Cosine, and Exponential Integrals, Vol. II. XXXVII+225 pp. (1940).

## Wave Propagation in Periodic Structures. Electric Filters and Crystal Lattices

BY LEON BRILLOUIN. Pp. 247, 5×8½ in. McGraw-Hill Book Company, Inc., New York, 1946. Price $4.00.

The rapidly increasing rate at which scientific knowledge is accumulating at the present time would appear to forecast an age of greater and greater specialization in the sciences. Such a state of affairs must undoubtedly be viewed with apprehension by many workers in these domains who have derived a great part of the pleasure in their work from the broadness of understanding with which scientific pursuits have supplied them in the past, and who believe that the interplay of ideas from various specialized fields of a subject such as physics is a healthy and stimulating influence on the development of the subject as a whole. That these fears are as yet ungrounded is demonstrated with force and clarity by Professor Brillouin in this small volume of less than 250 pages, wherein a surprisingly small body of mathematical discipline and associated physical ideas are shown to be quite adequate for the description of a wide range of seemingly diverse physical phenomena, running the gamut from mile long electrical transmission lines to the passage of electrons through crystal lattices.

As its title indicates, the book deals with the general aspects of wave propagation through periodic structures, and examples and applications are drawn from many fields in which such phenomena occur: electric and mechanical filters, vibrations of crystal lattices, x-ray diffraction in crystals, and the quantum theory of metals, to quote some leading examples. The characteristic appearance of transmission and attenuation bands for waves propagating in such periodic structures is demonstrated to have its important physical consequences in each of the above phenomena in such a way that one realizes that a comprehension of the phenomena in any one case almost automatically leads to the understanding of the principles involved in the others. The mathematical apparatus required to discuss adequately almost all of the problems which arise is of such simplicity as to require only the barest acquaintance with the calculus as background for understanding the development of the ideas presented.

This volume, unlike many books, is not intended as a reference work but as a key to understanding. No attempt is made to treat in detail the various phenomena selected as examples for the general ideas presented. These may be found in many other books. But there are few, if any, other books which demonstrate so directly the broader comprehension which can be obtained of these same physical phenomena when one steps back and examines them as a group linked by a common mathematical and physical background. It is in this respect that the true value of the book becomes immediately apparent.

Professor Brillouin is well known through his other books for the clarity of his exposition, and it is indeed fortunate that he has chosen to make available to others his thoughtful understanding of a subject to which he has been an outstanding contributor.

*University of California*

# New Booklets

North American Philips Company, Inc., 100 East 42 Street, New York 17, New York, has published a 6-page folder (R1063) entitled *Industrial Control with X-Ray Diffraction*. The text describes the principles of x-ray diffraction and how it is performing difficult jobs in modern industrial applications. Typical x-ray diffraction film is shown and explained. Geiger-counter x-ray spectrometer is discussed in connection with qualitative and quantitative analysis work.

North American Philips also announces a new 4-page folder describing the new Norelco air trimmer, which consists of a stator having three concentric cylinders that slide in the spaces between the four concentric rings of the rotor. Free on request.

New Enterprises, Inc., 84 State Street, Boston 9, Massachusetts, has issued a brochure setting forth its objectives and methods of operation. It was incorporated in February, 1946, "for the purpose of making venture capital more readily available for the development of untried business enterprises of a scientific nature. . . . To qualify for consideration, a new venture must be one of pronounced technical characteristics--a new process, a new or improved technique which shows promise of significant future possibilities."

Leeds and Northrup Company, 4902 Stenton Avenue, Philadelphia 44, Pennsylvania, issues quarterly a $10\frac{1}{2}\times15\frac{1}{2}$-inch bulletin containing numerous photographs and articles describing the use of Leeds and Northrup controls in industry. 8 pages.

Fischer and Porter Company, Department 6F-C, Hatboro, Pennsylvania, has published a new bulletin describing its "Flowrator" instruments for measuring flow rate of liquids and gases. 24 pages. Available on request.

*Bakelite Review* for April 1947 contains 28 pages of attractive pictures and articles about consumer goods molded of plastic material. Published quarterly by Bakelite Corporation, 30 East 42d Street, New York 17, New York.

The Tube Department of Radio Corporation of America, Harrison, New Jersey, has resumed issuance of *Application Notes*, which were popular before the war. The first postwar Note is called *Input Admittance of Receiving Tubes*. 20 pages.

Another new publication of the Tube Department is Form No. CRPS-102 entitled *RCA Phototubes, Cathode-Ray Tubes, and Special Tubes*. 16 pages, 10 cents per copy.

Public Affairs Committee, Inc., 22 East 38th Street, New York 16, New York, has published a 32-page pamphlet entitled *The Struggle for Atomic Control*. It was written by William T. R. Fox, Associate Professor of Political Science at Yale University. 20 cents per copy.

Corrosion Publishing Company, 1131 Wolfendale Street, Pittsburgh 12, Pennsylvania, is announcing a booklet of 94 pages entitled *Stress Corrosion Cracking of Mild Steel* by James T. Waber and Hugh J. McDonald. A monograph, it is in large part a reprint of a series of articles which appeared in *Corrosion and Material Protection*. It presents a general theory of stress corrosion and the importance of nitrogen was deduced from it. $2 per copy.

Farrand Optical Company, Inc., Bronx Boulevard and East 238th Street, New York 66, New York, has published *Bulletin 801* entitled *Ultra-Violet Monochromators*. Six instruments are pictured and described. 12 pages.

Burrell Technical Supply Company, 1942 Fifth Avenue, Pittsburgh 19, Pennsylvania, offers a 4-page leaflet describing its precision Mixblend laboratory mixer, *Baker's Analyzed* C. P. Potassium Iodide, Taylor slide comparators.

General Aniline and Film Corporation, 270 Park Avenue, New York 17, New York, has issued a new *Carbonyl Iron Powder* booklet. 34 pages. Available on request.

International Resistance Company, 401 North Broad Street, Philadelphia 8, Pennsylvania, announces its *Bulletin C-2*, which gives complete specifications, characteristics, and dimensions for IRC fixed and adjustable power wire wound resistors, ferrule, and bracket types. 6 pages. Available on request.

*The General Radio Experimenter* for March, 1947, published by General Radio Company, Cambridge, Massachusetts, features an article on search receivers for radar counter-measures. 8 pages. Available on request to engineers, scientists, and technicians writing on company or professional letterhead.

# Here and There

## Personnel

Charles C. Bidwell, head of the department of physics at Lehigh University, retired July 1 with the rank of Professor Emeritus.

Five new members have been appointed to the technical staff of the Midwest Research Institute, as follows: in inorganic chemistry, Solon D. Fisher; in organic chemistry, Kenneth R. Hoffman; in engineering mechanics, Eugene F. Hamilton, Richard H. Scheil, and Tage Mortensen.

J. Robert Oppenheimer of the University of California has been appointed to succeed Frank Aydelotte in October, 1947, as Director of the Institute for Advanced Study. Dr. Oppenheimer is a graduate of Harvard and received advanced training in Cambridge University and Göttingen, where he took his Ph.D. He has for the last decade been professor of theoretical physics both in the University of California and in the California Institute of Technology. He was director of the laboratory at Los Alamos which perfected the atomic bomb and is a member of various Government committees for the control of atomic energy.

The Institute for Advanced Study has three Schools: Mathematics, which includes mathematical physics; Economics, which includes history and political science; and Humanistic Studies, which consists at the moment largely of Greek archaeology and the history of art. The Institute provides facilities for postdoctorate research. The Doctor's degree is required for admission, and no degrees are given by the Institute itself.

The appointment of Professor Oppenheimer does not indicate any change in the policy of the Institute as regards the subjects which will be pursued. As it happens, Professor Oppenheimer is a scientist who had as an undergraduate a broad humanistic training.

Dr. Aydelotte emphasized very strongly his approval of this appointment. It would have been difficult to find in the United States a man more ideally qualified for the directorship.

The Institute has a strict rule of retirement at sixty-five. Dr. Aydelotte was kept on until sixty-seven by the trustees at the urgent request of the faculty. He will continue to occupy offices at the Institute for his work in connection with the Rhodes Scholarships, the Guggenheim Fellowships, and the American Friends Service Committee.

## U. S. Atomic Energy Commission Announces Distribution of "Heavy Water"

Heavy water and deuterium gas are now being made available by the United States Atomic Energy Committee for research purposes within the United States. The abundance of the heavy hydrogen isotope in the material is approximately 99.9 percent. Quantities will be limited to normal research requirements.

The Stuart Oxygen Company of San Francisco, California, will act as contracting agent for distribution. This company began small-scale production and distribution soon after the discovery of deuterium. In the postwar period, because of the increased need for deuterium in research the Stuart Company's production has been far below the demand. The quantities being made available are from stock produced by other operators during the war for the Manhattan District.

The material will be distributed with charges based on the cost of handling and distribution. The cost of production of the material itself will not be included. Distribution in this manner is being effected under authority of the Atomic Energy Act of 1946 which provides for the fostering and assistance of research by the Commission.

Allocation will be handled in a manner similar to that for radio-isotopes. For complete information write to U. S. Atomic Energy Commission, Research Division, Field Operations, Oak Ridge, Tennessee, attention Isotopes Branch.

## Special Expedition Studied Eclipse

A B-29 was used by the National Geographic Society-Army Air Forces cooperative expedition on May 20 in connection with the total eclipse of the sun in Brazil. The plane carried a heavy load of scientific instruments for making studies of cosmic rays in the vicinity of the equator.

Other tests performed by the cooperative expedition dealt with Einstein's theory of relativity, under the direction of Professor G. Van Biesbroeck, astronomer of the Yerkes Observatory of the University of Chicago. The principal objective was an effort to determine whether light rays from certain stars are bent as the rays pass near the sun on their way to the earth, as predicted by Einstein in his theory of relativity.

As a result of the influence of the gravitational field of the sun, light is bent, and star images registered on the photographic plates appear to be shifted away from the sun slightly beyond their actual positions. If this shift amounts to 1.75 seconds of arc, it will be additional evidence that Einstein's theory is correct.

As a check on how much the star images are moved on his photographic plates, Professor Van Biesbroeck will photograph the same stars at night six months later from the same spot. At that time the sun will not be present to bend their rays. Measuring the difference, if any, between the positions of the star images on the two photographs taken six months apart will show how much the light rays were bent during the eclipse.

## New Observatory at Colorado

The University of Colorado is collaborating with Harvard University on the creation of a new solar observatory devoted to the study of the region of space which lies between the sun and earth. The new station will be an expansion of the present High Altitude Observatory, where Dr. Walter O. Roberts carries on a study of the sun's outer regions with a coronagraph.

According to present plans, the heart of the new set-up will be a large tube, about six feet in diameter and twenty feet long, set in a dome. In the tube will be placed at least five observing instruments: a large coronagraph, a small coronagraph to provide automatic "tracking" on the sun, another large telescope devoted to observation of short-wave radiation, and two smaller ones to keep continuous moving picture records of routine sun conditions. In addition, other instruments will aid in the study of cosmic rays and paths of meteorites as a means of providing information about the outer reaches of the atmosphere.

### Polymer Research Clinics at Brooklyn

Two summer laboratory clinics remain in the series sponsored by the Institute of Polymer Research of the Polytechnic Institute of Brooklyn. From July 21 to 26 a clinic will be held on "Advanced X-Ray Diffraction". Attendance will be limited to about ten, and the fee is $100. Professor I. Fankuchen is in charge. The September 8–12 clinic is on the subject of "Polymerization Techniques". Attendance will be limited to twelve; fee is $150. Professor Herman Mark is in charge.

### Microwave Fellowships at Stanford

The Microwave Laboratory, Division of the Physics Department of Stanford University, has announced a number of fellowships, research assistantships, research associateships, and postdoctorate research fellowships for the academic year 1947–1948. Students who are working in the Microwave Laboratory may receive their degrees in either the Physics or Electrical Engineering Departments. Stipends for the four classes of awards range from $1000 to $4000. For further information and application address Professor William W. Hansen, Director, Microwave Laboratory, Stanford University, California.

### Matthew Luckiesh Awarded I.E.S. Medal

Matthew Luckiesh, director of the Lighting Research Laboratory, General Electric Company, has been awarded the I.E.S. Gold Medal, given annually by the Illuminating Engineering Society "for meritorious achievement which has conspicuously furthered the profession, art, and knowledge of illuminating engineering." The medal will be presented to Dr. Luckiesh at the Illuminating Engineering Society National Technical Conference to be held September 15–19 in New Orleans.

### Symposium on Applied Mathematics

A Symposium on Applied Mathematics will be held at Brown University, Providence, Rhode Island, August 2–4, 1947, under the sponsorship of the American Mathematical Society and the cosponsorship of the American Institute of Physics. The subject of the Symposium will be "Nonlinear Problems in the Mechanics of Continua." All persons interested in receiving further information concerning the Symposium should write to Professor W. Prager, Brown University, Providence 12, Rhode Island. Copies of the program and reservation cards will be sent to them three weeks before the Symposium.

## Calendar of Meetings

# Infinite-Rejection Filters

ALBERT M. STONE AND JAMES L. LAWSON
*Radiation Laboratory,* Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received May 20, 1946)

The characteristics of certain bridged-$T$ filter structures have been investigated theoretically and an experimental confirmation of this theory at u.h.f. has been obtained. In theory it is possible to obtain infinite attenuation at a designated frequency, while retaining essentially the same band width as that for the uncompensated filter. A model has been constructed which has a band width of $\frac{1}{2}$ Mc/sec. at 3000 Mc/sec. with an attenuation at center frequency of over 70 db. This is to be compared with the attenuation from a similar uncompensated filter of 20 db. Certain other known filter expressions have also been reduced to forms readily utilizable at these frequencies. Their utility for u.h.f. applications is discussed. The distortion produced in otherwise rectangular pulses of short duration has been investigated both theoretically and experimentally. Curves are presented which show the resultant wave form as a function of the tuning of the filter.

## I. INTRODUCTION

It has been known for some time that a parallel-resonant filter of the bridged-$T$ structure may be designed for complete (i.e., infinite) rejection of the frequency to which it is tuned. This infinite rejection is obtained regardless of the finite $Q$ of the coils and condensers of the filter and is limited solely by one's skill in adjusting a single resistive element.[1] At the same time as long as the ratio of unloaded[2] $Q$ to loaded $Q$ (*viz.*, line loading plus external resistance loading) is large compared with unity, the band width, measured between the points where the power transmitted is 3 db below the off-resonance value, is virtually indistinguishable from that of the normal (i.e., finite rejection) filter consisting of the tuned circuit alone. The principal object of this article is to present these results in readily usable form for u.h.f. work and to point out some salient features hitherto unstressed.

The applications of infinite-rejection filters are as varied as ingenuity affords. The particular problem which prompted the present analysis was that of eliminating an interfering *c-w* (or low-frequency modulated) carrier without, at the same time, destroying the usefulness of a pulsed 10-cm radar system. The analysis, therefore, is divided into two parts: (1) an investigation of the criteria for infinite rejection at microwave frequencies, and (2) an investigation of the distortion produced in rectangular pulses by such filters.

---

[2] The $Q$ of a bandpass circuit will be defined as the ratio of the center frequency to the band width. For a simple circuit such as the single-tuned type, $Q = L\omega_0/r$, where $r$ is the series resistance, $L$ the inductance, and $\omega_0$ the resonant radian frequency.

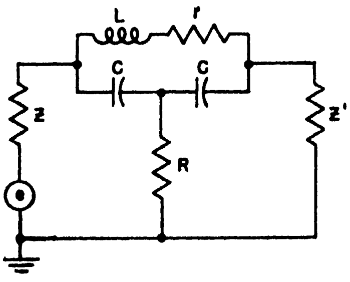

FIG. 1. Schematic diagram of an infinite-rejection filter with tap between condensers.

The essential modification of the ordinary filter consists of a tap from the center of the coil or condenser arm to ground (see Fig. 1) through a resistance $R$. (There may be reactance in this arm as well; it has been disregarded, however, as it merely complicates matters and leads to nothing fundamentally new.) It will be shown in Section II that a proper choice of $R$ (see Fig. 1) can be made so that *no* power is passed from the generator to the load at the resonant frequency. In fact the resistance required is $R=(rQ_0^2)/4$, where $Q_0$ is the unloaded $Q$ of the circuit, defined as $L\omega_0/r$, $\omega_0$ is the resonant radian frequency, and the other symbols have conventional meanings. It is immaterial whether the coil or the condenser is center-tapped. However, if the circuit is considered to be an $L$, $R''$, $C$ all in parallel, a center tap on the resistance $R''$ brought to ground through $R$ will not achieve the desired result. Physically this must be so, for at resonance the parallel $L$, $R''$, $C$ circuit is merely $R''$. A circuit of this type obviously cannot attenuate completely (see Fig. 2).

In the third section an alternative method of accomplishing this same result will be presented which, however, can be shown to be precisely equivalent to the methods mentioned above. The application of these results to *i-f* and video frequencies will appear obvious. Several possible methods for obtaining infinite-rejection u.h.f. filters will be discussed in this section and some experimentally obtained results will be presented.

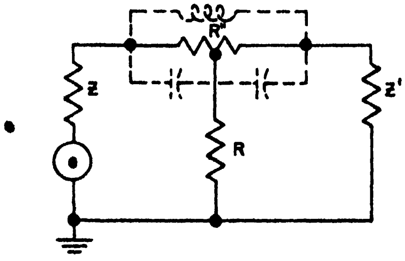

FIG. 2. Modification of Fig. 1 not leading to infinite rejection.

Finally, in Section IV the results of an analysis of the pulse distortion produced by such a filter will be presented.

## II. CIRCUIT ANALYSIS

The circuit of Fig. 1 is in the form of a bridged-$T$ section with the capacitance tapped and hence can be developed by the usual methods of circuit analysis[3] into the symmetrical-lattice form, Fig. 3. This lattice is precisely equivalent to the bridged-$T$, having the same poles and zeros and the same frequency behavior. For simplicity the generator and its internal impedance (or the line impedance if we consider the generator matched to the line) and the load have been split off. The dotted lines signify repetition of the corresponding elements. It is not difficult to see that the symmetrical lattice is nothing more nor less than the usual four-arm bridge, as shown in Fig. 4, where $Z_a$ is the series element and $Z_b$ is the shunt element of the lattice. Now from this it is easy to picture physically why the circuit of Fig. 1 gives infinite rejection. To balance the bridge one tunes the resonant circuit as is customary, and then, by adjusting $R$, a condition of zero load current is obtained. In such a state the power that would normally pass on to the load is absorbed in the added resistance. This condition of balance is, obviously, the one that makes $Z_b=Z_a$. It is unnecessary to carry this calculation out in detail. The result may be

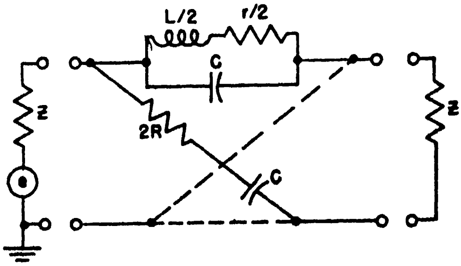

FIG. 3. Lattice development of infinite-rejection filter.

---

[3] E. A. Guillemin, *Communication Networks* (John Wiley and Sons, New York, 1935), Vol. 2, Chap. IV.

stated; the bridge is balanced when

$$\omega_0^2 = 2/LC, \tag{1}$$

and, simultaneously,

$$R = (rQ_0^2)/4. \tag{2}$$

Equation (1) states that the tuning of the circuit is independent of the added shunt element (but this is only true if it is non-reactive). Equation (2) gives the added condition that increases the maximum attenuation in the resonance curve indefinitely. It is clear that, for the ordinary values of $Q_0$ met in high frequency and u.h.f. work, $R$ is easily realizable physically. If the two capacitances in Fig. 1 are unequal, the same conditions (1) and (2) hold, but $C/2$ is now the series sum of the two.

The case of the tapped coil leads to results which are expressed precisely by Eq. (1) and Eq. (2). (Compare Fig. 5 and Fig. 1.) The symmetrical-lattice development of the tapped-coil circuit is shown in Fig. 6. If the two half-coils are identical, the value of $L$ to be used in Eq. (1) is

$$L = 2L_1 + 2kL_1, \tag{3}$$

where $L_1$ is the self-inductance of the half-coil, and $k$ is the coefficient of coupling. (This choice of identical coils is not an essential restriction but leads to facility in computation.)

It is desirable for ease of discussion, once the criterion for infinite rejection has been established, to compute the actual output power passed by the filter as a function of frequency; or, rather, to compute the dimensionless fraction, the output power divided by the output power in the absence of the filter. The latter output power is simply $e^2/4Z$, if it is assumed that load and line are matched and that $e$ represents the generator voltage. It is sufficient to consider only the circuit of Fig. 1. Let $i_L$ be the output current. We form the dimensionless quantity $F$ by

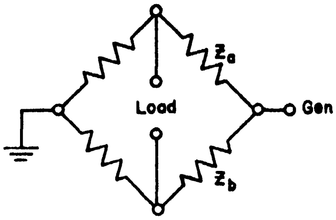

Fig. 4. Circuit equivalent to Fig. 3.

$$F = \frac{4|i_L|^2 Z^2}{e^2}. \tag{4}$$

We are not interested in any phase factor since the output of the filter usually is applied to the grid of a tube. The following definition is introduced:

$$\omega/\omega_0 \equiv m = \frac{\omega(LC)^{\frac{1}{2}}}{2}.$$

Then, with the previous definition of $Q_0$ and the balance condition, Eq. (2), one arrives at

$$F = \frac{4Z^2R^2[m^2Q_0^2(m^2-1)^2 + (1-m^2)^2]}{(2R+Z)^2\left[mZQ_0(m^2-1) - \dfrac{4mR}{Q_0}\right]^2 + \left[2RZ + \dfrac{4R^2}{Q_0^2} - m^2(Z^2+6RZ+4R^2)\right]^2}. \tag{5}$$

In simplifying this expression it is convenient to introduce the further definition

$$R \equiv \beta Z/4. \tag{6}$$

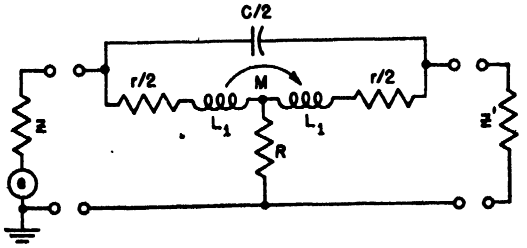

Fig. 5. Infinite-rejection filter with tapped coil.

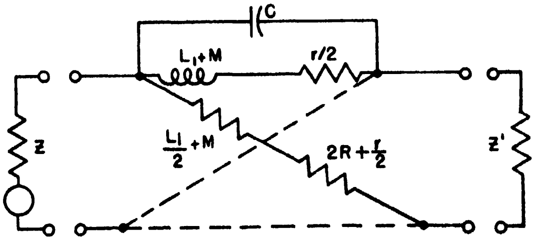

Fig. 6. Lattice development of Fig. 5.

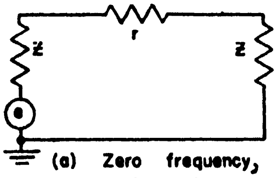
Thus $\beta$ is the *standing-wave ratio at resonance looking toward the unbalanced filter terminating* *the line.*[4] (In this connection use is made of the fact that, for a reasonably high-$Q$ filter, $L\omega_0/r = R'/L\omega_0$, where $R'$ is the equivalent shunt resistance.) If terms in $1/Q^4$ and higher powers in the denominator of Eq. (5) are neglected, that equation can be written

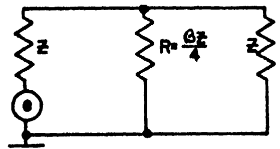
$$F \cong \left[\frac{\beta}{\beta+2}\right]^2 \left[\frac{m^2(1-m^2)^2}{m^2(1-m^2)^2+\left(\frac{\beta+2}{2Q_0}\right)^2}\right]. \quad (7)$$

For most practical purposes $m=1$ very closely. Hence Eq. (7) becomes

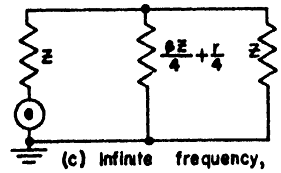
$$F \cong \left[\frac{\beta}{\beta+2}\right]^2 \frac{(1-m^2)^2}{(1-m^2)^2+\left[\frac{\beta+2}{2Q_0}\right]^2}. \quad (8)$$



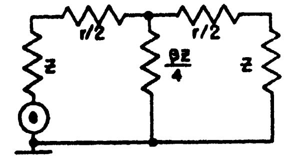
(a) Zero frequency, tapped condenser



(b) Infinite frequency, tapped condenser



(c) Infinite frequency, tapped coil



(d) Zero frequency, tapped coil

FIG. 7. Limiting cases of Figs. 1 and 5.

In the region far from resonance, the limiting value of $F$, from Eq. (5), is

$$F_\infty = \left[\frac{\beta}{\beta+2}\right]^2 \quad (9)$$

for high frequencies; and

$$F_0 = 1 \quad (10)$$

at low frequencies. The curve is symmetrical if $\beta \gg 2$ and $r \ll Z$, a condition which is usually realized in practice. (The value of $\beta$ is often of the order of 10, $Q_0$ is often several hundred, and $Z/r$ is often 2000 or more.) These limiting cases can be seen from simple reasoning. At zero frequency, the circuit of Fig. 1 becomes that of Fig. 7a. Here it is clear that

$$F = \frac{1}{\left(1+\frac{r}{2Z}\right)^2} \cong 1.$$

For very high frequencies, the circuit of Fig. 1 is similar to that of Fig. 7b, and it is again obvious that

$$F = \left[\frac{\beta}{\beta+2}\right]^2$$

as found above.

If, as in Fig. 5, the inductance is center-tapped to ground, the behavior is slightly different except near resonance. For very high frequencies, the circuit equivalent to Fig. 5 is that of Fig. 7c and

$$F_\infty = \left[\frac{\beta}{\beta+2}\right]^2.$$

For low frequencies, the circuit is that of Fig. 7d and likewise

$$F_0 = \left[\frac{\beta}{\beta+2}\right]^2.$$

Thus there is a slight difference in the low and high frequency behavior of the two cases, i.e., tapped coil or condenser, which disappears when $\beta$ is large. (This difference is more apparent than real, for it arises solely because all the losses have been considered to be connected with the coil and none with the condenser.)

---

[4] The standing-wave ratio is the ratio of the sum of the incident and reflected wave peak amplitudes to their difference.

It is interesting to compare the expression (8) for $F$ with that for the *unbalanced* network ($R$ infinite). Details will be omitted. The result is, with $\beta$ preserving the previously assigned meaning and value,

$$F' = \frac{4[Q_0^2(1-m^2)^2+m^2]}{4Q_0^2(1-m^2)^2+m^2(\beta+2)^2}. \qquad (11)$$

Equation (8) reduces to Eq. (11) in the limit of large $\beta$ as it must, i.e., when the equivalent shunt resistance of the resonant circuit is very large. However, $F'$ approaches unity at both very high and very low frequencies and thus is symmetrical about $m=1$.

The band width of the infinite-rejection, or balanced, filter may be defined as the difference in the two frequencies where $F$ has half its value at infinite frequency. From Eq. (8) this requires that

$$\frac{(1-m^2)^2}{(1-m^2)^2+\left[\dfrac{\beta+2}{2Q_0}\right]^2} = \tfrac{1}{2}. \qquad (12)$$

The term $(1-m^2)$ can be replaced closely by $2\delta m$, where $\delta m$ is the shift of frequency from the ($m=1$)-value. Thus Eq. (12) becomes

$$\delta m = \pm(\beta+2)/4Q_0,$$

and the band width at the half-power, or 3-db-down, point is thus

$$B = \frac{\beta+2}{2Q_0} f_0 \text{ cycles/sec.}, \qquad (13)$$

where $B$ is the band width and $\omega_0 = 2\pi f_0$.

For the unbalanced filter in this notation the band width is given simply by

$$B' = \frac{[(\beta+2)^2-8]^{\frac{1}{2}}}{2Q_0} f_0 \text{ cycles/sec.} \qquad (14)$$

and hence reduces to Eq. (13) for large values of $\beta$. A sketch of the antiresonance behavior of the balanced and unbalanced filter is given in Fig. 8. In this figure the minimum in the unbalanced filter curve is given by Eq. (11) while, of course, for the balanced case,

$$F_{\text{res}} = 0. \qquad (15)$$

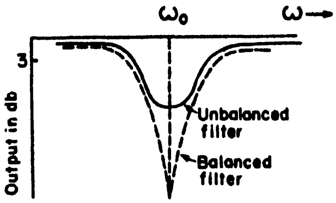


FIG. 8. Schematic behavior of antiresonance curve.

If one defines

$$\gamma \equiv Q_0/Q_L, \qquad (16)$$

where $Q_L$ is the loaded $Q$ of the circuit (because of line loading and external resistance loading) $\gamma$ can be related to $\beta$ by

$$\frac{\beta+2}{2} = \gamma. \qquad (17)$$

The value of the loaded $Q$ of the unbalanced filter at resonance may be seen almost from inspection of Fig. 9. The quantity $Q_0$ is defined as $Q_0 \equiv \beta Z/L\omega_0$; $Q_L$ is likewise defined as $R_1/L\omega_0$, where $R_1$ is the parallel resistance across the terminals of the inductance, i.e., $R_1 = 2\beta Z/(2+\beta)$. Hence:

$$\gamma \equiv Q_0/Q_L = (\beta+2)/2.$$

Now Eq. (11) may be rewritten at resonance as

$$F_{\text{res}}' = \left[\frac{2}{\beta+2}\right]^2 = \frac{1}{\gamma^2}, \qquad (18)$$

which can be easily visualized. The depth of the attenuation cut taken by the filter depends only on the ratio of loaded to unloaded $Q$, and hence principally on the coefficient of coupling of the line to the filter. In principle, infinite attenuation at resonance could be obtained with the unbalanced filter by enormous coupling to the line. However, in such a case, the band width likewise

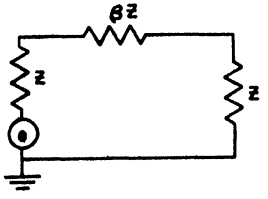

FIG. 9. Circuit for determining loaded $Q$.

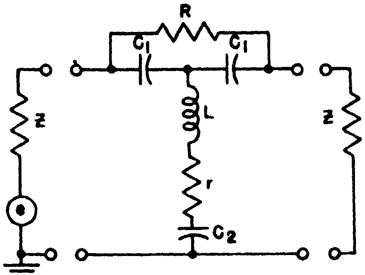

Fig. 10. Circuit equivalent to Fig. 5.

becomes enormous; for Eq. (14) may be written as

$$B' = \frac{f_0}{2Q_0}(\gamma^2 - 2)^{\frac{1}{2}} = \frac{f_0}{2Q_0}\left[\frac{1}{F_{res}'} - 2\right]^{\frac{1}{2}}, \qquad (19)$$

and as $F'$ decreases $B'$ increases.

In the case of the balanced circuit, while $F_{res} = 0$, the band width however is still finite as found above in Eq. (13); *viz.*, in this notation,

$$B = \gamma f_0/2Q_0 = \frac{f_0}{2Q_L}, \qquad (20)$$

and the attenuation at high frequencies, from Eq. (9), is

$$F_\infty = \left[\frac{\gamma - 1}{\gamma}\right]^2. \qquad (21)$$

It is interesting now to put in some figures for a possible u.h.f. application. Let the desired band width be ±0.5 Mc/sec. at 3000 Mc/sec. Thus $Q_L = 3000$. Let $Q_0 = 30{,}000$, and hence $\gamma = 10$. Then, in this case, according to Eq. (21),

$$F_\infty = 0.81,$$

which represents an insertion loss of about 1 db and, of course, $F_{res} = 0$. For the same filter unbalanced,

$$F_{res}' = 0.01,$$

and the band width would be ±0.5 Mc/sec. within 1 percent for both filters.

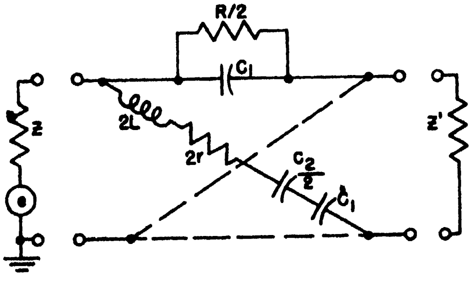

Fig. 11. Lattice development of Fig. 10.

The circuits of Fig. 1 and of Fig. 5, discussed in some detail in this section, by no means exhaust the possibilities of single-section infinite-rejection filters. In fact they are merely prototypes: variants can be obtained by standard transformation theorems. For example, the circuit of Fig. 10 is potentially equivalent to that of Fig. 5. From the symmetrical-lattice development in Fig. 11, it can be shown, with some manipulation, that the condition for infinite rejection is that

$$\omega_0^2 = \omega_2^2 + \frac{r}{R}\omega_1^2, \qquad (22)$$

and

$$R/r = Q_0^2 n^2\left(\frac{n^2}{4} + m^2 - 1\right), \qquad (23)$$

where

$$Q_0 = \frac{L\omega_0}{r}, \quad \omega_2^2 = \frac{1}{LC_2}, \quad \omega_1^2 = \frac{2}{LC},$$

$$n = \frac{\omega_2}{\omega_0}, \quad n = \frac{\omega_1}{\omega_0}.$$

The extension to the case where the capacitances $C_1$ are not equal is readily accomplished but leads to nothing essentially new.[5]

---

[5] Some interesting asymmetry properties are present in this filter. For instance, the possible values of $R/r$ range from 4 to ∞; i.e., when $m = 0$ the value of 4 obtains, and when $m = 1$, $R/r \rightarrow \infty$ and $rn^2/R \rightarrow 0$. In the limiting case of small values of $n^2 (C_1 \gg C_2)$, Eqs. (22) and (23) lead to

$$\omega_0^2 \cong \omega_2^2, \qquad (a)$$

$$R = 4r. \qquad (b)$$

When $n^2$ becomes very large $(C_1 \ll C_2)$, the limiting value of the frequency, again is

$$\omega_0^2 \cong \omega_2^2, \qquad (c)$$

but now we have

$$R = rQ_0^2 n^4/2 \qquad (d)$$

and

$$\omega_1^2/\omega_0^2 \cong (R/r)^{\frac{1}{2}}/Q_0. \qquad (e)$$

(Cf. Eq. (d) and Eq. (2).) From Eqs. (d) and (c) it can be seen that the apparent pull of the resonant frequency from that of the shunt arm alone is somewhat illusory, despite Eq. (22). Thus one possible small advantage ensues. For a given value of $R$ infinite rejection may be obtained by varying $C_1$, and, hence, $n$. If the frequency pulling (which is small as noted) is not serious, this may be a convenient method.

For reference, we write the expression for the fraction of the unfiltered energy transmitted by this balanced filter as a function of frequency.

$$F'' \cong \frac{(f^2-1)^2 R/r}{\left[\frac{R}{4r} + \frac{R^2}{4}\right]\left[\frac{n^2(1+2r)^2}{4Rr} + \frac{4}{n^2}\left(f^2 - m^2 - \frac{n^2}{4}\right)^2\right]},$$

where $f = \omega/\omega_0$.

While the circuit of Fig. 10 may be better than that of Fig. 1 or Fig. 5 for some applications, it suffers from two defects: (1) six circuit elements are necessary *vs.* five in the former case, a defect of some importance in u.h.f. applications; (2) the frequency of infinite rejection only approximates the resonant frequency of the shunt resonant element, and each adjustment of $R$ requires readjustment of $\omega_0$. Furthermore, $R$ cannot be readily visualized or calculated in terms of standing-wave ratios.

Finally, it should be mentioned that, for tuning the balanced filter of Fig. 1 over a comparatively narrow range of frequencies, it is desirable to change both $L$ and $C$, although either one alone can be varied. The condition of balance, from Eq. (2), may be written as

$$R=\frac{\omega_0{}^2L^2}{4r}$$

and, if one eliminates $\omega_0{}^2$ by noting that near resonance $\omega_0L\cong 2/C\omega_0$,

$$R\cong L/2rC. \tag{24}$$

Since $r$ represents the losses in the tuned circuit, it is practically constant during the tuning, and hence the filter remains balanced with $R$ fixed if $L$ and $C$ are changed together in such a way that their ratio stays constant. If, however, $L$ alone is varied or $C$ alone is varied as the frequency is varied, say by $l$ percent or $c$ percent, respectively, for a 1 percent change in $\omega_0$, $R$ must be changed by $(2+l)$ percent or $(1+c)/2$ percent, respectively. Depending on the method and difficulty of changing $R$, we can attempt to tune in one of the three ways.

## III. APPLICATION TO u.h.f. FILTERS

In the previous section we found that a filter of unlimited attenuation could be realized practically, at least for cases where the circuit constants are lumped. The following question now arises: what modifications are necessary when one deals with corresponding distributed-parameter circuits, i.e., u.h.f. lines and u.h.f. resonant cavities? It turns out that this same analysis is applicable, for it is well known that a single-mode cavity resonator can be completely specified in terms of $Q$, $\omega_0$, and $R''$ and, likewise, a u.h.f. line has a definite input impedance (usually real). The cavity resonator can be shunted across the line, or placed in series with one side of the line. In the latter case we have exactly the unbalanced filter of Fig. 1 or Fig. 5 discussed above. The only remaining question is how we can arrange the analogue of $R$, for there is no obvious condenser or inductance to be center-tapped.

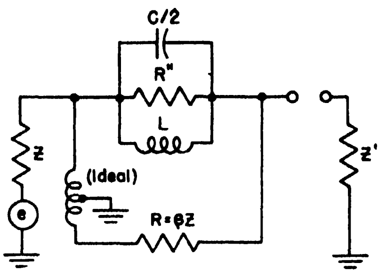

FIG. 12. Infinite-rejection filter in the form of a three-arm bridge.

Before proceeding to a discussion of the methods of realizing the balanced filter it is worth while to introduce still another circuit which can be shown to be precisely equivalent to the balanced filter.

Figure 12 shows essentially a three-arm bridge. Let us assume an ideal 1:1 (auto) transformer such that the impedances are infinite, and close coupled, so that the coefficient of coupling is unity. One is interested in the load current as a function of $R$ and $\omega$. This is given by

$$i_L=\frac{e\beta^2Z^2\left(1-\omega^2\dfrac{LC}{2}\right)}{Z(\beta+2)\left[2\beta Z^2\left(1-\omega^2\dfrac{LC}{2}\right)+j\omega LZ(\beta+2)\right]}, \tag{25}$$

where $i_L$ is the load current and all other symbols have their previous meanings and $R$ is taken

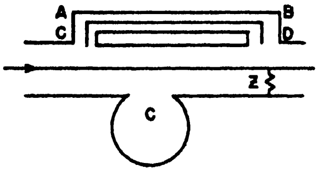

FIG. 13. u.h.f. realization of Fig. 12.

equal to $R''$, i.e., $\beta Z$. Again we form the fraction

$$F=\frac{4|i_L|^2Z^2}{e^2}$$

and find

$$F=\frac{4\beta^2(1-m^2)^2}{(\beta+2)^2\left[4(1-m^2)^2+\frac{(\beta+2)^2}{Q_0^2}m^2\right]}. \quad (26)$$

Remembering that $m^2$ is virtually unity, we note that Eq. (26) is identical with Eq. (8). Thus the attenuation for low frequencies is given by the ratio of $\beta$ to $(\beta+2)$, just as was found before. The band width to the 3-db-down points therefore must be exactly the same. Hence it may be concluded that the bridge circuit is precisely equivalent to the balanced-filter circuit, even to the necessary loss of resonance.

This suggests at once a simple method to obtain the balanced-filter behavior at u.h.f. Consider the circuit of Fig. 13; $C$ is a cavity which is equivalent to the lumped resonant circuit of Fig. 12. The power absorbed in the load $Z$ is made up of two parts: one part comes directly through $C$ to $Z$, the other through the branch line to $Z$. This latter suffers a 180° change of phase by making $\overline{AC}$ and $\overline{BD}$ each a quarter wave-length. Then the power through the branch path arrives at $D$ with phase reversed from that of the power arriving directly. The amount of power bypassed is controlled by the probes in the stub lines. This circuit, as a little thought will show, is the u.h.f. analog of Fig. 12 and hence should possess its advantages. One device of this type has been constructed and will be discussed below.

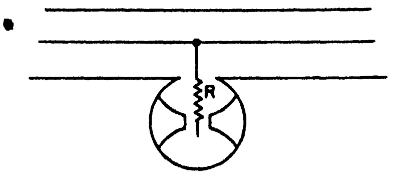

FIG. 14. u.h.f. analog of Fig. 1.

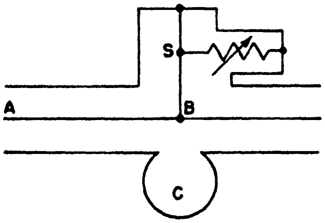

FIG. 15. Second u.h.f. analog of Fig. 1.

Another application of these ideas to a u.h.f. filter is suggested by Fig. 1. Can this circuit be carried directly over to ultra high frequencies? Suppose one had a cavity as in Fig. 14. It is quite clear intuitively that by symmetry if a probe is placed midway between the interior posts of the cavity and connected by a resistor to the center conductor, i.e., ground, it is the complete analog of Fig. 1. However, this procedure is difficult experimentally. Alternatively we might connect $R$ from ground, not to the center point between the posts, but to a point in the coupling window at the midpotential of the window. Thus we would be reasonably sure of obtaining again the analog of Fig. 5. Finally, we may incorporate this idea in a practical way as follows: $C$ again is the cavity (Fig. 15), and $A$ the center conductor of a coaxial line. This is stub-supported at the point $B$, symmetrically located with respect to the (symmetrical) cavity $C$. Now, if the stub center conductor $S$ could be made lossy, with a real resistance between $B$ and ground equal to $rQ_0^2/4$ (where $r$ is the equivalent series loss of the cavity and $Q_0$ is the unloaded $Q$ of the cavity), we would expect the balanced-filter results to apply. This can be achieved by coupling a real load to the stub cavity as shown. By adjusting

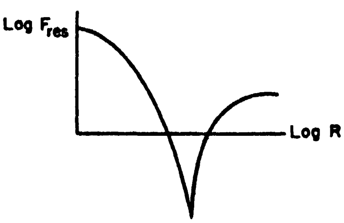

FIG. 16. Log$F_{res}$ vs. log$R$.

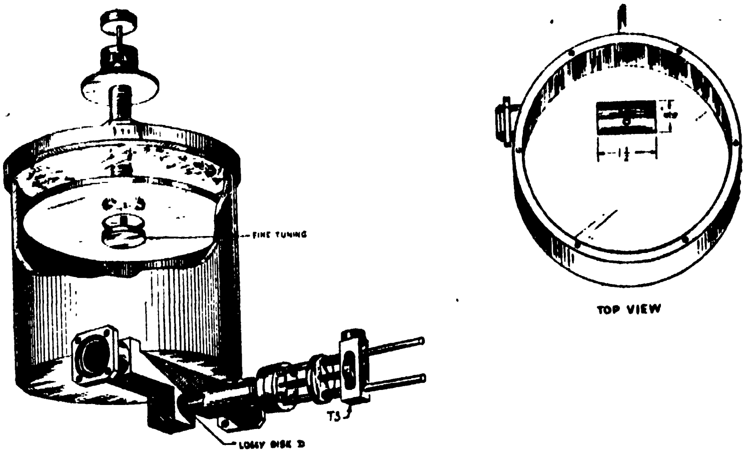
FIG. 17. Infinite-rejection filter.



the coupling, choosing the load properly, and placing it at the proper distance from the probe, any equivalent real value of impedance can be introduced into $S$, and the reactive part can effectively be absorbed in the cavity reactance. Thus, since $B$ is essentially at the midpoint of the effective voltage across the cavity $C$, we can balance the filter by this adjustment and by tuning $C$. It should also be noted that there should be no "frequency-pulling" (to the extent that the added reactance at $B$ is small) because the balanced filter and unbalanced filter have the same resonant frequency (see Fig. 8). Furthermore it is not essential that the voltage across the iris be completely symmetrical with respect to $B$. (Note discussion in first part of Section II.) A filter of this design has been constructed, and the data obtained from it will be presented below.[6]

A word should first be said, however, concerning how critical the tuning procedure can be. The sharpness of tuning as $\omega$ is varied can be seen from Fig. 8. In practice, however, this adjustment is usually not very difficult, for one may tune the cavity by stubs moving on fine threads in a region of weak field. The sharpness as $R$ is varied can be calculated. The result is

$$F_{\text{res}}=\frac{4\left(1-\dfrac{4R}{\beta}\right)^2}{\dfrac{16}{Q^2}(R+1)^2+\left[(2R+1)\left(2+\dfrac{4}{\beta}\right)\right]^2} \tag{27}$$

to the same degree of approximation as previously used.

It is noted that $F_{\text{res}}$ becomes zero, as it should, for $R=\beta/4$. A logarithmic plot of $F_{\text{res}}$ is given in Fig. 16. The adjustment of $R$ is thus seen to be critical and, experimentally, needs a little care. (For the curve drawn, $Q$ was assumed 3000 and $\beta=20$; then one can simplify further to obtain

$$F_{\text{res}}\cong\left[\frac{2\left(1-\dfrac{4R}{\beta}\right)}{[2R+1]\left[2+\dfrac{4}{\beta}\right]}\right]^2.)$$

For any particular cavity it is wise to choose the load and load position (or, failing this, to use the proper transformer) such that $R$ at $B$ is approximately the correct value to start with.

In order to retain full benefit of the infinite-rejection circuit, it is clear from Eq. (20) that the loaded $Q$ should be high, and thus for large values of $\beta$, the unloaded $Q$ must be very high. For a band width of 0.5 Mc/sec. at 3000 Mc/sec., a loaded $Q$ of 6000 is needed, and clearly a cavity operating in the $TE_{0,1,1}$ mode[7] is indicated in order to obtain the necessary $Q_0$ of 30,000 or more so as to have a small loss off resonance (see Eq. 21). Conveniently enough, an "echo box" can be modified for this use.[8]

---

[6] Acoustic applications of a filter of this type suggest themselves but will not be discussed here.

[7] See W. L. Barrow and W. W. Mieher, Proc. I.R.E. **28**, 184 (1940).

[8] The "echo box" is merely a high $Q$ cavity. The ratio of stored to dissipated energy is so high that, once excited, the echo box will "ring" for a considerable time.

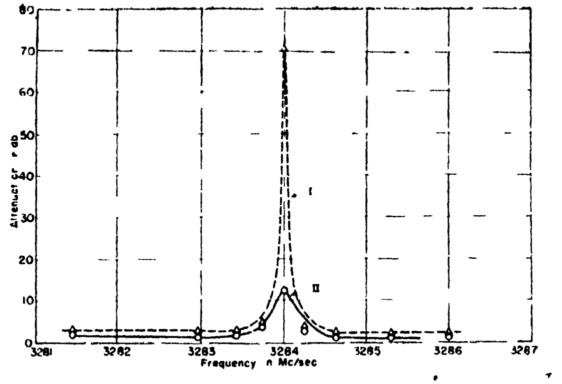


FIG. 18. Filter characteristics. Curve I, balanced filter; Curve II, unbalanced filter.

Although the tuning of the filter is exceedingly sharp for very high rejection ratios (cf. Figs. 8 and 16), and therefore the standard Radiation Laboratory echo box (1943) had to be eventually supplanted by a cavity of similar design but of $\frac{1}{4}$-in. steel plate for the sake of mechanical rigidity, the following results will be reported from a modified standard echo box. Figure 17 is a drawing of the cavity. The loss in the side stub is provided by the resistive disk $D$, whose resistance was adjusted by scraping to the (roughly) calculated value. Further adjustment was provided by the tuning stub $TS$ which, if $R_0$ is the value of the resistance, makes the real impedance at $B$ any value from 0 to $R_0$. Thus the resistance at $A$ can be adjusted to the proper value. (The inevitable reactance introduced can be simply absorbed in that of the cavity.) Iris coupling to the $TE_{0,1,1}$ mode requires the rather peculiar off-set shown. With the filter coupled between the generator and receiver (through a standing-wave detector) by considerable lossy line, curves of filter output *vs.* frequency were obtained. These are shown in Fig. 18. Curve I is for the filter adjusted for infinite rejection; Curve II is for $R$ considerably different from the correct value. It is seen that Curve II is the usual rejection-filter characteristic. Curve I is virtually identical with it at the half-power points and above, but increases the rejection ratio to very large values. The 70-db point was the last measured value and was limited by the receiver sensitivity. There is nothing to make one believe it could not be extended considerably further, although even at the 70-db point considerable difficulty is encountered merely in the frequency instability of the (klystron) signal generator. Table I summarizes the experimental measurements and compares them with the values computed from theory. It is clear that the agreement is satisfactory.

TABLE I. Comparison of theoretical and experimental results.

| Design characteristics | Modified echo box | | Cavity with center posts | | Probe-type filter | |
|---|---|---|---|---|---|---|
| $f_0$ in Mc/sec. | 3284 | | 3160 | | 3233 | |
| $\beta$ | 5.78 | | 16.8 | | 2.7 | |
| $B'$ in Mc/sec. | 0.5 | | 14.7 | | 1.04 | |
| | Exp. | Theor. | Exp. | Theor. | Exp. | Theor. |
| $\gamma$ | 4.2 | 4.63 | 10 | 9 4 | 3.6 | 2.35 |
| $B/B'$ | 1.02 | 1.05 | 1.14 | 1.01 | 1.15 | 1 21 |
| Insertion loss in db | 1.1 | 1.06 | 2 25* | 1 0 | 6.1** | 5 |
| $F_{\text{res}}/F_{\text{res}}'$ in db | 60 | ∞ | 35 | ∞ | 11 | ∞ |

* There was an asymmetry in the resonance curve due to imperfect matching between line and load. This partly accounts for this discrepancy.

** Averaged over asymmetry.

A word might be said of two preliminary constructions. To check the theory, a cavity of the type sketched in Fig. 14 was constructed as a balanced filter. Figure 19 describes it, and Table I gives the experimental and theoretical results obtained with it. For cases where extreme sharpness is not required this filter is easy to make, easy to adjust, and easy to operate.

Finally, the u.h.f. analog of Fig. 12 has likewise been constructed from a modified echo box. This is shown in Fig. 20. Because of inability to couple properly by means of probes, the tabulated theoretical and experimental results shown in Table I are not in as good agreement as in the other two cases.

## IV. PULSE DISTORTION PRODUCED BY FILTER

Although the results of investigations into the distortion introduced in an initially rectangular pulse emerging from a single-tuned filter (pass or rejection type) are probably well known for the case where the filter is tuned to the carrier frequency of the pulse, not as much information seems to be available for the case where the filter is not tuned precisely to the carrier.[3]

The mathematical expression for the transfer impedance of an infinite-rejection filter becomes too involved for tractability in Fourier analysis. Thus one is forced to idealize the actual problem. This can be done, however, with practically no modification of the actual state of affairs, for the attenuation characteristic of an infinite-rejection filter very closely resembles that of a single-tuned circuit with a $Q$ far too high to be realized experimentally. Thus the following is required of the single-tuned circuit: (1) it shall have the same band width as the infinite-rejection filter, and (2) it shall have the same attenuation at resonance. The correspondence in shape then follows automatically. The experimental filter described in Section III had a band width of 0.5 Mc/sec. at 3000 Mc/sec., with a loss off resonance of approximately 1 db. Let us take the attenuation at resonance as 60 db. Then the appropriate constants for the idealized filter are $Q_0 = 6\times 10^6$ and $R = 2000$, where $Q_0$, the unloaded $Q$ of the filter, is defined by $Q_0 = R/L\omega_0$. The term $L$ is the equivalent lumped inductance of the filter, and $R$ is the equivalent shunt resistance, measured in units of line impedance.

The system function, i.e., ratio of output to input voltage, is given by

$$h(\omega) = \frac{1 + 2j\dfrac{Q_0}{\omega_0}(\omega - \omega_0)}{2 + R + 4j\dfrac{Q_0}{\omega_0}(\omega - \omega_0)}, \tag{28}$$

where $j \equiv (-1)^{\frac{1}{2}}$, and $\omega_0$ is defined by

$$\omega_0^2 \equiv \frac{1}{LC}.$$

Now, let $e_1$ be a rectangularly modulated sinusoidal carrier of radian frequency $\omega$, with unit amplitude and pulse duration $\tau$ seconds.

Before we proceed to a mathematical formulation of the resulting output voltage $e_2$, we may describe the process in physical terms. The incoming pulse shock-excites the filter. The filter "rings" for the duration of the pulse at the frequency of the pulse, with a steady-state amplitude dependent on the resonance characteristic of the filter. To this steady-state value is added a transient oscillation decaying exponentially to zero at a rate determined by the $Q$ and $R$ of the filter. At the conclusion of the pulse, the steady oscillation disappears, and all that is left is the decaying term, but now to it is added a second decay term out of phase, initiated by the "shock" of returning the carrier level to zero. If, in addition, the filter is somewhat detuned from the carrier (of frequency $\omega_1$) the decay terms, representing self-resonant transient oscillations, beat with the steady-state oscillations at a frequency equal to the difference between the two. Thus the resultant shape of the pulse is cooperatively determined by (a) the $Q$ and $R$ of the filter, and (b) the frequency difference $\Delta f = (\omega_0 - \omega_1)/2\pi$ cycles/sec.

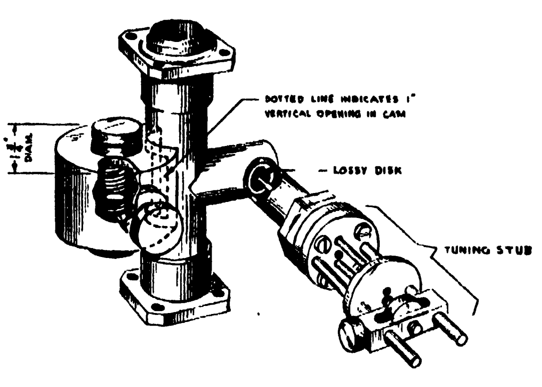

FIG. 19. u.h.f. filter.

Returning to a mathematical formulation of this result, we see that the function $e_2(t)$ can be obtained from $e_1(t)$ by a technique now fairly standard.[9] The Fourier spectral distribution of the unit pulse of duration $\tau$ is multiplied by $h(\omega)$, expanded into partial fractions, and reintegrated with respect to $\omega$ (with, of course, proper attention to the choice of path of integration in the complex plane) In short, there

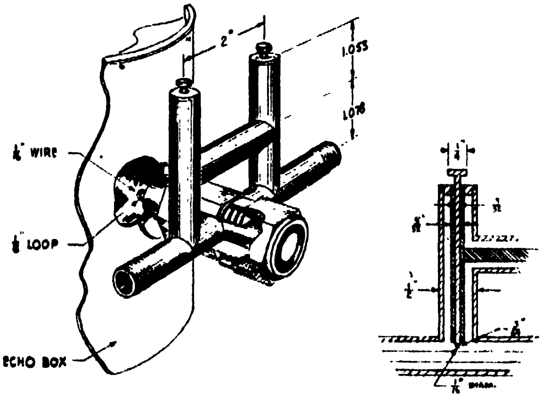

FIG. 20. Bridge-type filter.

---

[9] E. A. Guillemin, *Communication Networks* (John Wiley and Sons, New York, 1935), Vol 2, Chap. XI.

results

$$e_2(t)=\frac{\exp j\omega_1 t}{2+R+4j\frac{Q_0}{\omega_0}(\omega_1-\omega_0)}\left\{1+2j\frac{Q_0}{\omega_0}(\omega_1-\omega_0)+\frac{R}{2}\exp[j(\omega_0-\omega_1)t]\times\exp\left[-\omega_0 t\frac{R+2}{4Q_0}\right]\right\},\quad 0\leq t\leq\tau;\quad (29)$$

$$e_2(t)=-\frac{\frac{R}{2}\exp[j\omega_1 t]}{2+R+4j\frac{Q_0}{\omega_0}(\omega_1-\omega_0)}\left\{\exp[j(\omega_0-\omega_1)t\times\exp\left[-\omega_0 t\frac{R+2}{4Q_0}\right]-\exp\left[-\omega_0\frac{R+2}{4Q_0}(t-\tau)\right]\times\exp[j(\omega_0-\omega_1)(t-\tau)]\right\},\quad \tau\leq t\leq\infty,\quad (30)$$

where, to repeat, $\omega_1$ is the radian frequency of the carrier, $\omega_0$ is the resonant radian frequency of the filter, and the factor multiplying $\exp[j\omega_1 t]$ is the resultant pulse shape.

Expressions (29) and (30) have been calculated for a 1-μsec. pulse and with differences of carrier frequency from filter frequency of 0, ±0.2, ±0.4, ±0.6, ±0.8, ±1, and ±1.5 Mc/sec. It is to be noted, of course, that the result is even in the difference frequency, as would be expected.

The final appearance of the pulse will depend strongly, of course, on further phase shifts, attenuation, and demodulation in the receiver. However, phase shift and attenuation can both be neglected in a well-constructed receiver (except possibly for a linear phase shift which merely shifts the origin of the pulse). A linear detector will have a video output, therefore proportional to $|e_2(t)|$ (disregarding the carrier frequency part). A square-law detector will have an output proportional to $|e_2(t)|^2$, and so on. The curves plotted from Eqs. (29) and (30) and shown in Fig. 21 are calculated from $|e_2(t)|^{\frac{3}{2}}$, i.e., for a three-halves power second detector.

The receiver on which measurements were made was carefully constructed, with an *i-f* band

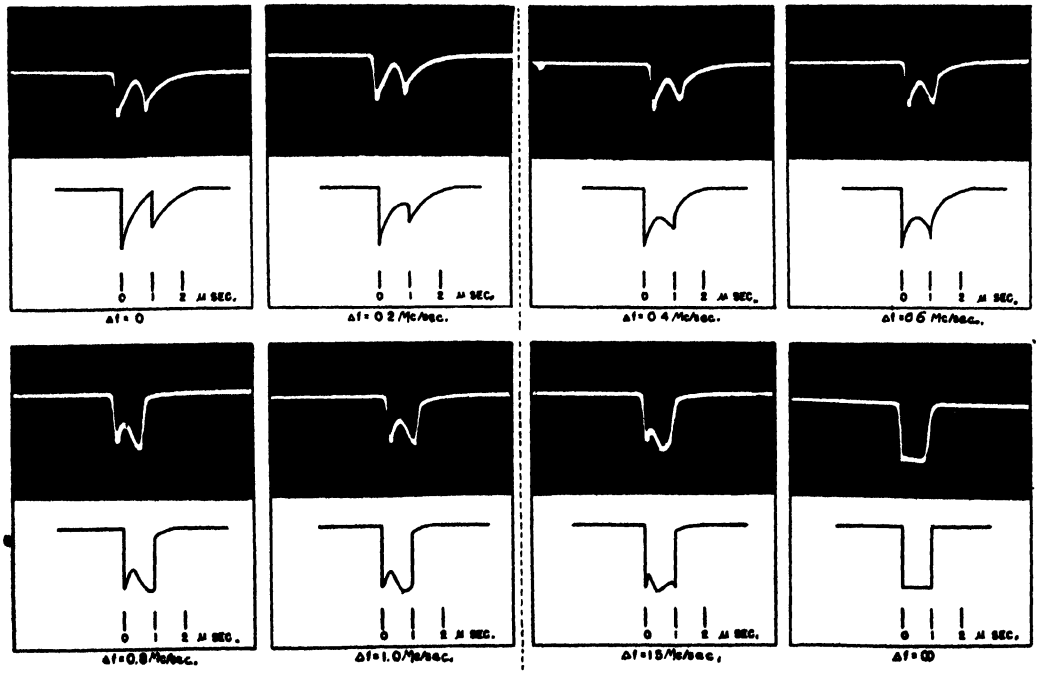

FIG. 21. Distortion produced in rectangular wave by a high $Q$ rejection filter detuned from the pulse frequency by $\Delta f$ Mc/sec.

width of some 13 Mc/sec. and a video band width of some 7 Mc/sec. The second detector was somewhere between linear and three-halves power law. One photograph reproduced in Fig. 21 shows the resultant rectangular wave form. The pulse was formed by driving the grid of a klystron amplifier (excited by a klystron oscillator) from cut-off to a conduction value. This resulted in a pulse virtually free from f-m. The output cavity of the amplifier was broadened in bandwidth by loading it externally. The other photographs carry self-evident explanations.

The agreement between experimentally determined and theoretically predicted curves is seen to be quite satisfactory, with the possible exception of the pulse for $\Delta f = 1.5$ Mc/sec., where $\Delta f \equiv (\omega_1 - \omega_0)/2\pi$. Such differences as remain can be accounted for by the lack of abruptness in the rise and fall of the pulse, somewhat inexact guesses as to $Q_0$ and $R$, and the slight difference in the law of the second detector assumed and that used. However, more accurate determination is hardly warranted.

It is clear that for small frequency differences the pulse is spread out to some two microseconds or so, with a more or less triangular shape, but in every case there is a fairly well defined discontinuity at $t = 1$ μsec. While the attenuation of the *center* frequencies in the pulse spectrum is essentially complete, enough energy remains to give respectable signals. One crude experiment showed a loss of about 2 db in the minimum discernible signal in receiver noise for a filter tuned so that $\Delta f = 0$. As $|\Delta f|$ increases, the depth of the cut in the pulse and the length of the tail decrease more or less uniformly until a case is reached where there is about one wiggle (due to the beat phenomenon mentioned above) across the top of the pulse ($\Delta f \cong 1$ Mc/sec.), then two wiggles with reduced amplitude, and so on. The explanation of the discrepancy between the theoretical and experimental curves for $\Delta f = 1.5$ Mc/sec. is probably that the difference frequency differs slightly from the nominal value. The larger $\Delta f$, the more phase change in the wiggles for a given error in frequency setting. The beats finally die out and a square pulse is regained when the filter is tuned far off resonance. It is therefore not hard to determine the tuning of the filter to a fairly considerable accuracy from the video appearance of a square pulse.

# Theory of Automatic Control Systems*

M. AVRAMY MELVIN
*Columbia University, New York, New York*

(Received June 7, 1946)

The theory of *robots* or reproducing power-amplifying systems is considered. After a general terminological orientation the study in the first part is confined to *simple robots*, the theory of which is equivalent to that of nonlinear springs with inertia and friction. The alacrity and fidelity of control are well exhibited by studying the behavior of a robot under constant tracking. Special emphasis is placed on the specification of conditions for *optimum performance*, i.e., minimum deviation or maximum fidelity after any given time. Curves are given for both proportional and on-off robots, from which the parameter values for optimum performance may be read.

In Part II the theory of proportional robots is analyzed in detail, especially from the point of view of conditions for optimum performance. Two subsequent papers will contain the theory for the on-off case and the general nonlinear robot case. The paper is organized as follows:

## PART I. DESCRIPTIVE ACCOUNT

### A. Terminology and Kinematic Description

A POWER ROBOT may be defined as a *reproducing power-amplifying system.* In other words the name refers to any automatic control system which reproduces the time variation of some quantity which is fed into it, but *with enormously amplified power.* Now, power (whether mechanical or electrical, see Glossary—Table I) is measured by a force-like quantity,** $m$, multiplied by the time variation of some position-like quantity, $\theta$, i.e.,

$$\text{Power} = m\frac{d\theta}{dt} \equiv mv.$$

The robot may then be said to reproduce the time variation, $v$, of the position of some guide, $\theta_g$, with an enormously increased $m$ so that a heavy *load* may be made to follow. The manner in which this is accomplished is by having a delicate *pick-up* operate a *motor* which applies power to the load. The pick-up is so constructed as to compare the position, $\theta_g$, of the guide with $\theta$ of the load and apply a restoring force $m'$ by

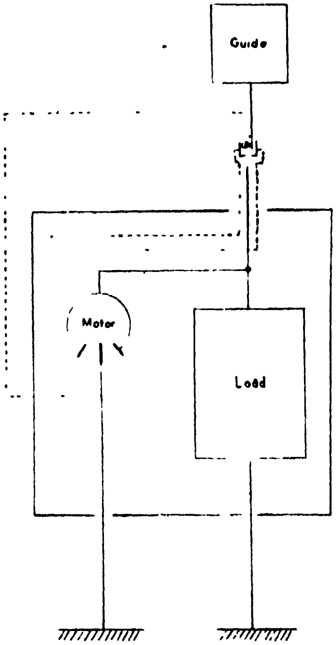

FIG. 1. Schematic diagram of a simple robot.

---

* This work was done in 1943–44 under Contract No. OEMsr-618 between Columbia University and the Office of Scientific Research and Development which assumes no responsibility for the accuracy of the statements contained herein. It was carried out with practically no reference to existing literature, which was, in any case, largely unavailable. Any deviations of terminology from that current among the workers in the field may be ascribed to this. It is hoped that the extensive glossary at the beginning will compensate somewhat for this deficiency. The terms used were carefully chosen with a view to suggestiveness, and some may recommend themselves to others.

** Apologies are here made for the notation, originally adopted in unpublished preceding reports for other reasons. It is to be noted that the theory is much more general than appears here, since $m$ and $\theta$ may be any pair of conjugate physical quantities (original report). But, for simplicity, one may think of $\theta$ as a position variable (or angle) and of $m$ as a force (or torque). The system then reproduces the motion or "tracking" of a *guide*, which is detected by the *pick-up* and applied *via* a *motor* to the *load* or controlled system.

means of the motor to reduce the magnitude of the difference, $D'=\theta_g-\theta$, between them. We shall call this difference the ***output deviation***, and shall designate as a ***simple robot*** any system in which the operation of the pick-up is made to depend directly on this output deviation, $D'$. Other more general types, such as *transmission* robots, may be discussed in another paper.

A schematic diagram of a simple robot is given in Fig. 1. It will generally be arranged that all reaction of the controlled system back on the guide will be negligibly small. We shall further include in the specification of a simple robot the physically natural requirement:

***m′ is a single valued integrable function of D′ in any finite domain.*** Let the phrase ***apparent work*** (i.e., as measured in the frame of reference moving with $v_g$) describe the integral $\int m'dD'$. We may then formulate the condition in words: ***The apparent work done against the motor is finite in any finite deviation and is zero upon the completion of any closed cycle.***

In general one may write the equation of motion of a simple robot as

$$Z[\theta]=m'(D'),$$

where $Z$ is what we may call the "displacement operator" or "stiffness" of the load (usually involving differential operators) and $m'$ is the restoring force function. In very many cases, including all those considered in this paper, the displacement operator is linear in $\theta$ and its derivatives (or integrals). Examples are translational inertia, rotational inertia about an axis, "1st power law" viscous resistance, magnetic damping, Hooke's law elastic stiffness, etc. In all such cases we may rewrite the equation of

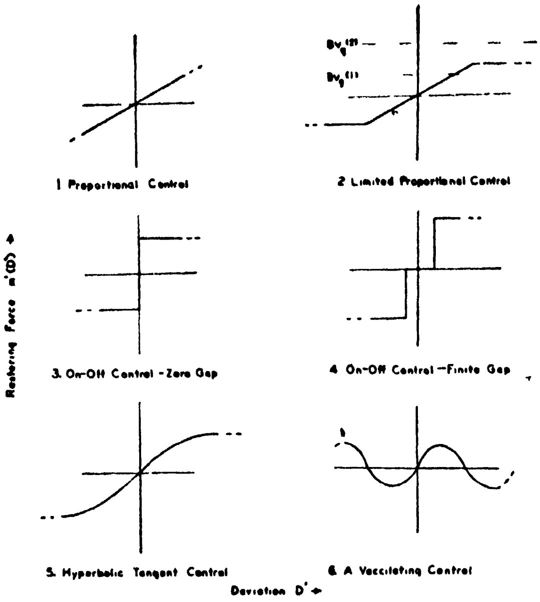

FIG. 2. Restoring force deviation graphs for various types of control.

motion in terms of $D'$:

$$Z[D'] = z(t) - m'(D')$$

where (1.01)

$$z(t) = Z[\theta_g(t)]$$

is the result of operating with $Z$ on the guide position as a function of time.

In general the pick-up is such that the restoring force (i.e., "cause") is not linearly proportional to the deviation ("effect"), so that the theory of robots will be in the domain of non-linear dynamics. The special linear case in which the pick-up does act to produce a restoring force proportional to the deviation is designated by the name of ***proportional control.*** It will be analyzed below so that it may serve as a standard of comparison for other, non-linear controls. The graphs of restoring force *versus* deviation for several types of control are given in Fig. 2.

A division which should be made from the point of view of a general theory is between ***faithful*** and ***vacillating*** (or faithless) robots as illustrated in Fig. 2. In a later paper[1] we shall give a precise and general definition of faithfulness, but tentatively we may indicate the distinction as follows: In a faithful robot the restoring force always acts so as to reduce the deviation, i.e., $m$ is always positive for positive $D$. Not so for a vacillating robot, a type which may occur, for example, in rotating control systems where, if the deviation exceeds a certain value, a new guide (or the old one from the other side) takes over as the center of attraction and the old one is deserted. Certain theorems which may be proved, such as the approach in constant tracking of every simple robot to a steady state of zero oscillation, may be proved only for faithful robots. The others may vacillate throughout eternity.

In any case, the efficiency of a robot will be measured by the ***fidelity with which the load is made to follow the guide,*** i.e., by the smallness of the ***time lag*** and ***oscillation*** of the output deviation $D'$ for changes in $\theta_g$. The more ideal the control system, the smaller will these quantities be. It is one of our prime objectives not only to deduce the general description of the phenomena but also to determine what values of the parameters will minimize lag and oscillation.

There are two interesting special cases:

I. The amplification of power associated with an oscillatory motion.

II. The amplification of power in the case of constant tracking.

The first is the case in which the guide moves with a given oscillatory motion, and the problem is to determine what the amplitude, frequency, and phase of the output deviation are. This is a generalization of the problem of forced oscillations in linear mechanics and we shall not discuss it in this paper.

The second case is that in which, beginning at a certain time when the velocity of the load is $v_b$ and the output deviation is $D_b$, the tracking velocity, $v_g$, of the guide becomes and remains constant. It is a generalization of the problem of free oscillations, or oscillations under a constant force, in linear mechanics. It is this ***case of constant tracking*** with which we shall primarily be concerned, for the fidelity of control of a robot is perhaps best brought out by studying its characteristics for this case (Fig. 3). After a certain time and number of cycles (finite or infinite) the system may attain a ***steady state.*** The steady state may be either one of no oscillation, i.e., perfect

---

[1] "Theory of damped non-linear oscillators with applications," referred to in the following as D.N.O.

following of the tracking motion, or of a steady oscillation with finite period and amplitude. The following or oscillation may be about the correct tracking motion or about a position lagging by a certain steady value behind the correct position. When it occurs, we shall denote this mean steady-state deviation from the guide position by the symbol $D_\infty'$ (an explicit definition will be given later), and it will be convenient to separate it out from the total output deviation, so that we may write

$$D \equiv D' - D_\infty'.$$

Here then, $D$ represents the deviation from the mean steady-state tracking position (Fig. 3). Since it is often relatively easy to correct for a steady space deviation like $D_\infty'$, it is desirable to concentrate merely on minimizing the oscillation and time lag of $D$.

When there is oscillation it is often convenient to start counting time and number of cycles from the first time when $D=0$. Let the interval between the beginning of constant tracking and this first zero of $D$ be represented by the symbol $T_0'$ (Fig. 3) so that, if $T'$ represents the time as measured from the beginning of constant tracking, we have

$$T = T' - T_0'.$$

When the general theory of a system for an arbitrary beginning time is worked out, $T_0'$ may be determined by an auxiliary calculation. The advantage of this shift of the origin of time to the beginning of the first cycle is that it will often simplify the ensuing formulas by eliminating a phase-shift term. Sometimes $T_0'$ is of interest for itself, in that a certain event for which the control is motivated in the first place is made to occur at that moment. Even in cases where steady permanent control is desired, it might be that the system could be brought immediately to the steady state at that moment by a suitable impulsive process.

If $D$ does oscillate in time we may wish to analyze its variation in each cycle independently. In such circumstances it will be convenient to start the time scale anew at the beginning of each cycle. The time so measured within each cycle will be denoted by the symbol $t$.

Let us designate the maximum and minimum $D$ in the $n$-th cycle (the *deviation amplitudes*) by $\bar{D}_n$ and $D_n$, respectively. Also let the period in the $n$-th cycle be represented by $P_n$. Upon inverting the expression for $\bar{D}_n$ as a function of $n$, one may arrive at the

*number-amplitude* function: $n(\bar{D})$

giving the number of cycles required for the maximum deviation to fall and remain below $\bar{D}$. The control characteristics of a system are per-

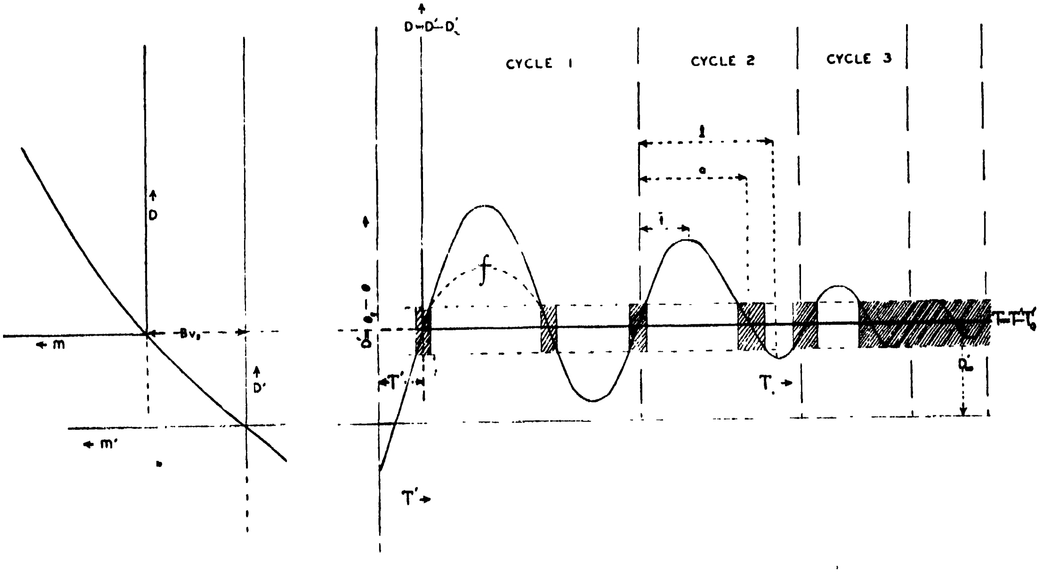

Fig. 3. Oscillations in a simple faithful robot under constant tracking.

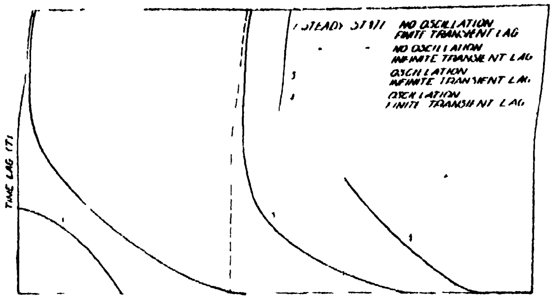

FIG. 4. Time lag *vs.* maximum deviation amplitude.

haps best exhibited by its

$$\textit{time-amplitude curves:}\quad T(\bar{D}) = \sum_{n=0}^{n(\bar{D})-1} P_n,$$

giving the time required up to the beginning of the cycle in which the maximum aplitude falls below $\bar{D}$. These may be plotted for various values of the relevant parameters.

The magnitude $\bar{D}_\infty$, after a steady state has been reached, will be finite or zero, depending on whether there is or is not a steady state of oscillation. The number of cycles and time required to reach the steady state exactly, which we designate

number of transient cycles: $n_\infty$

and

$$\text{transient lag,}\quad T_\infty = \sum_{n=0}^{n_\infty - 1} P_n,$$

respectively, may be finite or infinite. Combining this with the possibility of zero or finite oscillation, we have the four main types of time-amplitude curves one may expect to encounter, sketched in Fig. 4. The functions should actually be represented as discrete, since the variables $\bar{D}$ and $T$ take on discrete values but, for convenience, we have drawn smooth curves through the points.

Besides the $\bar{D}-T$ curves, which set upper limits to the deviations after any particular time, we may be concerned to know what fraction of the time of any cycle the system spends with a deviation in the interval $dD$ between $D$ and $D+dD$. In other words, we should like to know the "distribution function" for the probability of finding the system in the neighborhood of any given deviation about the mean tracking position. Since it is proportional to the time spent within unit interval about $D$, this distribution function is inversely proportional to the time rate of change of $D$ at that point. Thus letting

$$V \equiv \partial D/\partial T,$$

and expressing it as a function $V(D)$ of $D$, we may write:

$$f(D)dD = \frac{1}{P}\left[\frac{1}{|V(D)|_R} + \frac{1}{|V(D)|_L}\right]dD,$$

where we have added together the time intervals for $dD$ when the deviation is increasing and decreasing, respectively, since both contribute to the probability of finding the system in $dD$. division by the period $P$ is merely to insure normalization, i.e.,

$$\int_{-D}^{D} f(D)dD = 1.$$

Because of the nature of oscillation (velocity zero at the amplitude limits) $f(D)$ will be of a general U-shape as sketched in Fig. 5. Now it is difficult to characterize this curve in a general way. For practical purposes, however, it will be of primary interest to know what fraction of the time of any cycle the system spends within any small interval in the ***neighborhood*** of the mean steady-state position, i.e., we wish to give ***the value of the ordinate, f, of the distribution curve at the abscissa,*** $D=0$. This we shall designate the ***fidelity fraction,*** since multiplying it by any small deviation interval $\Delta D$ about $D=0$ gives an approximation to the fractional time spent within that interval. Since the area under the total curve has been normalized to unity, it is clear that $f$ is also represented by the shaded area in Fig. 5. An explicit formula for $f$ in terms of the velocity $V_n$ at the beginning of the $n$-th cycle and the velocity $V$ at the time $a$ of the return passage through zero $D$ is

$$f = \frac{1}{P_n}\left(\frac{1}{|V_n|} + \frac{1}{|V(a)|}\right)$$ [***]

---

[***] As pointed out by the referee, the quantity $f$ here defined is more applicable to the first half of the cycle rather than to the total cycle. It is still, however, an approximate index of fidelity and may be taken as having certain advantages of simplicity. In any case, it had already been used in the treatment of the special cases given later.

## B. Dynamical Equation of Robots with Usual Load

Thus far our considerations have been quite general. But it is convenient here to limit ourselves to the very important common case where the sluggishness of the load or controlled system is governed mainly by inertia and frictional resistance so that the equation of motion of the robot may be written

$$\begin{gathered} I\frac{dv}{dT'}+Bv=m'(D') \\ \left.\begin{aligned} v&=v_b \\ D'&=\theta_u-\theta_b \end{aligned}\right\}\text{at } T'=0, \end{gathered} \tag{1.02}$$

where $I$ is the inertia of the load and the $B$ its frictional resistance per unit velocity and, as is the nature of the robot, the applied force $m'$ is a function of the deviation $D'$. (In the case of a transmission robot, $D'$ must be taken as representing the input deviation.) The subscript $b$ in the initial condition equations represents the values of the indicated quantities at the beginning $T'=0$. In terms of $\theta$, the differential equation may be written

$$I\frac{d^2\theta}{dT^2}+B\frac{d\theta}{dT}=m'(\theta_u-\theta)=m_0\mu'(\theta_u-\theta)$$

where we have taken out a constant *characteristic strength* factor $m_0$ (which may be defined conveniently in any particular type of system) and have left the functional dependence in the dimensionless restoring force function $\mu'(\theta_u-\theta)$.

Now, in developing the theory for this usual load case, it is convenient to choose new dimensionless measures of time, velocity, and force such that

$$\frac{m'}{m_0}\equiv\mu' \quad \frac{B}{I}T'\equiv\mathrm{T} \quad \frac{B}{m_0}v\equiv\omega \quad \frac{B^2}{m_0I}\theta\equiv\phi.$$

Therefore,

$$\frac{B}{I}t\equiv\tau \quad \frac{B}{m_0}V\equiv\dot{\omega}_u-\omega\equiv\Omega \quad \frac{B^2}{m_0I}D'\equiv\Delta' \tag{1.02'}$$

$$\frac{I}{m_0}\cdot\frac{dv}{dt}\equiv\frac{d\omega}{d\tau} \quad \text{etc.,}$$

where

$$\kappa\equiv m_0I/B^2.$$

Thus we are measuring *all forces in fractions of the characteristic strength* and *all times in fractions of the time constant* of the load when slowing down freely under no applied load; and we are measuring *all velocities in fractions of the characteristic steady-state velocity of the load,* i.e., its motion against friction when the constant characteristic strength of the motor is applied steadily. With these notations the basic robot equation (1.02) takes the form

$$\frac{d^2\phi}{d\mathrm{T}'^2}+\frac{d\phi}{d\mathrm{T}'}=\mu'[\kappa(\phi_u-\phi)],$$

or if we express the equation in terms of

$$\Delta'=\phi_u-\phi$$

we get

$$\frac{d^2\Delta'}{d\mathrm{T}'^2}+\frac{d\Delta'}{d\mathrm{T}'}=\left(\frac{d^2}{d\mathrm{T}'^2}+\frac{d}{d\mathrm{T}'}\right)\phi_u-\mu'(\kappa\Delta').$$

This is the form which the fundamental operator equation (1.01) assumes in usual load systems.

If we confine ourselves to the case of constant tracking beginning at $\mathrm{T}'=0$,

$$\phi_u=\omega_u\mathrm{T}'$$

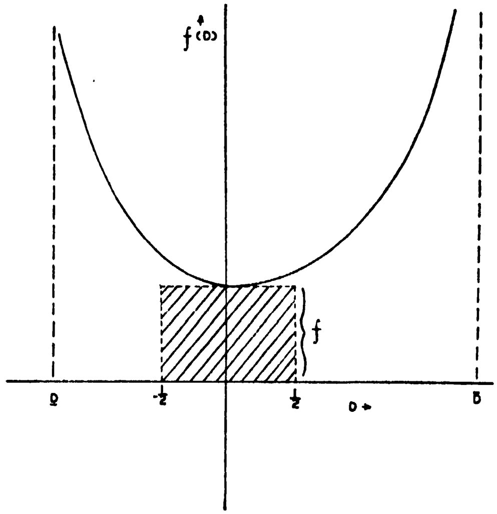

FIG. 5. Distribution function for probability of finding deviation in any neighborhood.

TABLE II. Steady-state deviations and modified force functions for various types of robots.

| Type of control | Restoring force deviation relation $\mu'(\Delta')$ | Steady state deviation $\Delta_\infty'$ | Modified restoring force function |
|---|---|---|---|
| Proportional | $\kappa\Delta'$ | $\frac{\omega_g}{\kappa}$ | $\kappa\Delta$ |
| Quadratic | $\hat{\Delta}'(\kappa\Delta')^2$ | $\hat{\omega}_g\frac{1}{\kappa}(\|\omega_g\|)^{\frac{1}{2}}$ | $\pm\|\kappa\Delta\pm(\|\omega_g\|)^{\frac{1}{2}}\|^2-\omega_g \quad (\pm=\hat{\omega}_g)$ |
| Cubic | $(\kappa\Delta')^3$ | $\frac{1}{\kappa}\omega_g^{\frac{1}{3}}$ | $(\kappa\Delta+\omega_g^{\frac{1}{3}})^3-\omega_g$ |
| *m*-th power | $\hat{\Delta}'\|\kappa\Delta'\|^m$ | $\hat{\omega}_g\frac{1}{\kappa}\|\omega_g\|^{1/m}$ | $\pm\|\kappa\Delta\pm\|\omega_g\|^{1/m}\|^m-\omega_g \quad (\pm=\hat{\omega}_g)$ |
| Exponential | $\hat{\Delta}'[e^{\kappa\|\Delta'\|}-1]$ | $\hat{\omega}_g\frac{1}{\kappa}\ln[1+\|\omega_g\|]$ | $\pm[e^{\|\kappa\Delta\pm\ln(1+\|\omega_g\|)\|}-(1+\|\omega_g\|)] \quad (\pm=\hat{\omega}_g)$ |
| Hyperbolic sine | $\sinh(\kappa\Delta')$ | $\frac{1}{\kappa}\sinh^{-1}\omega_g$ | $\sinh(\kappa\Delta+\sinh^{-1}\omega_g)-\omega_g$ |
|  |  | $\|\omega_g\|<1$: $\quad\|\omega_g\|>1$: |  |
| Hyperbolic tangent | $\tanh(\kappa\Delta')$ | $\frac{1}{\kappa}\tanh^{-1}\omega_g$ or $\pm\infty$ | $\tanh(\kappa\Delta+\tanh^{-1}\omega_g)-\omega_g$ |
| On-off zero-gap |  | 0 or $\pm\infty$ |  $\omega_g \quad (\pm=\hat{\omega}_g)$ |
| On-off finite-gap |  $\delta$ | $\pm\delta$ or $\pm\infty$ |  $\omega_g \quad (\pm=\hat{\omega}_g)$ |

$\hat{a}$ means "sign of $a$" or $\frac{a}{|a|}$

and we have:

$$\frac{d^2\Delta'}{dT'^2}+\frac{d\Delta'}{dT'}=\omega_g-\mu'(\kappa\Delta')\equiv-\mu$$

$$(\mu')\qquad\left.\begin{aligned}\Delta'&=-\phi_b\\ \frac{d\Delta'}{dT'}&=\omega_g-\omega_b\equiv\Omega_b\end{aligned}\right|\text{at } T'=0, \tag{1.03}$$

where $\kappa$, $\omega_g$, $\phi_b$, $\omega_b$, $\Omega_b$ are then constants calculable in terms of the given data, and where we have introduced the symbol

$$\mu\equiv\mu'-\omega_g$$

for the ***modified force function***, i.e., the restoring force measured from the level $\omega_g$ instead of zero.

Now it is demonstrated in D.N.O.[1] that the final steady state in constant tracking of any faithful robot is one of zero oscillation, and consists of a constant steady deviation given by setting the right-hand side of the differential equation (1.03) equal to zero:

$$\omega_g-\mu'(\kappa\Delta')=0$$

or

$$\Delta_\infty'=\frac{1}{\kappa}\mu'^{-1}(\omega_g)$$

where $\mu'^{-1}$ is the inverse function corresponding to $\mu'$. Applications of this result to various types of control are given in Table II. It is thus possible to simplify the system of equations of motion (1.03) by introducing the modified force function and expressing everything in terms of the modified deviation $\Delta$:

$$\mu(\kappa\Delta)\equiv\mu'[\kappa\Delta']-\omega_g=\mu'[\kappa(\Delta+\Delta_\infty')]-\omega_g.$$

This shift of reference level of $\mu$ is illustrated in

Fig. 3. If $\Delta$ becomes zero at some finite time, $T_0'$, before the steady state is reached, i.e., in case of at least one oscillation, it is possible to simplify the equations a little further. Introducing the modified force function, and measuring the time in terms of T from the first zero of $\Delta$, we have:

$$\frac{d^2\Delta}{dT^2}+\frac{d\Delta}{dT}=-\mu'(\kappa\Delta)$$

$$\left.\begin{aligned}&\Delta=0\\&\frac{d\Delta}{dT}=\omega_g-\omega_0\equiv\Omega_0\end{aligned}\right\}\text{at } T=0, \tag{I.04}$$

where, if the solution to the problem for arbitrary beginning data is known, $\omega_0$ or $\Omega_0$ may be calculated readily. Conversely, if one has the solution for general values of $\Omega_0$ as a parameter, one may determine the particular value required to fit the initial data

$$\Delta=-\phi_b-\Delta_\infty' \quad \Omega=\Omega_b \text{ at } T=-T_0'.$$

In general, if $\mu'$ is of any other functional form but linear, the differential equation is non-linear in that the right-hand side is a function of the *dependent* variable, and the solution of the system will require special devices in various cases. We shall discuss this question in D.N.O.[1] and in a subsequent paper[2], but for the present we confine ourselves to noting that, once the problem is solved, all the control characterizing concepts defined above may be found, translated, of course, in dimensionless terms. These are listed for reference in Table III. All these quantities generally depend, of course, on the parameters $\kappa$, $\omega_0$, and $\omega_g$ as well as the indicated arguments.

The visualization of the motion is facilitated if it is represented on a diagram on which $\Omega$ is plotted as ordinate against $\Delta$ as abscissa. This gives the "path curve" in the "state plane" (or "phase space") of our damped non-linear oscillator. The differential equation governing the path of the representative point in the state plane follows from a simple rearrangement of (I.04)

$$\frac{d\Omega}{d\Delta}=-1-\frac{\mu(\kappa\Delta)}{\Omega} \tag{I.04'}$$

with the same initial conditions. The time is now merely a parameter tracing the representative point as it moves along the path curve.

It will be shown in D.N.O.[1] that for every faithful robot the path curve is a continuous right-handed (clockwise) spiral closing in on the point $\Delta_\infty'$ which lies on the $\Delta$ axis. This spiral may be bounded between two comparison spirals beginning at the same initial point and made up of successive pieces of linear oscillator spirals with certain frequencies which may be worked out in each case. In this way follow immediately criteria for oscillation and overdamping, and the possible existence of any finite number of oscillations in the transient state of non-linear oscillators. Upper and lower bounds to the number of oscillations and times required for the deviation to fall to any desired value may then be set.

## C. Optimum Performance Curves

If after solving the constant tracking case as represented in (I.04) for any particular system, and finding for instance

$$\bar{\Delta}(T,\kappa,\Omega_0,\omega_g)$$

and

$$f_\Delta(T,\kappa,\Omega_0,\omega_g),$$

we return to the ordinary measures of time and

TABLE III. Control characterizing concepts translated in dimensionless terms.

| | |
|---|---|
| $\Delta_\infty'$ | mean steady-state deviation from guide position |
| $\Delta$ | deviation from mean steady-state deviation |
| $T_0'$ | time when $\Delta$ first becomes zero after the beginning of constant tracking |
| $\bar{\Delta}_n$ | maximum value of $\Delta$ in $n$-th cycle |
| $\underline{\Delta}_n$ | minimum value of $\Delta$ in $n$-th cycle |
| $\pi_n$ | period of oscillation in $n$-th cycle |
| $n(\bar{\Delta})$ | number-amplitude function |
| $\bar{\Delta}(T)$ | amplitude-time function |
| $n_\infty$ | number of transient cycles required to reach the steady state |
| $T_\infty$ | transient lag, i.e., time required to reach the steady state |
| $f_\Delta=\frac{1}{\pi_n}\left[\frac{1}{\lvert\Omega_n\rvert}+\frac{1}{\lvert\Omega(a)\rvert}\right]$<br>$\equiv\kappa f$ | fidelity fraction, i.e., approximate fractional time per cycle spent within unit $\Delta$ interval about steady-state deviation |

---

[2] "Theory of on-off and relay control systems," J. App. Phys. (To be published.)

position, we may write

$$(D)\quad \bar{D}=\frac{m_0I}{B^2}\Delta\left(\frac{B}{I}T,\ \frac{m_0I}{B^2},\ \frac{B}{m_0}V_0,\ \frac{B}{m_0}v_g\right),\qquad (1.05)$$

$$(f)\quad f=\frac{B^2}{m_0I}f_\Delta\left(\frac{B}{I}T,\ \frac{m_0I}{B^2},\ \frac{B}{m_0}V_0,\ \frac{B}{m_0}v_g\right).\qquad (1.06)$$

It is interesting to investigate the dependence of $\bar{D}$ upon the various system parameters. We shall illustrate by considering the dependence upon the friction coefficient $B$, whose influence on the times required for reducing $\bar{D}$ and for increasing $f$ may be considerable. It is then important practically to determine (with a given time) for what value of $B$, $\bar{D}$ is a minimum, and for what value $f$ is a maximum. We shall designate these two values (or sets of values) by the symbols $B_{\min}$ and $B_{\max}$, respectively.

Consider first the determination of $B_{\min}$. This is obtained from the conditions

$$\frac{\partial\bar{D}}{\partial B}=0;\quad \frac{\partial^2\bar{D}}{\partial B^2}>0.$$

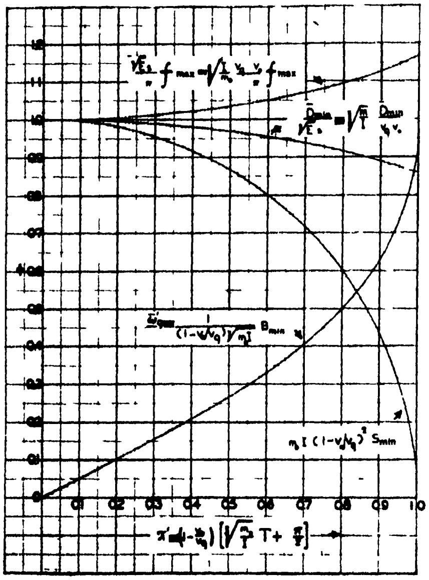

FIG. 6. Optimum performance curves for minimum deviation and maximum fidelity—proportional robot in constant tracking.

In general this value of $B_{\min}$ will depend on the time as well as the parameters, and to every time there will be associated a minimizing value $B_{\min}$. The value of $\bar{D}$ associated with $B_{\min}$ may be obtained by substituting into Eq. (1.06). $\bar{D}_{\min}$ and $B_{\min}$ as ordinates may both be plotted against the associated time $T$. Examples of such curves for proportional and on-off control robots obtained from the mathematical analysis in Part II and a subsequent paper are given in Figs. 6, 7, and 8. The curves are approximate only, and valid under the conditions for short period oscillations, i.e., for low damping $B$ relative to motor strength $m_0$. It is further shown in the mathematical analysis that real minimum values of $\bar{D}_{\min}$, and maximum values of $f_{\max}$, may be obtained only for certain ranges of $B$ and $T$. These ranges are diagrammed in Fig. 9. For generality the ranges of negative $B$ and $T$ are also given.

The actual value of $T$, and therefore $B_{\min}$, to be chosen depends of course on the requirements of the situation. In many cases ($\bar{D}_x=0$) it will be found that $\bar{D}_{\min}$ may be made as small as desired by choosing a sufficiently large $T$. But generally we do not wish this time to be unduly long. The most practical procedure to be followed for systems with adjustable $B$ is then probably this:

*For a given power source $m_0$, load inertia $I$, constant velocity of tracking $v_g$, and initial load velocity $v_0$, if we designate a deviation amplitude which is not to be exceeded, we determine a point on the ($\bar{D}_{\min}-T$) curve. By making the friction coefficient in the system have the value $B_{\min}$ associated with the abscissa of this point, we ensure that the desired diminution in $\bar{D}$ will occur in the shortest possible time. This time is given by the common abscissa.*†

---

† The formal proof that the conditions for

*$\bar{D}$ minimum with respect to $B$ at constant $T$*

are entirely equivalent to those for

*$T$ minimum with respect to $B$ at constant $\bar{D}$*

is easy. It follows immediately from the expression

$$\bar{D}-\bar{D}(B,T)=0$$

that

$$\left(\frac{\partial T}{\partial B}\right)_{\bar{D}}=-\frac{(\partial\bar{D}/\partial B)_T}{(\partial\bar{D}/\partial T)_B},$$

and from this the desired conclusion may be drawn except in the case where the denominator on the right-hand side also vanishes (i.e., in the steady state).

As indicated above, just as one may seek to find an optimum value of $B$ for minimizing the deviation, one may instead determine a $B_{\max}$ to maximize the fidelity fraction. $B_{\max}$ is determined to satisfy the conditions

$$\partial f/\partial B=0; \quad \partial^2 f/\partial B^2<0.$$

Plots of $f_{\max}$ and $B_{\max}$ curves analogous to the $\bar{D}_{\min}$ and $B_{\min}$ curves may be made and the following prescription carried out:

*For a given power source $m_0$, load inertia $I$, constant velocity of tracking $v_q$, and initial velocity $v_0$, if we designate a fidelity fraction which is to be exceeded, we determine a point on the $f_{\max}$ curve. By making the friction coefficient in the system have the value $B_{\max}$ associated with the abscissa of this point, we ensure that the desired increase in $f$ will occur in the shortest possible time. This time is given by the abscissa.*

Such curves as $\bar{D}_{\min}$–$B_{\min}$ and $f_{\max}$–$B_{\max}$ may conveniently be referred to as *curves for optimum performance.*

We may define the *sensitivity* of a maximum or minimum as *the relative change in the ordinate for a unit change in the abscissa* away from the extremum. It is proposed that this is a fairly relevant criterion in most cases where the local importance of a maximum or minimum is to be estimated. With application to the functions $\bar{D}(B)$ and $f(B)$ this yields

$$S_{\min}=\frac{1}{\bar{D}_{\min}}\frac{\partial^2\bar{D}}{\partial B^2}\bigg|_{B_{\min}} \qquad S_{\max}=-\frac{1}{f_{\max}}\frac{\partial^2 f}{\partial B^2}\bigg|_{B_{\max}},$$

where in each case the second derivative is evaluated at the extremum, i.e., where the first derivative vanishes. Once the extremum problems have been solved, plots of $S_{\min}$ and $S_{\max}$ similar to those described for $\bar{D}_{\min}$ and $f_{\max}$ may of course be made.

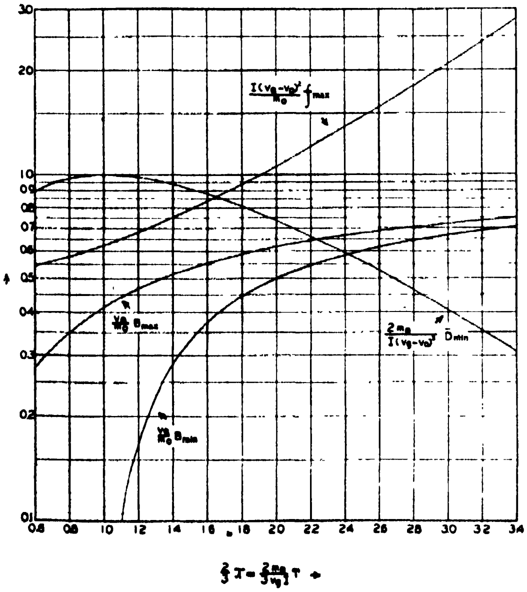

FIG. 7. Optimum performance curves for minimum deviation and maximum fidelity —on-off robot in constant tracking.

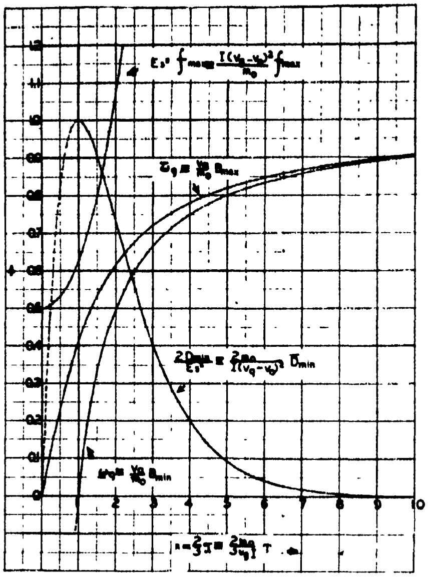

FIG. 8. Optimum performance curves on a semi-logarithmic plot—on-off robot in constant tracking.

So far, in the interest of clarity we have described the curves for optimum performance in general without specifying the restrictions which may be placed, by dimensional considerations, on the manner of occurrence of the various parameters. But it may be of *considerable practical value* to determine in general *upon what involvements of the parameters the optimum performance curves depend.* Various minimal sets of such variables may be found, with differing advantages.

Here we shall make a particular choice which brings out clearly the dependence on $B$: If the abbreviations

$$\frac{m_0 T}{v_g I}\equiv \mathcal{T}\qquad \frac{I v_g^2}{m_0}\equiv E\qquad 1-\frac{v_0}{v_g}\equiv s \qquad (\text{I}.07)$$

are introduced, it is readily seen that (I.05) and (I.06) may be rewritten

$$(D')\quad \bar{D}=\frac{E}{\omega_g^2}\Delta\left(\omega_g\mathcal{T},\ \frac{E}{\omega_g^2},\ \omega_g s,\ \omega_g\right) \qquad (\text{I}.08)$$

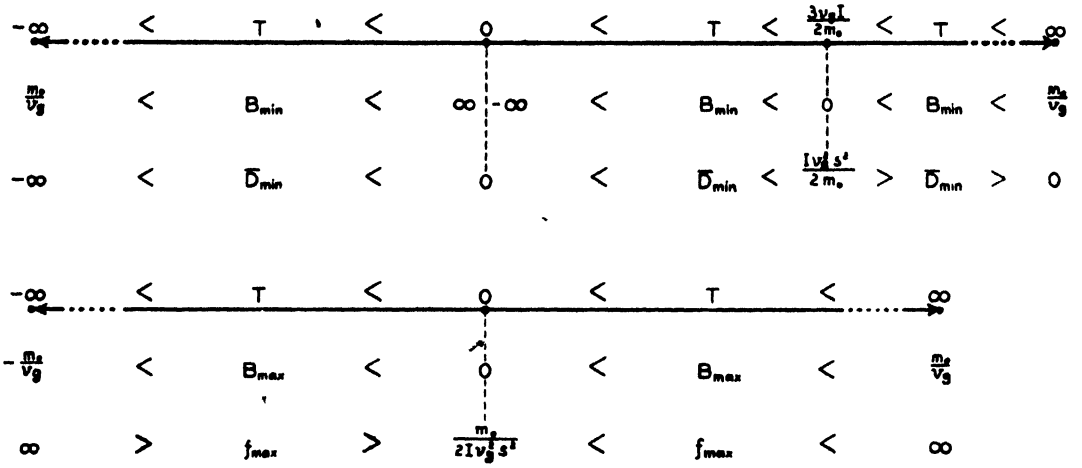
$$(f')\quad f=\frac{\omega_g^2}{E}f_\Delta\left(\omega_g\mathcal{T},\ \frac{E}{\omega_g^2},\ \omega_g s,\ \omega_g\right). \qquad (\text{I}.09)$$

It is clear from the definitions (I.07) of $\mathcal{T}$, $E$, and $s$ that they in no way involve $B$. The functions in $(D')$ and $(f')$ depend on $B$ only through

$$\omega_g\equiv\frac{B}{m_0}v_g.$$

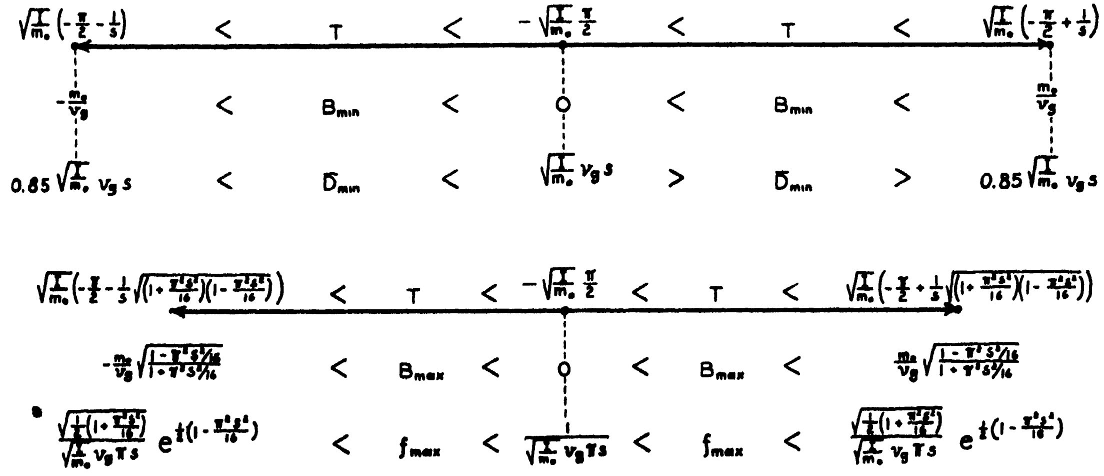
Therefore all extremalizing values of $B$ may be obtained by setting

$$\frac{\partial\bar{D}}{\partial\omega_g}=0,\qquad \frac{\partial f}{\partial\omega_g}=0.$$



$-\infty < T < 0 < T < \frac{3v_gI}{2m_0} < T < \infty$
$\frac{m_0}{v_g} < B_{min} < \infty \,|\, -\infty < B_{min} < 0 < B_{min} < \frac{m_0}{v_g}$
$-\infty < \bar{D}_{min} < 0 < \bar{D}_{min} < \frac{Iv_g s^2}{2m_0} > \bar{D}_{min} > 0$
$-\infty < T < 0 < T < \infty$
$-\frac{m_0}{v_g} < B_{max} < 0 < B_{max} < \frac{m_0}{v_g}$
$\infty > f_{max} > \frac{m_0}{2Iv_g s^2} < f_{max} < \infty$

ON - OFF ROBOTS



$\sqrt{\frac{I}{m_0}}\left(-\frac{\pi}{2}-\frac{1}{s}\right) < T < -\sqrt{\frac{I}{m_0}}\frac{\pi}{2} < T < \sqrt{\frac{I}{m_0}}\left(-\frac{\pi}{2}+\frac{1}{s}\right)$
$-\frac{m_0}{v_g} < B_{min} < 0 < B_{min} < \frac{m_0}{v_g}$
$0.85\sqrt{\frac{I}{m_0}}v_g s < \bar{D}_{min} < \sqrt{\frac{I}{m_0}}v_g s > \bar{D}_{min} > 0.85\sqrt{\frac{I}{m_0}}v_g s$
$\sqrt{\frac{I}{m_0}}\left(-\frac{\pi}{2}-\frac{1}{s}\sqrt{\left(1+\frac{\pi^2s^2}{16}\right)\left(1-\frac{\pi^2s^2}{16}\right)}\right) < T < -\sqrt{\frac{I}{m_0}}\frac{\pi}{2} < T < \sqrt{\frac{I}{m_0}}\left(-\frac{\pi}{2}+\frac{1}{s}\sqrt{\left(1+\frac{\pi^2s^2}{16}\right)\left(1-\frac{\pi^2s^2}{16}\right)}\right)$
$-\frac{m_0}{v_g}\sqrt{\frac{1-\pi^2s^2/16}{1+\pi^2s^2/16}} < B_{max} < 0 < B_{max} < \frac{m_0}{v_g}\sqrt{\frac{1-\pi^2s^2/16}{1+\pi^2s^2/16}}$
$\frac{\sqrt{\frac{1}{2}\left(1+\frac{\pi^2s^2}{16}\right)}}{\sqrt{\frac{I}{m_0}}v_g\pi s}e^{\frac{1}{2}\left(1-\frac{\pi^2s^2}{16}\right)} < f_{max} < \frac{1}{\sqrt{\frac{I}{m_0}}v_g\pi s} < f_{max} < \frac{\sqrt{\frac{1}{2}\left(1+\frac{\pi^2s^2}{16}\right)}}{\sqrt{\frac{I}{m_0}}v_g\pi s}e^{\frac{1}{2}\left(1-\frac{\pi^2s^2}{16}\right)}$

PROPORTIONAL ROBOTS

FIG. 9. Domain of real $\bar{D}_{min}$ and $f_{max}$ with associated ranges of the time and the friction coefficient.

These equations yield

$$(\omega_g)_{\min} \quad (\omega_g)_{\max}$$
$$\bar{D}_{\min} \quad f_{\max}$$

and the sensitivities, etc., solely in terms of the quantities

$$\mathcal{T} \quad E \quad s$$

and no others. *Thus for any simple robot the optimum performance curves depend upon the time and physical parameters only in the three combinations defined in (I.07).* When quantities are expressed in terms of $\mathcal{T}$, $E$, and $s$, we shall say that they are "in $\mathcal{T}Es$ measure."

We shall now illustrate the use of the optimum performance curves by a practical example. Consider a system with the following parameters:

| | |
|---|---|
| motor strength | $m_0 = 1$ kw. $= 10^{10}$ erg/sec. |
| inertia | $I = 1000$ kg $= 10^6$ g |
| guide velocity | $v_g = 3.6$ km/hr. $= 100$ cm/sec. |
| initial load velocity | $v_0 = 1.8$ km/hr. $= 50$ cm/sec. |
| $E = 1$ | $s = \frac{1}{2}$. |

Suppose we wish to determine the optimum conditions for the deviation amplitude not to exceed 0.45 cm, i.e.,

$$\frac{\bar{D}_{\min}}{(E)^{\frac{1}{2}}s} = 0.9.$$

We find from Fig. 6 for proportional robots:

$$\mathcal{T}' = 0.86 \qquad \mathrm{T} = \left(\frac{I}{m_0}\right)^{\frac{1}{2}}\left(-\frac{\pi}{2} + \frac{\mathcal{T}'}{s}\right) = 0.0015 \text{ sec.}$$

$$\underline{\bar{\omega}}_g' = 0.57 \qquad B = 28 \times 10^6 \text{ dynes per cm/sec.}$$
$$= 28.6 \text{ kg per cm/sec.}$$

$$(E)^{\frac{1}{2}}\pi s f_{\max} = 1.11 \qquad f_{\max} = 0.707 \text{ cm}^{-1}.$$

Thus the optimal friction coefficient is such as to produce a drag of about 29 kg for a velocity 1 cm/sec. After 15 ten thousandths of a second the deviation amplitude will have fallen below 0.45 cm. To use the fidelity fraction, we consider the sample question: What fraction of a cycle does the system spend within a deviation equal to $\frac{1}{5}$ the deviation amplitude, i.e., within 0.09 cm of the correct position? The answer is $0.707 \times 2 \times 0.09 = 0.127 \simeq \frac{1}{8}$ of a cycle.

When we now consider an on-off robot with the same parameters we find we can no longer choose the minimizing deviation at 0.45 cm, since this already exceeds the upper limit for which $\bar{D}_{\min}$ is real. In fact we have a real minimum only when

$$\bar{D}_{\min} \leqslant \frac{I(v_g - v_0)^2}{2m_0} = 0.125 \text{ cm}$$

in this case. Taking $\bar{D}_{\min}$ equal to $\frac{1}{4}$ its value in the preceding example, i.e., at 0.1125 cm, we find

$$\frac{2\bar{D}_{\min}}{Es^2} = 0.9,$$

for which Fig. 7 yields:

$$\tfrac{2}{3}\mathcal{T} = 1.53 \qquad T = 0.023 \text{ sec.}$$

$$\underline{\omega}_g = 0.35 \qquad B_{\min} = 35.7 \text{ kg per cm/sec.}$$

$$\bar{\omega}_g = 0.54 \qquad B_{\max} = 55 \text{ kg per cm/sec.}$$

$$Es^2 f_{\max} = 0.81 \qquad f_{\max} = 3.24 \text{ cm}^{-1}.$$

The fidelity fraction in this case yields the result that the system will probably spend a fraction

$$3.24 \times 2 \times \frac{0.1125}{5} = 0.146 \text{ of a cycle}$$

within a deviation equal to $\frac{1}{5}$ the amplitude about the correct position.

## PART II. THEORY OF SIMPLE ROBOTS WITH PROPORTIONAL CONTROL

### A. Complete Solutions as Functions of Time Optimum Performance Curves

We shall now consider a particular type of control for which detailed analytical and graphical solutions will be given. This is the case of the simple robot with *proportional control* in which the restoring force is linearly proportional to the deviation, i.e.,

$$m = m_0(\theta_g - \theta).$$

The basic equation for the robot with usual load may then be written

$$I\frac{d^2\theta}{dT'^2} + B\frac{d\theta}{dT'} = m_0(\theta_g - \theta)$$

$$\left.\begin{aligned} \theta &= \theta_b \\ \frac{d\theta}{dT'} &= \omega_b \end{aligned}\right\} \text{at } T' = 0. \tag{II.01}$$

Introducing the dimensionless measures given by (I.02′) and taking the case of constant tracking, we have

$$\frac{d^2\Delta'}{dT'^2}+\frac{d\Delta'}{dT'}+\kappa\Delta'=\omega_g$$

$$\left.\begin{aligned}\Delta'=\Delta_b'=-\phi_b\\ \frac{d\Delta'}{dT'}=\omega_g-\omega_b\equiv\Omega_b\end{aligned}\right\}\text{at } T'=0. \tag{II.02}$$

Upon integration of (II.02) we get:

$$\Delta'=\frac{\omega_g}{\kappa}+(\phi_b+\omega_g/\kappa)e^{-T'/2}\frac{\sin\nu_0(T'-T_0')}{\sin\nu_0T_0'} \tag{II.02′}$$

with

$$T_0'=\frac{1}{\nu_0}\left[\pi-\sin^{-1}\frac{1}{[1+(-z_b/\nu_0)^2]^{\frac{1}{2}}}\right]$$

$$=\frac{1}{\nu_0}\left[\pi-\tan^{-1}\left(\frac{\nu_0}{-z_b}\right)\right]$$

$$=\frac{1}{\nu_0}\left[\frac{\pi}{2}-\tan^{-1}\frac{z_b}{\nu_0}\right]$$

where we have introduced the convenient abbreviations

$$z_b\equiv\frac{\Omega_b}{\phi_b+\omega_g/\kappa}-\tfrac{1}{2}\equiv\frac{I}{B}\frac{v_g-v_b}{\theta_b+Bv_g/m_0}-\tfrac{1}{2}$$
$$\nu_0\equiv(\kappa-\tfrac{1}{4})^{\frac{1}{2}}\equiv\frac{(4m_0I-B^2)^{\frac{1}{2}}}{2B} \tag{II.03}$$

It is clear that the mean steady-state deviation in this type of system with proportional control is then

$$\Delta_\infty'=\frac{\omega_g}{\kappa}\quad D_\infty'=\frac{B}{m_0}v_g$$

and is just *the deflection which evokes the restoring force required to drag the system along against friction at the velocity $v_g$*. This is of course only a special case of the general result for $\Delta_\infty'$ described in the preceding section. For the time dependent deviation from $\Delta_\infty'$ there are three cases:

*Case I*: $\nu_0^2>0$. *Oscillatory Approach to Steady State*

$$\Delta=(\phi_b+\omega_g/\kappa)e^{-T'/2}\frac{\sin\nu_0(T'-T_0')}{\sin\nu_0T_0'}.$$

As $v_0$ approaches 0, $T_0'$ may be represented approximately by

$$T_0'\simeq\frac{\pi}{\nu_0}+\frac{1}{z_b}\quad\text{if}\quad z_b<0,$$

$$T_0'\simeq\frac{1}{z_b}\qquad\text{if}\quad z_b>0.$$

The deviation amplitude in the steady state $\Delta_\infty$ is zero, and the number of transient cycles $n_\infty$ and time $T_\infty$ required to reach the steady state are both infinite.

*Case II*: $\nu_0^2=0$. *Critically Damped Approach to Steady State*

$$\Delta=(\phi_b+\omega_g/\kappa)e^{-T'/2}\left(\frac{T'}{T_0'}-1\right)$$

where

$$T_0'=\infty\quad\text{if}\quad z_b<0,$$

$$T_0'=\frac{1}{z_b}\quad\text{if}\quad z_b>0.$$

Thus we see that the number of cycles $n_\infty$ before the asymptotically approached steady state is either 0 or ½, depending on whether $z_b$ is less than or greater than zero. In the latter case Δ becomes zero once at $T_0'$, and overshoots the mark, later subsiding asymptotically to zero again. Examining the structure of $z_b$, we see that this occurs under the following sets of circumstances:

$I/B$ sufficiently large
$v_g-v_b$ sufficiently large
$\theta_b$ small, $m_0/Bv_g$ sufficiently large.

*Case III*: $\nu_0^2<0$. *Overdamped Approach to Steady State*

$$\Delta=(\phi_b+\omega_g/\kappa)e^{-T'/2}\frac{\sinh|\nu_0|(T'-T_0')}{\sinh|\nu_0|T_0'}$$

where

$$T_0' = \frac{1}{|\nu_0|}\sinh^{-1}\frac{1}{[(-z_b/\nu_0)^2-1]^{\frac{1}{2}}}$$

$$= -\frac{1}{|\nu_0|}\tanh^{-1}\frac{|\nu_0|}{-z_b}$$

$$= \ln\left|\frac{z_b+|\nu_0|}{z_b-|\nu_0|}\right|^{1/2|\nu_0|}.$$

It appears that $T_0'$ has a real positive finite value only for $z_b > |\nu_0|$. Thus the smallest possible real values of $T_0'$ and the number $n_\infty$ of transient cycles during the approach to the steady state of zero deviation are governed by the rule

$$T_0' \text{ finite} \quad n_\infty = \tfrac{1}{2} \quad \text{if } z_b > |\nu_0|$$
$$T_0' = \infty \quad n_\infty = 0 \quad \text{if } z_b < |\nu_0|.$$

This is to be compared with the corresponding condition in Case II: A schedule of the possible real $T_0'$ in the various cases, together with an analysis, by means of the unit circle in the trigonometric plane, of the limits approached, is given in Table IV.

For fixed $z_b > 0$, it is clear from the nature of the function $(1/x)\tanh^{-1}x$ that $T_0'$ has its minimum value at $\nu_0 = 0$, i.e., for critical damping. Thus, *if the objective is to attain* $T_0'$ *as quickly as possible, we shall certainly strive to keep the damping below the critical value.*

We pass now to the consideration of the amplitude time dependence in the various cases. The most interesting circumstances are those in which there is oscillation as in Case I, or when there is overshoot in Cases II and III.

*Case* I: If we shift to the time scale

$$T = T' - T_0'$$

$$\Delta = (\phi_b + \omega_g/\kappa)e^{-(T+T_0')/2}\frac{\sin\nu_0 T}{\sin\nu_0 T_0'}$$

TABLE IV. Smallest real $T_0'$ as a function of $\nu_0$ and $z_b$ for the proportional robot.

$\longleftarrow \nu_0^2$

| | $\nu_0$ Real: oscillation<br>$T_0' = \frac{1}{\nu_0}\left\lvert \pi - \tan^{-1}\frac{\nu_0}{-z_b}\right\rvert = \frac{[\ ]}{\nu_0}$ | | $\nu_0 \to$ zero<br>Critical damping | zero $\leftarrow \lvert\nu_0\rvert$ | $\nu_0$ Imaginary: overdamping |

| ↑<br>$z_b$ | | | | | |
| $z_b$ zero | $T_0' = \pi/2\nu_0$ |  | $\frac{\pi}{2\nu_0} \to \infty$ | $\infty$ | $\infty$ |
| ↑ | | | | | |
| $z_b$ minus | • |  | $\frac{\pi}{\nu_0} \to \infty$ | $\infty$ | $\infty$ |

$z_b$ can be plus or minus.
$\nu_0$ can be real or imaginary.

we may represent the beginning of each cycle by

$$\mathrm{T}_n=\frac{2n\pi}{\nu_0}\qquad (n=0,\,1,\,2,\,\cdots)$$

and the middle (node) by

$$\mathrm{T}_{n+\frac{1}{2}}=\frac{(2n+1)\pi}{\nu_0}=\mathrm{T}_n+\frac{\pi}{\nu_0}.$$

The times when the maximum and minimum deviations occur in the cycle are found by examining the zeros of the velocity

$$\Omega\equiv\frac{d\Delta}{d\mathrm{T}}=\frac{\phi_b+\omega_g/\kappa}{\sin\nu_0\mathrm{T}_0'}e^{-(\mathrm{T}+\mathrm{T}_0')/2}$$

$$\times\left[-\tfrac{1}{2}\sin\nu_0\mathrm{T}+\nu_0\cos\nu_0\mathrm{T}\right]$$

to be

$$\bar{\mathrm{T}}_n=\mathrm{T}_n+\frac{1}{\nu_0}\tan^{-1}2\nu_0$$

$$\underline{\mathrm{T}}_n=\mathrm{T}_n+\frac{1}{\nu_0}\tan^{-1}2\nu_0+\frac{\pi}{\nu_0}.$$

In particular

$$\bar{\mathrm{T}}_0=\frac{1}{\nu_0}\tan^{-1}2\nu_0.$$

The maximum amplitude of deviation in the $n$-th cycle, or the amplitude-time function, is then:

$$\bar{\Delta}_n=\bar{\Delta}_0e^{-\mathrm{T}_n/2},$$

where $\Delta_0$, the maximum deviation amplitude in the first cycle, is

$$\bar{\Delta}_0=(\phi_b+\omega_g/\kappa)e^{-(\bar{\mathrm{T}}_0+\mathrm{T}_0')/2}\,\frac{\sin\nu_0\bar{\mathrm{T}}_0}{\sin\nu_0\mathrm{T}_0'}.$$

But

$$\bar{\mathrm{T}}_0+\mathrm{T}_0'=\frac{1}{\nu_0}\left[\pi-\tan^{-1}\frac{\nu_0}{-z_b}+\tan^{-1}2\nu_0\right]$$

$$=\frac{1}{\nu_0}\left[\pi-\tan^{-1}\left(\nu_0\frac{2z_b+1}{-z_b+2\nu_0^2}\right)\right],$$

and

$$\frac{\sin\kappa_0\bar{\mathrm{T}}_0}{\sin\nu_0\mathrm{T}_0'}=\left(\frac{1+(z_b/\nu_0)^2}{1+(1/2\nu_0)^2}\right)^{\frac{1}{2}},$$

so that

$$\bar{\Delta}_0=(\phi_b+\omega_g/\kappa)\left(\frac{\nu_0^2+z_b^2}{\nu_0^2+\frac{1}{4}}\right)^{\frac{1}{2}}$$

$$\times\exp-\frac{1}{2\nu_0}\left[\pi-\tan^{-1}\left(\nu_0\frac{2z_b+1}{-z_b+2\nu_0^2}\right)\right].$$

*Case* II, $z_b>0$: The time when the maximum deviation amplitude occurs is here given by

$$\mathrm{T}=2\quad\text{or}\quad \mathrm{T}'=\mathrm{T}_0'+2=\frac{1}{z_b}+2,$$

and the associated maximum deviation amplitude is

$$\bar{\Delta}=2z_b(\phi_b+\omega_g/\kappa)e^{-(1+1/2z_b)}.$$

*Case* III, $z_b>|\nu_0|$: With respect to the shifted time scale, $\Delta$ may here be written:

$$\Delta=(\phi_b+\omega_g/\kappa)((z_b/\nu_0)^2-1)^{\frac{1}{2}}\left[\frac{z_b-|\nu_0|}{z_b+|\nu_0|}\right]^{1/4|\nu_0|}$$

$$e^{-\mathrm{T}/2}\sinh|\nu_0|\mathrm{T}.$$

The time when the maximum amplitude of overshoot is reached is found by examining the zero of $d\Delta/d\mathrm{T}'$, to be

$$\bar{\mathrm{T}}=\frac{1}{\nu_0}\tanh^{-1}2|\nu_0|=\ln\left[\frac{1+2|\nu_0|}{1-2|\nu_0|}\right]^{1/2|\nu_0|}$$

which, upon insertion into the expression for $\Delta$, yields the maximum amplitude

$$\bar{\Delta}=(\phi_b+\omega_g/\kappa)\left(\frac{z_b^2-|\nu_0|^2}{\frac{1}{4}-|\nu_0|^2}\right)^{\frac{1}{2}}$$

$$\times\left[\frac{1-2|\nu_0|}{1+2|\nu_0|}\,\frac{z_b-|\nu_0|}{z_b+|\nu_0|}\right]^{1/4|\nu_0|}.$$

It is clear from the above expressions that in order that there shall actually be finite real values for T and $\Delta$, it is also necessary that

$$|\nu_0|<\tfrac{1}{2}\ (\nu_0\ \text{pure imaginary}).$$

But this is merely the condition that

$$\kappa\equiv\frac{m_0I}{B^2}>0$$

i.e., *in order that the time and amplitude of overshoot may not increase indefinitely it is necessary that the restoring force factor be positive.* This requirement is otherwise obvious on physical grounds.

We shall now determine the fidelity fraction for Case I, which is the only case in which the concept has much interest. The expression for $\Omega$ given above may be rewritten

$$\Omega(\mathrm{T}) = -\Delta_b\nu_0(1+(z_b/\nu_0)^2)^{\frac{1}{2}}e^{-(\mathrm{T}+\mathrm{T}_0')/2}\cos\nu_0\mathrm{T} - \tfrac{1}{2}\Delta(\mathrm{T}),$$

and if we evaluate this at $\mathrm{T}=\mathrm{T}_n$ and $\mathrm{T}=\mathrm{T}_{n+\frac{1}{2}}$, we find

$$\Omega(\mathrm{T}_n) = \nu_0\bar{\Delta}_n e^{\bar{\mathrm{T}}_0/2}(1+1/4\nu_0^2)^{\frac{1}{2}}$$

$$= \nu_0 \exp\frac{1}{2\nu_0}\tan^{-1}2\nu_0(1+1/4\nu_0^2)^{\frac{1}{2}}\bar{\Delta}_n$$

$$\Omega(\mathrm{T}_{n+\frac{1}{2}}) = -\Omega(\mathrm{T}_n)e^{-\pi/2\nu_0}.$$

Inserting these expressions into the formulas for $f_\Delta$, and remembering that the period $\pi_n$ is given by the constant $2\pi/\nu_0$, we have

$$f_\Delta = \frac{1}{2\pi}\exp-\frac{1}{2\nu_0}\tan^{-1}2\nu_0(1+e^{\pi/2\nu_0})\frac{1}{\bar{\Delta}_n(1+1/4\nu_0^2)^{\frac{1}{2}}}.$$

*Thus, except for a constant factor, the fidelity fraction varies inversely with the deviation amplitude.*

In ordinary dimensional and $\mathcal{T}Es$ measure (see definitions (I.11) Section (C) Part I) the amplitude-time function may be written.

$$\bar{D} = \bar{D}_0 e^{-(B/2I)T} \equiv \bar{D}_0 e^{(\omega_g/2)\mathcal{T}}$$

and the fidelity fraction is:

$$f = f_0 e^{(B/2I)T} \equiv f_0 e^{(\omega_g/2)\mathcal{T}},$$

where

$$\bar{D}_0 = \left(\theta_b + \frac{B}{m_0}v_g\right)\left(\frac{\nu_0^2+z_b^2}{\nu_0^2+\frac{1}{4}}\right)^{\frac{1}{2}} \times \exp-\frac{1}{2\nu_0}\left[\pi - \tan^{-1}\left(\nu_0\frac{2z_b+1}{-z_b+2\nu_0^2}\right)\right],$$

$$f_0 = \frac{1}{2\pi}\exp-\frac{1}{2\nu_0}\tan^{-1} \times 2\nu_0(1+e^{\pi/2\nu_0})\frac{1}{\bar{D}_0(1+1/4\nu_0^2)^{\frac{1}{2}}}.$$

For simplicity we shall set $\theta_b=0$ in the following analysis. The definitions (I.03) may then be written in $\mathcal{T}Es$ measure

$$\nu_0 = \left(\frac{E}{\omega_g^2} - 1\right)^{\frac{1}{2}}$$
$$z_b = \frac{Es}{\ } - \tfrac{1}{2} \equiv s(\nu_0^2+1) - \tfrac{1}{2}. \tag{II.04}$$

The argument of the arc-tangent in the exponent of $\bar{D}_0$ then takes the form

$$\nu_0\frac{2z_b+1}{2\nu_0^2-z_b} = \nu_0\frac{2s(\nu_0^2+1)}{\nu_0^2(2-s)-s+\frac{1}{2}}$$

We shall examine in detail only the approximation $\nu_0>>1$ corresponding to short period oscillations, or low damping $B$ relative to the square root of the product of motor strength $m_0$ by inertia $I$. For this limit the arc-tangent approaches $\pi/2$ and we may write

$$\bar{D}_0 \simeq \omega_g(1+s^2\nu_0^2)^{\frac{1}{2}}e^{-(\pi/4\nu_0)}$$

or, making use of the fact that in this approximation

$$\nu_0 = \frac{(E)^{\frac{1}{2}}}{\omega_g},$$

we may write

$$\bar{D} = (\omega_g^2+Es^2)^{\frac{1}{2}}\exp-\left(\frac{\pi}{4(E)^{\frac{1}{2}}}+\frac{\mathcal{T}}{2}\right)\omega_g$$

$$= \left(\left(\frac{Bv_g}{m_0}\right)^2 + \frac{Iv_g^2}{m_0}\left(1-\frac{v_0}{v_g}\right)^2\right)^{\frac{1}{2}} \times \exp\left(-\frac{B}{2I}T - \frac{\pi B}{4(m_0I)^{\frac{1}{2}}}\right).$$

We pause here for a moment to draw some general conclusions. It is clear from the expression that *the deviation amplitude at any given time will be smaller the smaller the guide velocity $v_g$ and its difference from the initial velocity of the system $v_0$, the smaller the inertia of the load $I$, and the greater the strength of the power source $m_0$* (above the maximizing value $m_0^*=8(I)^{\frac{1}{2}}/\pi B$). As mentioned before, the inertia of the load, the strength of the power source, etc., will often be fixed by other considerations. The most controllable factor is likely to be the friction coefficient $B$ as contained in the parameter $\omega_g$. We now proceed to determine for what values of $\omega_g$, $\bar{D}$ is a minimum, the value of this minimum, and its sensitivity (defined in the introduction).

It will be convenient to introduce the abbreviations

$$\mathcal{T}' = (E)^{\frac{1}{2}} s\left(\tau + \frac{\pi}{2(E)^{\frac{1}{2}}}\right)$$

$$\equiv \left(1 - \frac{v_0}{v_g}\right)\left(\left(\frac{m_0}{I}\right)^{\frac{1}{2}} T + \frac{\pi}{2}\right)$$

$$\omega_g' \equiv \frac{\omega_g}{(E)^{\frac{1}{2}} s} \equiv \frac{B}{(m_0 I)^{\frac{1}{2}}} \frac{v_g}{v_g - v_0}$$

as measures of the time and guide velocity in this case. With these notations we may write

$$\bar{D} = (E)^{\frac{1}{2}} s (1 + \omega_g'^2)^{\frac{1}{2}} e^{-(\omega_g'/2)\mathcal{T}'}.$$

From the formula for $\bar{D}$ we find, consecutively,

$$\frac{\partial \bar{D}}{\partial \omega_g'} = \bar{D}\left[\frac{\omega_g'}{1 + \omega_g'^2} - \frac{\mathcal{T}'}{2}\right],$$

$$\frac{\partial^2 \bar{D}}{\partial \omega_g'^2} = \frac{1}{\bar{D}}\left(\frac{\partial \bar{D}}{\partial \omega_g'}\right)^2 + \bar{D}\frac{1 - \omega_g'^2}{1 + \omega_g'^2}.$$

Thus

$$(\omega_g')_{\min} \equiv \underline{\omega}_g' = \frac{1 - (1 - \mathcal{T}'^2)^{\frac{1}{2}}}{\mathcal{T}'} \quad \omega_g'^2 = \frac{2\omega_g'}{\mathcal{T}'} - 1$$

$$\bar{D}_{\min} = (E)^{\frac{1}{2}} s \left(\frac{2\underline{\omega}_g'}{\mathcal{T}'}\right)^{\frac{1}{2}} e^{-(\omega_g'/2)\mathcal{T}'}$$

$$S_{\min} \equiv \frac{1}{\bar{D}_{\min}} \frac{\partial^2 \bar{D}}{\partial \omega_g'^2} \left(\frac{d\omega_g'}{dB}\right)^2$$

$$= \frac{1}{m_0 I (1 - v_0/v_g)^2} \left(\frac{\mathcal{T}'}{\underline{\omega}_g'} - 1\right) > 0,$$

where we have indicated the necessary condition that the extreme value represent a minimum by the inequality on $S$.

In the neighborhood of $\mathcal{T}' = 0$ we have

$$(\omega_g')_{\min} \simeq \frac{\mathcal{T}'}{2}$$

$$\frac{\bar{D}_{\min}}{(E)^{\frac{1}{2}} s} \simeq e^{-(\mathcal{T}'/2)^2} \tag{II.05}$$

$$m_0 I (1 - v_0/v_g)^2 S_{\min} \simeq 1,$$

and in the neighborhood of $\mathcal{T}' = 1$

$$\underline{\omega}_g' \to 1 \quad \frac{d\underline{\omega}_g'}{d\mathcal{T}'} \to \infty \quad \text{(cusp)}$$

$$\frac{\bar{D}_{\min}}{(E)^{\frac{1}{2}} s} \to (2)^{\frac{1}{2}} e^{-\frac{1}{2}} \sim 0.85 \tag{II.06}$$

$$S_{\min} \to 0.$$

This limiting behavior, as well as the variation throughout the interval, is exhibited in Fig. 2, where $\omega_g'$, $\bar{D}_{\min}/(E)^{\frac{1}{2}} s$, and $m_0 I (1 - v_0/v_g)^2 S_{\min}$ are all plotted as functions of the time variable $\mathcal{T}'$. Beyond $\mathcal{T}' = 1$ there is no real minimum for $\bar{D}$.

In similar fashion to the above we may carry out the analysis for the fidelity fraction. We find

$$f_0 = \frac{1}{\pi} \frac{\cosh \frac{\pi}{4(E)^{\frac{1}{2}}} \omega_g}{\bar{D}_0} \equiv \frac{1}{\pi} \frac{\cosh \frac{\pi}{4} s \omega_g'}{\bar{D}_0},$$

so that

$$f = \frac{1}{\pi} \frac{\cosh \frac{\pi}{4} s \omega_g'}{\bar{D}}.$$

Making use of the preceding analysis of $\bar{D}$, we find

$$\frac{\partial f}{\partial \omega_g'} = f\left[\frac{\pi s}{4} \tanh \frac{\pi s}{4} \omega_g' - \frac{\omega_g'}{1 + \omega_g'^2} + \frac{\mathcal{T}'}{2}\right]$$

$$\frac{\partial^2 f}{\partial \omega_g'^2} = \frac{1}{f}\left(\frac{\partial f}{\partial \omega_g'}\right)^2 + f\left[\left(\frac{\pi s}{4}\right)^2 \operatorname{sech}^2 \frac{\pi s}{4} \omega_g' - \frac{1 - \omega_g'^2}{1 + \omega_g'^2}\right]. \tag{II.07}$$

If we set

$$\frac{\pi s}{4} \omega_g' \simeq 0$$

corresponding to the inequality $E >> \omega_g^2$, we may rewrite these expressions in the simplified form

$$\frac{\partial f}{\partial \omega_g'} = -f\left[\frac{\omega_g'}{1 + \omega_g'^2} - \frac{\mathcal{T}'}{2}\right]$$

$$\frac{\partial^2 f}{\partial \omega_g'^2} = \frac{1}{f}\left(\frac{\partial f}{\partial \omega_g'}\right)^2 + f\left[\left(\frac{\pi s}{4}\right)^2 - \frac{1 - \omega_g'^2}{1 + \omega_g'^2}\right].$$

From these we may deduce that to this approximation $(\underline{\omega}_g')_{\max}$ *is equal to* $(\omega_g')_{\min}$. Thus

$$(\omega_g')_{\max}=\underline{\omega}_g'=\frac{1-(1-\mathcal{T}'^2)^{\frac{1}{2}}}{\mathcal{T}'}$$

$$f_{\max}=\frac{1}{\pi\bar{D}_{\min}}=\frac{1}{\pi(E)^{\frac{1}{2}}s}\left(\frac{\mathcal{T}'}{2\underline{\omega}_g'}\right)^{\frac{1}{2}}e^{(\omega_g'/2)\mathcal{T}'}$$

$$m_0I(1-v_0/v_g)^2S_{\max}=\frac{\pi^2s^2}{16}+1-\frac{\mathcal{T}'}{\omega_g'}\leq 0.$$

$\pi(E)^{\frac{1}{2}}s\,f_{\max}$ is also plotted in Fig. 6. We note that the only difference in the conditions determining $f_{\max}$ and $\bar{D}_{\min}$ here is that the maximizing condition holds in a more restricted range, i.e.,

$$\frac{\underline{\omega}_g'}{\mathcal{T}'}\leq\frac{1}{1+(\pi s/4)^2},$$

which, together with the preceding equations, determines the following inequalities for the domain in which $f$ is still maximized

$$-\left(\frac{1-\pi^2s^2/16}{1+\pi^2s^2/16}\right)^{\frac{1}{2}}\leq\omega_g'\leq\left(\frac{1-\pi^2s^2/16}{1+\pi^2s^2/16}\right)^{\frac{1}{2}}$$

$$-[(1+\pi^2s^2/16)(1-\pi^2s^2/16)]^{\frac{1}{2}}\leq\mathcal{T}'$$
$$\leq[(1+\pi^2s^2/16)(1-\pi^2s^2/16)]^{\frac{1}{2}}$$

$$\frac{1}{(E)^{\frac{1}{2}}\pi s}\leq f_{\max}\leq\frac{1}{(E)^{\frac{1}{2}}\pi s}[\tfrac{1}{2}(1+\pi^2s^2/16)]^{\frac{1}{2}}e^{\frac{1}{2}(1-\pi^2s^2/16)}.$$

The formulas given here and above are the base for the general summary diagram (Fig. 9) at the end of the Part I indicating the domains of the variables in which we get real extrema for $\bar{D}_{\min}$ and $f_{\max}$.

### B. PATH CURVES IN THE POSITION-VELOCITY PLANE

For future use[1,2] we shall now work out the result of eliminating the time between the expression (II.02′) and its time derivative $\Omega\equiv d\Delta'/d\tau$ which satisfies the relation

$$\Omega+\tfrac{1}{2}(\Delta'-\omega_g/\kappa)=-\nu_0(\Delta_b'-\omega_g/\kappa)$$
$$\times e^{-\mathrm{T}'/2}\frac{\cos\nu_0(\mathrm{T}'-\mathrm{T}_0')}{\sin\nu_0\mathrm{T}_0'}.\qquad\text{(II.02'')}$$

Making the substitutions (which correspond to an "affine" transformation in the $\Omega-\Delta$ plane)

$$\Delta\equiv\Delta'-\omega_g/\kappa\quad y\equiv\Omega+\tfrac{1}{2}(\Delta'-\omega_g/\kappa),$$

with some rearrangement we may write (II.02′) and (II.02″):

$$\nu_0\Delta=-((\nu_0\Delta_b)^2+y_b^2)^{\frac{1}{2}}e^{-\mathrm{T}'/2}\sin\nu_0(\mathrm{T}'-\mathrm{T}_0'),$$
$$y=-((\nu_0\Delta_b)^2+y_b^2)^{\frac{1}{2}}e^{-\mathrm{T}'/2}\cos\nu_0(\mathrm{T}'-\mathrm{T}_0'),$$

from which we may find

$$\mathrm{T}'=\mathrm{T}_0'+\frac{1}{\nu_0}\tan^{-1}\frac{\nu_0\Delta}{y}=\frac{1}{\nu_0}\left[\tan^{-1}\frac{z}{\nu_0}-\tan^{-1}\frac{z_b}{\nu_0}\right],$$

where we have introduced the "clock-hand variable"

$$z\equiv-y/\Delta\equiv-(\Omega/\Delta+\tfrac{1}{2}).$$

Thus

$$(\nu_0\Delta)^2+y^2=[(\nu_0\Delta_b)^2+y_b^2]$$
$$\times\exp-\frac{1}{\nu_0}\left[\tan^{-1}\frac{z}{\nu_0}-\tan^{-1}\frac{z_b}{\nu_0}\right]\qquad\text{(II.08)}$$

which becomes in polar coordinates the equation of a right-handed (clockwise) equiangular spiral

$$\rho=\rho_be^{-(\psi-\psi_b)/2\nu_0}$$

with

radius vector $\rho\equiv((\nu_0\Delta)^2+y^2)^{\frac{1}{2}}$
(clockwise) angle $\psi\equiv\tan^{-1}(z/\nu_0)$.

Thus, in the case of underdamping (Case I) *the "path" of the linear robot in the phase-plane ($\Omega-\Delta'$ plane) is an affine distortion of a right-handed logarithmic spiral with center at $\omega_g/\kappa$ (or $\Delta=0$).* For the further analysis it is desirable to elucidate the meaning of what we have called the "clock-hand variable" $z$. We note that, in the $\Omega-\Delta$ plane, the successive values of $z$ correspond to straight lines through the origin arranged in clockwise increasing order. $z$, which equals the

negative slope $-\frac{1}{2}$

of these lines, goes from $-\infty$ to $+\infty$ twice in making one complete circuit; once in going from the $+\Omega$ axis to the $-\Omega$ axis, and a second time in going from the $-\Omega$ axis back to the $+\Omega$ axis. The zero of $z$ is not the $\Delta$ axis but rather the line

$$\Omega/\Delta=-\tfrac{1}{2}.$$

In the case of overdamping $\nu_0^2<0$ (Case III) we may write $\nu_0=i|\nu_0|$ and our basic Eq. (II.08) goes over to the form

$$y^2-|\nu_0|^2\Delta^2=(y_b^2-|\nu_0|^2\Delta_b^2)$$
$$\times\left|\frac{z_b-|\nu_0|}{z_b+|\nu_0|}\,\frac{z+|\nu_0|}{z-|\nu_0|}\right|^{1/2|\nu_0|}. \quad \text{(II.08')}$$

We see that all the curves beginning in the region $z_b<-|\nu_0|$ (i.e., the right-upper or left-lower portion of the plane) go in to zero touching along the line $z=-|\nu_0|$. All curves beginning in the region $z>|\nu_0|$ (i.e., right-lower or left-upper portion of the plane) overshoot $\Delta=0$, crossing the $\Delta$ axis at the points

$$\Omega=\pm[y_b^2-|\nu_0|^2\Delta_b^2]\left|\frac{z_b-|\nu_0|}{z_b+|\nu_0|}\right|^{1/4|\nu_0|}.$$

Finally all curves beginning in the intermediate region

$$-|\nu_0|<z_b<|\nu_0|$$

move counter-clockwise into the origin, touching the line $z=-|\nu_0|$ like all the others. If extrapolated backward ($z$ fixed, $z_b$ shifting) these lines are all asymptotically parallel to the line $z=|\nu_0|$.

In the case of critical damping $\nu_0=0$ (Case II), the equation of the path-curve takes the form

$$y^2\equiv(\Omega+\Delta\ 2)^2=(\Omega_b+\Delta_b/2)^2e^{1/z-1/z_b}, \quad \text{(II.08'')}$$

and the intermediate region of Case III has shrunk down to the line $y=0$ or $\Omega=-\Delta/2$.

It is interesting and important to note that if one takes the limit of (II.08') as the restoring force constant $\kappa\to0$ and $|\nu_0|\to\frac{1}{2}$, one obtains in the limit

$$\Omega=\Omega_b,$$

which is definitely *not* the general solution in this case.[2] This situation, where the limit of the solution when a coefficient *approaches zero* is not the same as the solution when the coefficient *is zero*, seems to be not uncommon in differential equations. Knowing that it occurs, one must then make special examination of the case at the limit. This case is contained in the analysis in the succeeding paper dealing with on-off systems.

# Computation of the Solutions of $(1+2\epsilon\cos 2z)y''+\theta y=0$; Frequency Modulation Functions

N. W. McLachlan
*London, England*

(Received January 9, 1947)

This equation pertains to a loss-free frequency modulation circuit. Floquet's theory is applied to obtain stable solutions when $\theta$, $\epsilon$ are outside the range of the approximation solution given by Carson in 1922. A method is described by means of which solutions may be computed to any degree of accuracy. The necessary formulae associated with the solution are derived, and convergence is discussed. A numerical example, illustrating the procedure to be followed, is worked out in detail. An appropriate normalization of the solutions is suggested in order to obtain standard frequency modulation functions. It is shown how the analysis may be extended to cover the case of the equation

$$d^2Q/dt^2+(R/L)(dQ/dt)+[Q/LC_0(1+2\epsilon\cos 2\omega_1 t)]=0,$$

which applies to a frequency modulation circuit having constant resistance $R$.

## 1. INTRODUCTION

THIS equation occurs in the theory of a method used for transmitting signal characters in radio broadcasting. The method is known as frequency modulation, and it is also the basis of the warble tone employed to reduce standing wave effects in acoustical test rooms. In the circuit shown schematically in Fig. 1A, the capacitance $C$ is a periodic function of the time $t$, being represented by the formula $C=C_0(1+2\epsilon\cos 2\omega_1 t)$, where $C_0$ and $\epsilon$ are parameters with $|\epsilon|<0.5$. If $Q$ is the quantity of electricity on the capacitance at any instant, the differential equation for the circuit is

$$(d^2Q/dt^2)+Q/LC_0(1+2\epsilon\cos 2\omega_1 t)=0. \qquad (1)$$

By writing $\omega_0{}^2=1/LC_0$, $\theta=(\omega_0/\omega_1)^2$, $\omega_1 t=z$, $y=Q$, (1) becomes

$$d^2y/dz^2+\theta y/(1+2\epsilon\cos 2z)=0. \qquad (2)$$

Expressed in this way, we see that if $|\epsilon|\geqslant 0.5$, $(1+2\epsilon\cos 2z)$ has zeros, and, therefore, $\theta/(1+2\epsilon\cos 2z)$ has corresponding infinities. These are avoided by imposing the restriction $|\epsilon|<0.5$. In radio broadcasting $|\epsilon|<<<0.5$, and to an adequate approximation (2) may be written

$$y''+(a\dot{-}2q\cos 2z)y=0, \qquad (3)$$

where $a=\theta$, and $q=\theta\epsilon$. Then (3) is the canonical form of Mathieu's differential equation. When (a), $a$ is very large and positive, (b) $a>>>q>0$, an approximate solution of (3) is given by

$$y=C\sum_{-\infty}^{\infty}J_r(q/2a^{\frac{1}{2}})\cos[(a^{\frac{1}{2}}-2r)z-\psi], \qquad (4)$$

$$=C\sum_{-\infty}^{\infty}J_r(\omega_0\epsilon/2\omega_1)\cos[(\omega_0-2r\omega_1)t-\psi], \qquad (5)$$

$C$ and $\psi$ being arbitrary constants. This form of solution was obtained by Carson in 1922.[1] Typical values of the various parameters in radio frequency modulation are: $f_0=\omega_0/2\pi=5\times 10^7$ c.p.s., $f_1=\omega_1/2\pi=5\times 10^3$ c.p.s., $f_0\epsilon=\omega_0\epsilon/2\pi$, $=\Delta f=\Delta\omega/2\pi=10^4$ c.p.s., this being the frequency deviation on either side of the central frequency $f_0$. Thus $\epsilon=2\times 10^{-4}$, so in (2) it is justifiable to take $(1+2\epsilon\cos 2z)^{-1}\simeq(1-2\epsilon\cos 2z)$. We also have $a=\theta=(f_0/f_1)^2=10^8$, and $q=\theta\epsilon=2\times 10^4$, so the conditions for (4) to be an approximate solution of (3) are satisfied. The values of the parameters for the acoustical warble tone do not always satisfy these conditions, and we have then to solve the equation

$$(1+2\epsilon\cos 2z)y''+\theta y=0 \qquad (6)$$

without using the above approximation. In succeeding sections it is shown how this may be accomplished to any desired degree of accuracy.

## 2. THEORETICAL CONSIDERATIONS

Since the coefficient of $y''$ in (6) Section 1 is single-valued and periodic in $z$, that of $y$ being

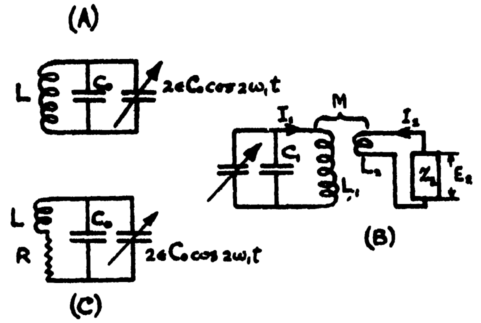

FIG. 1. (A) Schematic representation of loss-free oscillatory circuit with periodically variable capacitance $C=C_0(1+2\epsilon\cos 2\omega_1 t)$. (B) As at (A) but the circuit loosely coupled by $L_2$ to a second circuit. (C) As at (A) but the circuit having constant resistance $R$.

constant, Floquet's theory may be applied.[2] Thus the solutions are either stable, unstable, or neutral, according to the values of $\theta$ and $\epsilon$. For present purposes we shall consider stable solutions. Thus linearly independent formal solutions are[4]

$$y_1(z)=\sum_{-\infty}^{\infty} c_{2r}\cos(2r+\rho)z, \tag{1}$$

and

$$y_2(z)=\sum_{-\infty}^{\infty} c_{2r}\sin(2r+\rho)z, \tag{2}$$

provided the point $(\theta, \epsilon)$ lies in certain regions of the $(\theta, \epsilon)$ plane defined below, and $0<\rho<1$. For other regions of the plane, the solutions take the forms

$$y_1(z)=\sum_{-\infty}^{\infty} c_{2r+1}\cos(2r+1+\rho)z, \tag{3}$$

and

$$y_2(z)=\sum_{-\infty}^{\infty} c_{2r+1}\sin(2r+1+\rho)z. \tag{4}$$

These forms will be comprehended readily by reference to McLachlan,[3] Chapter 4, in which there are stability charts for Mathieu's equation (3) Section 1. In these the $(a, q)$ plane is mapped out into regions where the solutions are (a) stable, (b) unstable. A similar chart may be drawn for Eq. (6) Section 1, but in this case although $\theta$ is unlimited, $\epsilon$ is restricted to the strip $|\epsilon|<0.5$, as illustrated in Fig. 2. The values of $(\theta, \epsilon)$ in which we are interested, lie *within* the stable regions, being on the iso-$\rho$ curves. The full-line curves correspond to the characteristic curves for solutions of Mathieu's equation of positive integral order, and pertain to kindred solutions of (6) Section 1. They are designated $\alpha_m$, $\beta_m$, with $m=2n$, $2n+1$, or $2n+2$. When the point $(\theta, \epsilon)$ lies *between* $\alpha_{2n}$ and $\beta_{2n+1}$, the solutions (1), (2) are used, whereas for the regions *between* $\alpha_{2n+1}$ and $\beta_{2n+2}$, (3), (4) are used. If these solutions are normalized as shown in Section 12, they may then be regarded as *frequency modulation functions*, or f-m functions for brevity.

## 3. RECURRENCE RELATIONS FOR THE COEFFICIENTS IN (1)–(4) SECTION 2

Substituting either (1) or (2) into (6) Section 1, and equating the coefficient of $\cos(2r+\rho)z$, or that of $\sin(2r+\rho)z$ to zero, $r=-\infty$ to $+\infty$, we obtain the recurrence relation

$$[\theta-(2r+\rho)^2]c_{2r}-\epsilon[(2r+2+\rho)^2c_{2r+2} \\ +(2r-2+\rho)^2c_{2r-2}]=0. \tag{1}$$

The relation for (3), (4) Section 2 is

$$[\theta-(2r+1+\rho)^2]c_{2r+1}-\epsilon[(2r+3+\rho)^2c_{2r+3} \\ +(2r-1+\rho)^2c_{2r-1}]=0. \tag{2}$$

Both (1), (2) are linear difference equations of the second order, and each has two independent solutions, the character of which we shall now investigate. Dividing (1) throughout by $c_{2r}$ and writing $v_{2r}=c_{2r+2}/c_{2r}$ we get

$$(2r+2+\rho)^2v_{2r}+(2r-2+\rho)^2v_{2r-2}^{-1} \\ =[\theta-(2r+\rho)^2]\epsilon^{-1}, \tag{3}$$

or

$$v_{2r}+\left(\frac{2r-2+\rho}{2r+2+\rho}\right)^2 v_{2r-2}^{-1}=\left[\frac{\theta-(2r+\rho)^2}{(2r+2+\rho)^2}\right]\epsilon^{-1}. \tag{4}$$

With $\theta$ finite, $|\epsilon|<0.5$, $0<\rho<1$, when $r\to+\infty$ (4) may be written

$$v_{2r}+v_{2r-2}^{-1}\sim-\epsilon^{-1}. \tag{5}$$

Then as $r\to+\infty$, $|v_{2r}|$ is either $\gtrless 1$. For the convergence of (1), (2) Section 2, $|c_{2r}|\to 0$ as $r\to+\infty$, so this solution rests on the condition

---

[2] G. Floquet, "Sur les equations differentielles lineares," Ann. de l'Ecole Normale Superieure, 12, 47 (1883).

[3] N. W. McLachlan, *Theory and Application of Mathieu Functions* (Oxford Press, New York, 1947).

$|v_{2r}|<1$. The second solution $d_{2r}$ pertains to $|v_{2r}|>1$, which means that $|d_{2r}|\to\infty$ with $r$, so in the present instance it is inadmissible. Suppose that $|\epsilon|<0.1$, then to a first approximation we may write

$$v_{2r}\simeq-\epsilon. \tag{6}$$

Substituting from (6) into (5) leads to

$$|v_{2r-2}|\simeq|\epsilon/(1-\epsilon^2)|<1. \qquad (7)^*$$

As $r\to+\infty$, the ratio of consecutive coefficients tends to this approximate value. The same conclusion may be reached if $r\to-\infty$.

The formulas corresponding to (3), (4) Section 2 may be derived from those above by writing $(2r+1)$ for $2r$.

#### 4. MINIMUM RATIO OF CONSECUTIVE COEFFICIENTS

If the order of the solution (function) is $(m+p)$, where $m^2=4r_m^2$, it is convenient to regard $c_m=c_{2r_m}$ as the *central* coefficient in the solution. Then, if $s\geq r_m$, $|v_{2s}|=|c_{2s+2}/c_{2s}|<1$, and for $p\leq r_m$, $|1/v_{2p}|=|c_{2p-2}/c_{2p}|<1$, so $|v_{2p}|>1$. In (4) Section 3 let $r=-1$, and we get

$$v_{-2}+\left(\frac{4-\rho}{\rho}\right)^2 v_{-4}^{-1}=\left[\frac{\theta-(2-\rho)^2}{\rho^2\epsilon}\right]. \tag{1}$$

Now $0<\rho<1$, $|\epsilon|<0.5$, and if $\theta\gg1$, the r.h.s. of (1) may be relatively large. The second member of (1) is then negligible and, therefore,

$$v_{-2}\simeq[\theta-(2-\rho)^2]/\rho^2\epsilon. \tag{2}$$

For instance if $\theta=100$, $\epsilon=0.2$, $\rho=0.323$,

$$v_{-2}=c_0/c_{-2}\simeq4650/1, \tag{3}$$

so the minimum ratio of consecutive coefficients is 1/4650. As $r$ decreases below $-1$, the ratio increases and tends ultimately to the value at (7) Section 3. Hence, as $r$ increases above $r=s$, $|v_{2r}|$ decreases slowly to an ultimate value of $|\epsilon/(1-\epsilon^2)|$; and as $r$ decreases below $r=p$, $1/v_{2r}$ attains a minimum value of $\epsilon\rho^2/[\theta-(2-\rho)^2]$ at $r=-1$, but thereafter rises and ultimately approaches $-\epsilon/(1-\epsilon^2)$. Between $r=-1$ and $r=r_m$, the ratio is positive if $\epsilon>0$.

The formulas corresponding to (3), (4) Section 2, are

$$v_{-3}+\left(\frac{5-\rho}{1-\rho}\right)^2 v_{-5}^{-1}=[\theta-(3-\rho)^2]/(1-\rho)^2\epsilon, \tag{4}$$

and

$$v_{-3}\simeq[\theta-(3-\rho)^2]/(1-\rho)^2\epsilon, \tag{5}$$

this being the reciprocal of the minimum ratio. The behavior of the coefficients with variation in $r$ is that already described.

#### 5. CONVERGENCE OF (1)–(4) SECTION 2

In Section 4 it is shown that as $r\to\pm\infty$, the ratio of consecutive coefficients is less than unity, and that $|c_{2r}|\to0$. Now $\left|{\cos \atop \sin}(2r+\rho)z\right|\leq1$, if $z$ is real, so by a known theorem the series concerned are absolutely and uniformly convergent. When differentiated term by term repeatedly, the ratio of the moduli of consecutive coefficients is less than unity as $r\to\pm\infty$. Hence the resulting series have the same properties as above, as also have those obtained by integrating term by term, for a similar reason.

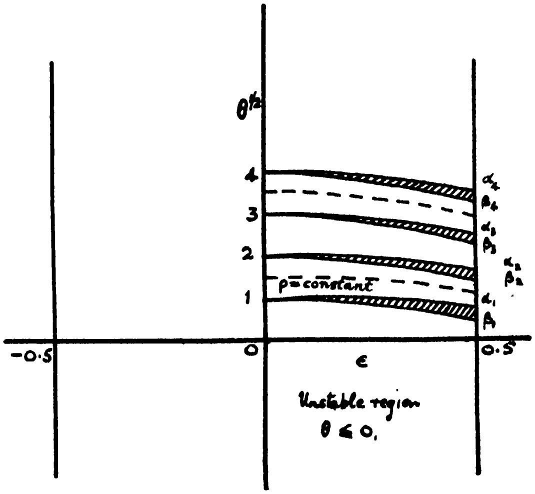

FIG. 2. Illustrating form of iso-$\rho$ chart for $(1+2\epsilon\cos2z)y''+\theta y=0$. $\alpha_1$, $\beta_1$, $\alpha_2$, $\beta_2$, $\cdots$ are the characteristic curves (solid) for solutions of integral order—not considered herein. The even-order characteristics are symmetrical about the $\theta^{\frac{1}{2}}$ axis, but those of odd order are asymmetrical although the chart is symmetrical. Iso-$\rho$ curves are indicated by broken lines. When $\theta>0$ and the point $(\theta^{\frac{1}{2}}, \epsilon)$ lies in an unshaded area, the solution is stable. If it lies in a shaded area between $\alpha_m$ and $\beta_m$, the complete solution is unstable and $\to\pm\infty$ as $z\to\pm\infty$.

---

* The sign of $v_{2r-2}$ is minus.

## 6. FORMULAS FOR CALCULATING TRIAL VALUES OF $\rho$

### a

Let

$$y = \cos\nu z + \epsilon c_1(z) + \epsilon^2 c_2(z) + \cdots, \qquad (1)$$

and

$$\theta = \nu^2 + \gamma_1\epsilon + \gamma_2\epsilon^2 + \cdots, \qquad (2)$$

where the $c(z)$ are continuous single-valued even functions of $z$; $\nu = (m+\rho)$ being real and positive. By substituting (1), (2) into (6) Section 1, taking the solution to be stable and the coefficient of $\cos\nu z$ unity, we may determine $\gamma_1$, $\gamma_2$, $\cdots$.[3] Then to a first approximation we find that

$$\theta \simeq \nu^2[1-(3\nu^2+4)\epsilon^2/2(\nu^2-1)]. \qquad (3)$$

If $\theta \gg 1$, and $\epsilon$ is small enough, (3) may be expressed in the form

$$\nu = (m+\rho)$$
$$\simeq [\theta(\theta-1)/\{\theta(1-\tfrac{3}{2}\epsilon^2)-(1+2\epsilon^2)\}]^{\frac{1}{2}}. \qquad (4)$$

Thus $m$ is the integral, and $\rho$ the fractional part of the r.h.s. of (4).

### b

We choose the form of differential equation at (2) Section 1 and expand $(1+2\epsilon\cos 2z)^{-1}$. Then

$$\begin{aligned}(1+2\epsilon\cos 2z)^{-1} = {} & (1+2\epsilon^2+6\epsilon^4+\cdots)\\ & -2\epsilon(1+3\epsilon^2+10\epsilon^4+\cdots)\cos 2z\\ & +2\epsilon^2(1+4\epsilon^2+\cdots)\cos 4z\\ & -2\epsilon^3(1+5\epsilon^2+\cdots)\cos 6z+\cdots. \qquad (1)\end{aligned}$$

If $\epsilon$ is such that terms in $\cos 4z$, $\cos 6z$, etc., may be neglected, we can write (2) Section 1 in the approximate form

$$y'' + (a-2q\cos 2z)y = 0, \qquad (2)$$

with

$$a = \theta(1+2\epsilon^2+6\epsilon^4+\cdots), \qquad (3)$$

and

$$q = \theta\epsilon(1+3\epsilon^2+10\epsilon^4+\cdots). \qquad (4)$$

Then from reference 3, page 83,

$$(m+\rho) \simeq [a-(a-1)q^2/\{2(a-1)^2-q^2\}]^{\frac{1}{2}}. \qquad (5)$$

The values of $\rho$ computed from either (4) **a**, or (5) are to be regarded as "trial" values, which may need to be improved during the process of computing the coefficients.

## 7. COMPUTATION OF THE COEFFICIENTS

Having obtained a "trial" $\rho$, the $c$'s are calculated by the method described in reference 3, Chapter 5. Unlike the $c$ therein, those to be computed for (1), (2) Section 2 do not decrease rapidly with increase in $r > r_m$, unless $\epsilon$ is very small. Moreover, it is necessary to introduce an approximate correction based upon (7) Section 3, when starting the computation.

## 8. EXAMPLE

### a

The following data pertain to an acoustical warble tone circuit: $f_0 = \omega_0/2\pi = 500$ c.p.s., $f_1 = \omega_1/2\pi = 50$ c.p.s., $\epsilon = 0.2$. $f_0$ is the central frequency which corresponds to the unmodulated condition $\epsilon = 0$. $\Delta f \simeq \epsilon f_0 = 100$ c.p.s., so the frequency range is approximately 400–600 c.p.s. The frequency of deviation or rate at which $f_0$ is modulated is $2f_1 = 100$ c.p.s., the modulation coefficient being $2\epsilon = 0.4$. As shown in Section 1, $|2\epsilon| < 1$. In the above data $f_1$ and $\epsilon$ are much greater than is usual in practice, where it is probable that $f_1 = 10$ c.p.s., and $\epsilon = 0.05$.

Using (4) **a** Section 6 with $\theta = (f_0/f_1)^2 = 100$ $\epsilon = 0.2$, yields

$$(m+\rho) = 10.322,$$

so

$$m = 10, \quad \text{and} \quad \rho = 0.322. \qquad (1)$$

Using (3)–(5) **b** Section 6, we find that $a = 109$, $q = 22.72$, giving

$$(m+\rho) = 10.323,$$

so

$$m = 10, \quad \text{and} \quad \rho = 0.323. \qquad (2)$$

Then $c_{10}$ is the central coefficient. The close agreement between the trial values of $\rho$ at (1), (2) should be noted, but this does not prove that they are accurate!

Taking one of the values of $\rho$, or the average, we calculate

$$\longrightarrow \quad c_2,\ c_4,\ c_6,\ c_8,\ c_{10},\ \breve{c}_{12},\ \breve{c}_{14},$$
$$\breve{c}_6,\ \breve{c}_8,\ c_{10},\ c_{12},\ c_{14},\ c_{16},\ c_{18}, \quad \longleftarrow$$

proceeding in the direction of the arrow in each case. Thus (a) we start at $c_2$ and work towards the central coefficient $c_{10}$, and (b) we start at $c_{18}$ and work towards $c_{10}$. In each case there is an overlap of two (or more if desired) coefficients, and if we have started far enough away from $c_{10}$

on either side, and the trial $\rho$ is sufficiently accurate, there ought to be adequate agreement between the pairs of coefficients $c_6$, $\bar{c}_6$; $c_8$, $\bar{c}_8$; etc. Failing this, re-computation using another value of $\rho$, and interpolation as in reference 3, Chapter 5, must be employed to attain the desired accuracy of the results.

### b. Procedure

First we shall show that, to the degree of accuracy contemplated in demonstrating the method of calculation (using a 10-inch slide rule) that $c_0$ may be neglected. By (3) Section 4, $c_{-2}=c_0/4650$, so with $r=0$, $\epsilon=0.2$, and $\rho=0.323$ in (1) Section 3, by neglecting $c_{-2}$ we obtain

$$\begin{aligned} c_0 &= \epsilon(2+\rho)^2c_2/(\theta-\rho^2) \\ &\simeq 0.0108c_2. \end{aligned} \tag{1}$$

With $r=1$ in (1) Section 3,

$$4.323^2c_4 = 5(100-2.323^2)c_2-0.323^2c_0, \tag{2}$$

$$= 472.8c_2-0.00113c_2, \tag{3}$$

by aid of (1). Thus the term $0.323^2c_0$ in (2) may be ignored, and we get

$$c_4 = 472.8c_2/4.323^2=25.1c_2. \tag{4}$$

$r=2$

$$6.323^2c_6 = 5(100-4.323^2)c_4-2.323^2c_2.$$

Substituting from (4) for $c_4$ we have

$$c_6 = 254.4c_2. \tag{5}$$

$r=3$

$$8.323^2c_8 = 5(100-6.323^2)c_6-4.323^2c_4,$$

so

$$c_8 = 1090c_2. \tag{6}$$

$r=4$

$$10.323^2c_{10} = 5(100-8.323^2)c_8-6.323^2c_6,$$

so

$$c_{10} = 1465c_2, \textit{ the central coefficient.} \tag{7}$$

It will be seen that owing to repetition, the squares of various numbers, e.g., $4.323^2$, need be obtained once only. We now continue and calculate the overlap coefficients $\bar{c}_{12}$, $\bar{c}_{14}$.

$r=5$

$$12.323^2\bar{c}_{12} = 5(100-10.323^2)c_{10}-8.323^2c_8,$$

so

$$12.323^2\bar{c}_{12} = 5(100-106.56)c_{10}-8.323^2c_8, \tag{8}$$

and, therefore,

$$\bar{c}_{12} = -814c_2. \tag{9}$$

This may be regarded as the "critical" point of the computation, because here $[100-(2r+0.323)^2]$ is smaller than for any other value of $r$. Consequently the influence of an inaccurate trial $\rho$ is greatest when $r=5$.

$r=6$

$$14.323^2\bar{c}_{14} = 5(100-12.323^2)\bar{c}_{12}-10.323^2c_{10},$$

so

$$\bar{c}_{14} = 270c_2. \tag{10}$$

### c

We now calculate the coefficients on the upper side of $c_{10}$, commencing with $c_{20}$. From (7) Section 3, the *limiting* value of the ratio of consecutive coefficients is approximately $-\epsilon/(1-\epsilon^2)=-0.2/0.96=-0.208$. But $|\bar{c}_{20}/c_{18}|>0.208$, so we shall tentatively assume that $c_{20}/c_{18}=-0.23$. Using (1) Section 3 with

$r=9$

$$16.323^2c_{16} = 5(100-18.323^2)c_{18}-20.323^2c_{20}. \tag{1}$$

Since

$$c_{20} = -0.23c_{18},$$

the last member of (1) is $95c_{18}$, so (1) yields

$$16.323^2c_{16}=-1180c_{18}+95c_{18}, \tag{2}$$

giving

$$c_{16}=-4.07c_{18}. \tag{3}$$

The second term on the r.h.s. of (2) is 8.05 percent of the first, so the error in taking $c_{20}/c_{18}=-0.23$ cannot exceed 1.85 percent, and in fact it is very much less. Enhanced accuracy would ensue by commencing with, say, $c_{26}$, but this is not justifiable for slide rule work. Continuing, we have

$r=8$ $$14.323^2c_{14}=5(100-16.323^2)c_{16}-18.232^2c_{18},$$

so $$c_{14}=14.8c_{18}. \tag{4}$$

$r=7$ $$12.323^2c_{12}=5(100-14.323^2)c_{11}-16.323^2c_{16},$$

so $$c_{12}=-44.5c_{18}. \tag{5}$$

$r=6$ $$10.323^2c_{10}=5(100-12.323^2)c_{12}-14.323^2c_{14},$$

so $$c_{10}=80c_{18}, \textit{ the central coefficient.} \tag{6}$$

$r=5$ $$8.323^2\bar{c}_8=5(100-10.323^2)c_{10}-12.323^2c_{12},$$

so $$\bar{c}_8=59.5_5c_{18} \text{ (critical point).} \tag{7}$$

$r=4$ $$6.323^2\bar{c}_6=5(100-8.323^2)c_8-10.323^2c_{10},$$

so $$\bar{c}_6=13.93c_{18}. \tag{8}$$

### d. Results in Terms of the Central Coefficient $c_{10}$

| | | Difference between overlap coefficients |
|---|---|---|
| $c_2=0.00068\,3c_{10}$ | | |
| $c_4=0.01715\ c_{10}$ | | |
| $c_6=0.1737\ c_{10}$ | $\bar{c}_6=0.1741\,c_{10}$ | $0.0004\,c_{10}$ |
| $c_8=0.745\ c_{10}$ | $\bar{c}_8=0.7444\,c_{10}$ | $-0.0006\,c_{10}$ |
| $c_{10}=1.00000\,0c_{10}$ | $c_{10}=1.0000\,c_{10}$ | $0.0000\,c_{10}$ |
| $\bar{c}_{12}=-0.556\ c_{10}$ | $c_{12}=-0.556\ c_{10}$ | $0.0000\,c_{10}$ |
| $\bar{c}_{14}=0.1845\ c_{10}$ | $c_{14}=0.185\ c_{10}$ | $0.0005\,c_{10}$ |
| | $c_{16}=-0.051\ c_{10}$ | |
| | $c_{18}=0.0125\,c_{10}$ | |

The agreement between $c_6$, $\bar{c}_6$; etc., is satisfactory for present purposes.

### e. Check on $\rho$

The agreement between the overlap coefficients in **d** does not warrant a check. When necessary, however, an improved value of $\rho$ may be found as follows: Put $r=5$ in (1) Section 3, and we get

$$[100-(10+\rho)^2]c_{10}-0.2[(12+\rho)^2c_{12}+(8+\rho)^2c_8]=0. \tag{1}$$

The computed values of $c_8$, $c_{12}$ are inserted in (1), which is then solved as a quadratic equation for $\rho$. Provided the difference between the trial $\rho$ and that obtained from (1) is a small fraction of the former, the new value of $\rho$ is likely to be the better value of the two. To the order of accuracy contemplated herein, the $\rho$ from (1) agrees with 0.323.

The complete computation may be checked by substituting (1) Section 2 into (6) Section 1 using the values of the $c$ in **d**, with $z=0$, or any other convenient value.

In **b** and **c** the computation has been set out deliberately in such a manner as to make the procedure easy to follow. For a systematic series of computations, the arrangement may be improved in a way which the professional computer will readily discern. Accuracy to as many decimal places as desired may be attained by well-known processes.

### 9. THE SOLUTION OF (1) SECTION 1

Writing $z=\omega_1 t$, $Q=y$ in (1), (2) Section 2, and using the $c$ in **d** Section 8, to the desired degree of approximation, we have

$$Q_1(t)\simeq\sum_1 c_{2r}\cos(2r+0.323)\omega_1 t, \quad (1)$$

and

$$Q_2(t)\simeq\sum_1^9 c_{2r}\sin(2r+0.323)\omega_1 t. \quad (2)$$

Hence the complete solution with two arbitrary constants is

$$Q(t)\simeq AQ_1(t)+BQ_2(t), \quad (3)$$

$$=C\sum_1^9 c_{2r}\cos[(2r+0.323)\omega_1 t-\phi], \quad (4)$$

where $C=(A^2+B^2)^{\frac{1}{2}}$, $\phi=\tan^{-1}(B/A)$. In practice either the circuit current or the e.m.f. induced in a coupled circuit is needed. The current is $dQ/dt$, while the e.m.f. is proportional to $dI/dt=d^2Q/dt^2$. Hence

$$dQ/dt\simeq -C\sum_1^9 (2r+0.323)\omega_1 c_{2r} \times\sin[(2r+0.323)\omega_1 t-\phi], \quad (5)$$

and

$$dI/dt\simeq -C\sum_1^9 (2r+0.323)^2\omega_1^2 c_{2r} \times\cos[(2r+0.323)\omega_1 t-\phi]. \quad (6)$$

The ratios of the coefficients in (4)–(6) in terms of the central coefficient, taken to be unity in each case, are set out in Table I.

### 10. SALIENT DIFFERENCES BETWEEN THE FORMS OF SOLUTIONS (4) OR (5) SECTION 1 AND (4) SECTION 9

If the numerical data satisfy conditions (a), (b) Section 1, the two forms of solution yield substantially the same results. But when this is not so, the procedure given in Section 8 must be used, and the following salient differences are exhibited:

TABLE I. Showing relative amplitudes of the side frequencies corresponding to $Q$, $I$, and $E$.

| $r$ | $Q(t)$ | $Q'(t)$ | $Q''(t)$ |
|---|---|---|---|
| 1 | 0.00068 3 | 0.00015 37 | 0.00003 47 |
| 2 | 0.01715 | 0.00719 | 0.00302 |
| 3 | 0.1737 | 0.1062 | 0.0649 |
| 4 | 0.745 | 0.6 | 0.483 |
| 5 | 1.00000 0 | 1.00000 0 | 1.00000 0 |
| 6 | −0.556 | −0.664 | −0.795 |
| 7 | 0.185 | 0.255 | 0.356 |
| 8 | −0.051 | −0.0806 | −0.127 |
| 9 | 0.0125 | 0.0222 | 0.0393 |

1. In (4) Section 1, the moduli of the coefficients equidistant from the central coefficient are equal, whereas in (4) Section 9 they are unequal, as will be seen from column 2 in Table I.

2. The coefficients in the series for $Q'(t)$, and $Q''(t)$ obtained by term differentiation of (4) Section 1, bear the same relation to each other as those in the series for $Q(t)$. The relative ratios for $Q'(t)$, and $Q''(t)$ obtained from (4) Section 9 differ from those for $Q(t)$, and the discrepancies are more marked the higher the derivative. Thus differentiation enhances the asymmetry about the central coefficient.

3. In (4) Section 1 the central frequency $f_0$, and the various side frequencies are affected to a trifling extent by capacitance variation, since $\epsilon$ is so small in a radio circuit. But owing to the relatively large value of $\epsilon$ in the warble tone circuit, in (4) Section 9, $f_0$ is increased by 3.23 percent to $1.0323f_0$, when $\epsilon=0.2$. Also each side frequency is increased by an amount dependent upon the value of $r$. For instance when $r=1$, the side frequency is $2.323f_1$ instead of $2f_1$, and when $r=9$, the corresponding values are $18.323f_1$ and $18f_1$. A common feature of the two forms of solution is that the side frequencies are spaced at integral multiples of $2f_1$ about the central frequency.

### 11. PROCEDURE WHEN $m$ IS LARGE

In Section 8 suppose that $f_1=10$ c.p.s., $\epsilon=0.05$, then $\theta=2500$, and $(m+\rho)\simeq\theta^{\frac{1}{2}}(1+3\epsilon^2/4)=50.375$. Thus $m=50$ and $\rho=0.375$. If the computation started at $c_2$ and were symmetrical about $c_{50}$, 49 coefficients would have to be calculated, thereby entailing considerable labor, especially if the trial $\rho$ were insufficiently accurate. When $\theta$ is large, this may be circumvented by calculating only the *significant* coefficients on each side of $c_m$. For a given $\theta$ the greater $\epsilon$ the larger is the number of significant coefficients. To determine the significant coefficient of lowest order, namely, $c_{2s}$ or $c_{2s+1}$, we use (1) or (2) Section 3, according as $m$ is even or odd. If $m$, $(m-2s)$ are large enough, the last member of (1) Section 3 may be neglected. Then if $s \gg 1$, we have

$$v_{2r}^{-1} = c_{2r}/c_{2r+2} \simeq 4(s+1)^2\epsilon/(\theta-4s^2). \qquad (1)$$

Provided adequate accuracy ensues when $v_{2r}^{-1}=h$, (1) yields the approximate formula

$$2s \simeq [h\theta/(h+\epsilon)]^{\frac{1}{2}}. \qquad (2)$$

With $\theta=2500$, $\epsilon=0.05$, $h=0.05$, (2) gives $2s=36$, so the number of significant coefficients on the lower side of $c_{50}$ is $(25-18)=7$. As in **b** Section 8 the value of $c_{34}$, the first coefficient omitted, may be calculated from $c_{34}/c_{36}=h$.

On the upper side of $c_m$, (1) Section 3 gives

$$v_{2r-2} = c_{2r}/c_{2r-2} \simeq 4(s-1)^2\epsilon/(\theta-4s^2), \qquad (3)$$

and (2) is usable here also. Hence including $c_m$, the total number of significant coefficients is $7+1+7=15$. If $h=0.1$ gave adequate accuracy, there would be eleven significant coefficients. Formula (2) is applicable when $m$ is odd, provided that $(2s+1)$ be written for $2s$. If $m$ is very large and $\epsilon$ very small (2) Section 1 may be written with adequate approximation

$$y''+\theta(1-2\epsilon\cos 2z)y=0, \qquad (4)$$

so the solution takes the form at (4) Section 1.

## 12. FREQUENCY MODULATION FUNCTIONS AND THEIR NORMALIZATION

Consider the coupled circuit shown schematically in Fig. 1B. If the coefficient of coupling is small, and the impedance of $Z_2$ much greater than that of the remainder of the circuit, the P.D. on $Z_2$ is nearly $E_2=MdI_1/dt$. Thus $I_2 \simeq E_2/Z_2$. If another circuit is coupled electromagnetically to $Z_2$, the P.D. across $Z_3$ will be approximately proportional to $d^2I_2/dt^2$, and so on. Thus the relative amplitudes of the side frequency P.D.S. in a particular circuit depend upon the number of circuits preceding it. In the $n$th circuit, the P.D. may be found by differentiating the series for $Q(t)$ in the first circuit $(n+1)$ times. This procedure is valid by virtue of uniform convergence as treated in Section 5. Accordingly it is proposed to base our definitions of the frequency modulation functions upon (1)–(4) Section 2, these being the forms of solution for the quantity $Q(t)$.

If in (1), (2) Section 2, $\rho=p/s$, a rational fraction in its lowest terms, the solutions are periodic in $z$ real, with period $2s\pi$, $s \geq 2$. Then if $K$ is a normalizing constant, we shall adopt the convention that[3]

$$\frac{K}{\pi s}\int_0^{2\pi s}\left[\sum c_{2r}\cos(2r+\rho)z\right]^2 dz$$
$$=\frac{K}{\pi s}\int_0^{2\pi s}\left[\sum c_{2r}\sin(2r+\rho)z\right]^2 dz$$
$$=K\sum_{-\infty}^{\infty} c_{2r}^2=1, \qquad (1)$$

so

$$K=\left[\sum_{\infty}^{\infty} c_{2r}^2\right]^{-\frac{1}{2}}. \qquad (2)$$

When $\rho$ is irrational, we use definition (2) above, i.e. we make $s\rightarrow+\infty$ in (1). Writing $E_{2r}^{(2n+\rho)}=Kc_{2r}$, we define the f-m functions of order $(2n+\rho)$ to be

$$\left.\begin{matrix} cf \\ sf \end{matrix}\right\}_{2n+\rho}(z,\epsilon)=\sum_{r=-\infty}^{\infty} E_{2r}^{(2n+\rho)} \begin{matrix}\cos\\ \sin\end{matrix}(2r+\rho)z, \qquad (3,4)$$

and those of order $(2n+1+\rho)$ to be

$$\left.\begin{matrix} cf \\ sf \end{matrix}\right\}_{2n+1+\rho}(z,\epsilon)=\sum_{r=-\infty} E_{2r+1}^{(2n+2+\rho)}$$
$$\times \begin{matrix}\cos\\ \sin\end{matrix}(2r+1+\rho)z. \qquad (5,6)^4$$

In this notation $c$, $s$, signify cos, sin, while $f$ indicates frequency modulation. When $\epsilon\rightarrow 0$, (3), (4)$\rightarrow\cos(2n+\rho)z$, $\sin(2n+\rho)z$, while (5), (6) $\rightarrow\cos(2n+1+\rho)z$, and $\sin(2n+1+\rho)z$, respectively. Thus all the $E$ tend to zero, except $E_{2n+1}^{(2n+\rho)}$, which tends to unity. Also when $\epsilon=0$, $\theta=(2n+\rho)^2$ or $(2n+1+\rho)^2$, as the case may be.

---

[4] For this case use (1), (2) with $(2r+1)$ for $2r$, and $K_1$ for $K$.

## 13. CHANGING THE SIGN OF $\epsilon$

This may be effected by writing $(\frac{1}{2}\pi - z)$ for $z$ in (6) Section 1. Making this change in (3)–(6) Section 12 yields solutions having the following properties: (a) they are neither odd nor even, (b) they do not reduce to the limiting forms in Section 12 when $\epsilon \rightarrow 0$, (c) they are unduly complicated. If we write $(-1)^r c_{2r}$ for $c_{2r}$, $(-1)^r c_{2r+1}$ for $c_{2r+1}$ in the respective recurrence relations (1), (2) Section 3, the sign of $\epsilon$ is changed. Using this substitution in (3)–(6) Section 12 with $-0.5 < \epsilon < 0$, we obtain the simple even and odd solutions (f-m functions)

$$\left.\begin{matrix} cf \\ sf \end{matrix}\right\}_{2n+p}(z, -\epsilon) = (-1)^n \sum_{-\infty}^{\infty} (-1)^r E_{2r}^{(2n+p)} \begin{matrix} \cos \\ \sin \end{matrix} (2r+p)z, \quad (1, 2)$$

and

$$\left.\begin{matrix} cf \\ sf \end{matrix}\right\}_{2n+1+p}(z, -\epsilon) = (-1)^n \sum_{-\infty}^{\infty} (-1)^r E_{2r+1}^{(2n+1+p)} \begin{matrix} \cos \\ \sin \end{matrix} (2r+1+p)z. \quad (3, 4)$$

The purpose of the multiplier $(-1)^n$ is to insure a conventional positive sign when $\epsilon = 0$, and the functions reduce to $+\cos(m+p)z$, and $+\sin(m+p)z$, respectively, with $m = 2n$ or $2n+1$.

## 14. OSCILLATORY CIRCUIT HAVING CONSTANT RESISTANCE BUT PERIODICALLY VARIABLE CAPACITANCE

This is shown schematically in Fig. 1C, the differential equation being

$$d^2Q/dt^2 + (R/L)dQ/dt + Q/LC_0(1 + 2\epsilon \cos 2\omega_1 t) = 0. \quad (1)$$

Using the substitutions given in Section 1, and putting $R/2L = \kappa$, we get

$$(1 + 2\epsilon \cos 2z)(y'' + 2\kappa y') + \theta y = 0. \quad (2)$$

Writing $y = e^{-\kappa z} u(z)$, (2) is transformed to

$$(1 + 2\epsilon \cos 2z)u'' + (\theta_1 - 2\epsilon_1 \cos 2z)u = 0, \quad (3)$$

with $\theta_1 = (\theta - \kappa^2)$, and $\epsilon_1 = \epsilon\kappa^2$. The formal solutions of (3) are of the type given at (1)–(4) Section 3. Substituting (1) Section 2 into (3) above, and equating the coefficient of $\cos(2r+p)z$ to zero for $r = -\infty$ to $+\infty$ yields the recurrence relation

$$[\theta_1 - (2r+p)^2]c_{2r} - [\epsilon(2r-2+p)^2 + \epsilon_1]c_{2r-2} - [\epsilon(2r+2+p)^2 + \epsilon_1]c_{2r+2} = 0. \quad (4)$$

The recurrence relation corresponding to (3), (4) Section 2, is (4) with $(2r+1)$ for $2r$. By analysis akin to that in Section 6, formulas for calculating $m$ and $p$ may be derived. Then the procedure follows on the lines of that in Section 8 *et seq.* Approximate solutions of (1) Section 1 and (1) above are given in reference 3, pages 280 and 283, the form being quite different from that herein.

# The Sensitized Luminescence of Manganese-Activated Calcite

James H. Schulman, Lyle W. Evans, and Robert J. Ginther
*Naval Research Laboratory, Washington, D. C.*

AND

K. J. Murata
*Geological Survey, U. S. Department of the Interior, Washington, D. C.**

(Received January 20, 1947)

Synthetic manganese-activated calcites are shown to be practically inert to ultraviolet excitation in the range 2000–3500A, while they are luminescent under cathode-ray excitation. The incorporation of small amounts of an auxiliary impurity along with the manganese produces the strong response to ultraviolet radiation hitherto ascribed to $CaCO_3$:Mn itself. Three such impurities have been studied: lead, thallium, and cerium. The first two induce excitation in the neighborhood of the mercury resonance line, while the cerium introduces a response principally to longer wave ultraviolet. The strong response to 2537A excitation shown by some natural calcites is likewise found to be due to the presence of lead along with the manganese, rather than to the manganese alone. The data do not warrant ascribing the longer wave-length ultraviolet-excited luminescence of all natural calcites to the action of an auxiliary impurity. The essential identity of the cathode-ray excited luminescence spectra of $CaCO_3$:Mn, $CaCO_3$:(Pb+Mn), $CaCO_3$:(Tl+Mn), and $CaCO_3$:(Ce+Mn) with the 2537A-excited spectra of the latter three is evidence that the luminescent center in all cases is the manganese ion or the $MnO_6$ group. It is shown that a "cascade" mechanism for the action of the auxiliary impurities, lead, thallium, and cerium, is incorrect; and that the phenomenon must be considered as a case of sensitized luminescence. Owing to the nature of cathode-ray excitation, the manganese activator can be excited by this agent even in the absence of a second impurity. For optical excitation, however, an absorption band for the ultraviolet must be established by building into the $CaCO_3$:Mn a second impurity or "sensitizer."

THE rose to orange-red luminescence of natural calcite has been studied by many investigators[1–5] and has been ascribed to the presence of manganese as an activator. The preparation of a synthetic manganese-activated calcite phosphor was described by Fonda,[6] who precipitated $CaCO_3$:Mn from a $CaCl_2$-$MnCl_2$ solution by means of $(NH_4)_2CO_3$. This material fluoresced with a rose color under 2537A excitation, the best preparation having 30 percent of the brightness of calcite from Franklin, New Jersey. Our attempts to duplicate this preparation yielded material much inferior in brightness to Fonda's product, judging by comparison with the best sample of calcite that we could obtain from the above locality.

It has recently been shown by Murata and Smith[7] that manganese-activated sodium chloride is not excited by 2537A radiation unless lead is also present as a "co-activator" in the phosphor. This observation, together with our inability to duplicate Fonda's work, suggested that an unsuspected impurity—possibly lead—was at least partially responsible for the luminescence of his preparations, and that the amount of this impurity was smaller in our work. This was found to be the case. When the reagents used to prepare the calcite were first purified before following Fonda's procedure for precipitation of the phosphor,** the product was almost completely inert to both 2537A*** and "3650A"*** excitation.

[7] K. J. Murata, and R. L. Smith, Am. Mineral **31**, 527 (1946).

** Preparation of the phosphors was carried out by Fonda's procedure, precipitation of the $CaCO_3$ from a $CaCl_2-MnCl_2$ solution at 70° by means of 50 percent excess $(NH_4)_2CO_3$ solution, followed by aging of the precipitate in its supernatant liquor for 10 minutes at the boiling point. 100 ml volumes of $CaCl_2-MnCl_2$ solution

Luminescence could be produced in the final calcite product by adding to the calcium chloride solution an auxiliary component—either a lead, thallium, or cerium salt—along with the manganese chloride prior to precipitation of the phosphor. The addition of lead or thallous chlorides as auxiliary impurities, giving $CaCO_3:(Pb+Mn)$ and $CaCO_3:(Tl+Mn)$, respectively, induced strong luminescence under 2537A excitation, but only a minor increase in the "3650A" excited luminescence. The color of the luminescence was rose, in samples of low brightness, to orange-red in samples of high brightness.† The brightest preparations of $CaCO_3:(Pb+Mn)$ were 90 percent as bright, under 2537A excitation, as an outstandingly efficient specimen of calcite from Langban, Sweden.

The addition of cerium to the $CaCl_2$-$MnCl_2$ solution (as cerous ammonium nitrate) prior to the precipitation gave a product that luminesced both under 2537A and "3650A" excitation, with a rose color in both cases. Enhancement of the response to the latter excitation was greater with cerium than with lead or thallium as the auxiliary impurity, cerium-bearing samples being much brighter than the $CaCO_3:Mn$.

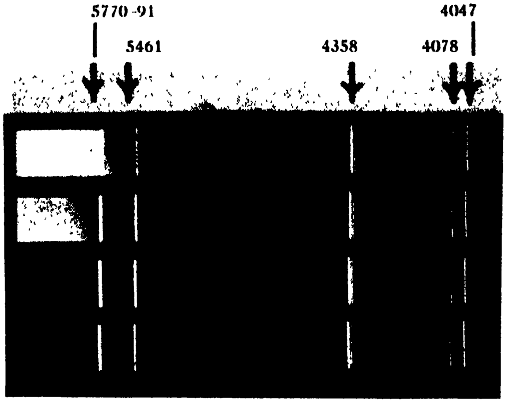

FIG. 1. Luminescence of synthetic manganese-activated calcites under 2537A excitation. Gaertner L231 spectrometer with camera attachment. Type II-F plate. Exposure times: 25 minutes. Exciting source: "Mineralite" lamp without filter.

A. Cadmium borate: Mn
B. Calcite: (Pb+Mn)
C. Calcite: (Tl+Mn)
D. Calcite: (Ce+Mn).

## LUMINESCENCE UNDER OPTICAL EXCITATION

The 2537A-excited luminescence spectra of synthetic calcites containing lead, thallium, and cerium additions are shown in Figs. 1 and 2. Included also in Fig. 1 is the 2537A-excited luminescence spectrum of a sample of manganese-activated cadmium borate phosphor having a quantum efficiency of 75–80 percent under this excitation. The spectra given by the three calcite preparations are essentially identical, starting at about 5780A and extending beyond the limits of sensitivity of the plate used.

Measurements of the brightness of a series of preparations of $CaCO_3:(Pb+Mn)$, $CaCO_3:(Tl+Mn)$, and $CaCO_3:(Ce+Mn)$ are given in

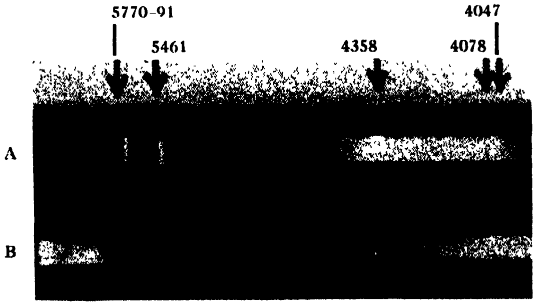

FIG. 2. Luminescence of synthetic calcite: (Ce+Mn) under 2537A excitation. Gaertner L231 spectrometer with camera attachment. Type II-F plate.

A. "Mineralite" lamp, no filter, 1 minute exposure.
B. Calcite: (Ce+Mn) excited by "Mineralite" through Corning 9863 filter. Exposure time: 16 hours. Luminescence between 4000–5000A caused by fused silica of lamp.

---

were used in all the experiments. The concentrations of our solutions were: $CaCl_2$, 0.162 molar; $(NH_4)_2CO_3$, 0.25 molar. These concentrations are twice as high as those employed by Fonda.

Purification of the $CaCl_2$ solution was accomplished by partial (33 percent) precipitation with $(NH_4)_2CO_3$ at 70°. Judging by the inertness of the final product, a greater degree of purification was effected by this procedure than by treatment of the $CaCl_2$ solution with $H_2S$. The $(NH_4)_2CO_3$ solution was purified by partial (33 percent) precipitation with $CaCl_2$ solution at 70°. It was not found necessary to purify the $MnCl_2$ solution, but this is desirable in general. Purification of the $MnCl_2$ may be effected by the same procedure used for purification of the $CaCl_2$.

*** 2537A excitation was provided by a low pressure mercury vapor lamp ("Mineralite" or "germicidal" lamp) equipped with a Corning No. 9863 filter. "3650A" excitation was provided by a 360BL lamp with the same filter, giving a broad band in the near ultraviolet (3300–4200A) with a peak near 3650A.

† Spectroscopic comparison of the luminescence of several preparations showed that the rose-colored fluorescence of the weaker samples is due to the superposition of visible (violet and blue) light from the exciting source upon the light emitted by the sample; during the brief afterglow following cessation of excitation the orange-red color of the luminescence is seen, since visible light from the lamp is no longer superimposed. The reflection of light from the exciting source becomes less important the brighter the phosphor, and the true orange-red luminescence color is therefore observed with these brighter samples even during excitation.

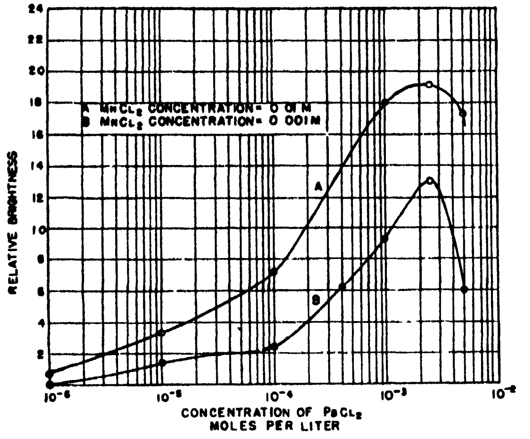

FIG. 3. Effect of lead concentration on brightness of synthetic calcites.

Table I, relative to the brightness of the above mentioned cadmium borate phosphor. In these measurements, circular plaques of the samples, one inch in diameter, were illuminated by a "Mineralite" lamp with a Corning 9863 filter and viewed by a barrier layer photo-cell through a red filter cutting off visible light below 5500A. A plaque of unactivated CaCO$_3$ was used to obtain the "dark response" of the system, which was due to the small amount of visible radiation from the lamp passed by both filters. The small correction obtained in this way was applied to all the readings.

The data on CaCO$_3$:(Pb+Mn) are further graphically illustrated in Figs. 3 and 4. An x-ray diffraction study of all the samples indicated that a number of them were mixtures of calcite and aragonite, instead of pure calcite. Those preparations in which aragonite was found are indicated by ● in the figures, while the pure calcite samples are indicated by ○.[††]

## LUMINESCENCE UNDER CATHODE-RAY AND SPARK-COIL EXCITATION

Visual observations were made of the cathode-ray excited luminescence of a group of synthetic calcite phosphors of the same manganese concentration, including a sample containing manganese alone, and samples containing manganese plus one of each of the auxiliary impurities: lead, thallium, and cerium. The phosphor samples were mounted side by side in $\frac{1}{8}''$ diameter$\times\frac{1}{16}''$ deep wells drilled into a brass plate, which was placed inside a demountable cathode-

** Polarographic and colorimetric analyses of several of the above samples showed that the mole ratios of Mn/Ca, Pb/Ca, and Ce/Ca in the solid were substantially the same as in the solution prior to precipitation, while in the case of thallium the Tl/Ca ratio in the phosphor was only one seventh of its value in the solution prior to precipitation. These results are in agreement with what is expected from elementary chemical considerations concerning the solubilities of the various carbonates, basic carbonates, and hydroxides involved.

---

[††] The preparation of the pure calcite form of CaCO$_3$, CaCO$_3$:Pb, CaCO$_3$:Tl, and CaCO$_3$:Ce by the hot precipitation, recommended by Fonda and used by us in most of the work, was found to be impossible, aragonite or, at best, mixtures of calcite and aragonite being formed instead. Apparently manganese has to be co-precipitated with the calcium carbonate in order to generate the calcite phase, although even in this case the formation of aragonite is not always prevented. Manganese-free calcite, with or without Pb, Tl, or Ce impurity, could be prepared only by low temperature precipitation. To obtain these materials a saturated calcium bicarbonate solution was made by bubbling carbon dioxide through a calcium carbonate suspension, filtering off the excess solid, and adding PbCl$_2$, TlCl, or CeCl$_3$ solution to the filtrate. From such solutions calcite was deposited at room temperature after a day or two.

ray tube. There was no perceptible color difference between the luminescence of $CaCO_3$:Mn, $CaCO_3$:(Pb+Mn), $CaCO_3$:(Tl+Mn) and $CaCO_3$:(Ce+Mn) when they were simultaneously bombarded with cathode rays (accelerating voltage, 800 volts; current density approximately 100 $\mu$amps/cm$^2$). The close proximity of the samples would tend to make any differences between them readily detectable.

Since the design of the demountable cathode-ray tube used in making these visual observations was not suited for use as a spectrographic source unit, the luminescence spectra of the above phosphors under spark-coil excitation, in air at a pressure of $10^{-2}$ mm Hg, were photographed instead (Fig. 5). It has been our observation that this type of excitation and cathode-ray excitation give the same luminescence spectrum with all the standard sulfide, silicate, fluoride, and tungstate phosphors. The visual observations and the spectrograms of Fig. 5 show the essential identity of the luminescence under corpuscular excitation of manganese-activated calcites with or without auxiliary impurities.

## NATURAL CALCITES

In order to determine whether or not the luminescence of natural manganese-bearing calcites is due to an auxiliary impurity, as with our synthetic samples, preliminary qualitative spectrographic analyses were made of brightly orange-red fluorescing (2537A excitation) natural calcites from the following localities: (1) Franklin, New Jersey; (2) Langban, Sweden; (3) Mount Spurr, Alaska Peninsula, Alaska; (4) Sunset Mine, Superior, Arizona; and (5) Guanajuato, Mexico. All of them were found to contain both manganese and lead. The manganese content of the samples ranged from tenths of a percent to several percent; and the lead from hundredths of a percent to over a percent. Neither thallium nor cerium could be detected in any of the samples, which therefore are samples of lead-induced luminescence. It follows that the "3650A" excited luminescence of these natural calcites is induced by some other impurity than those put into our synthetic samples, or is due to the manganese alone.

Chemical analysis of the outstandingly bright Langban calcite showed that it contained 1.3 weight percent of lead and 3.0 weight percent of manganese, which is the order of magnitude of both impurities present in our synthetic samples.

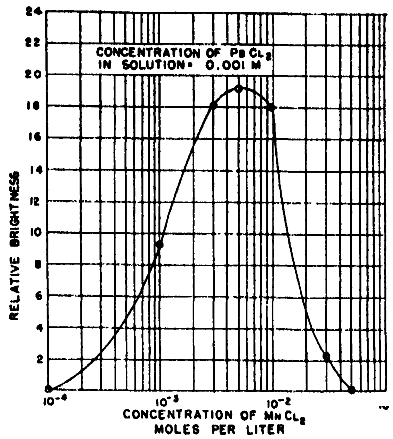

FIG. 4. Effect of manganese concentration on brightness of synthetic calcites.

The well-formed crystals from Guanajuato, Mexico, showed a sharply-zoned fluorescence that was restricted to the outermost millimeter of the crystals. Spectrographic analysis of the fluorescent and non-fluorescent portions showed that the manganese content was approximately 0.1 percent in both. The fluorescent portion, however, also contained several tenths of a

percent of lead, whereas the non-fluorescent portion had no detectable lead.

The preliminary study of natural calcites thus confirms the results obtained with our synthetic samples, and demonstrates that the luminescence of natural calcites under excitation in the region of mercury resonance radiation is due—not to manganese alone, as has hitherto been believed—but to the simultaneous presence of manganese and lead in the crystal.

## DISCUSSION

The lack of fluorescence response of $CaCO_3$:Mn to optical excitation by ultraviolet radiation in the neighborhood of the mercury resonance line, and the development of such a response by the incorporation of auxiliary impurities such as lead, thallium, or cerium, may be considered from three different viewpoints. First, it may be postulated that the manganese activator alone in the calcite structure does not constitute a luminescent center, but that luminescence emission is possible only from a more complex center containing lead, thallium, or cerium in addition to the manganese. The auxiliary impurities and the manganese are accordingly interpreted as "co-activators."[7] This interpretation is ruled out by the fact that all samples of manganese-activated calcite, whether or not they luminesced under ultraviolet excitation, responded to cathode-ray and spark-coil excitation with the same luminescence emission spectrum. The cathode-ray excited luminescence is essentially identical with the optically-excited luminescence of the preparations responsive to the latter type of excitation. This luminescence is of the typical orange-red color associated with manganese in sixfold coordination with oxygen,[8, 9] as would be expected if $Mn^{++}$ replaced $Ca^{++}$ substitutionally in calcite. This shows that the $Mn^{++}$ ions or the $MnO_6$ groups existing in the crystal constitute in themselves luminescent centers, independent of the presence or absence of an auxiliary impurity and of the nature of the impurity when present.

A second interpretation is that we are dealing here with a "cascade" process in the case of ultraviolet excitation of the phosphors containing an auxiliary impurity along with the manganese. According to this simple picture, the manganese and the auxiliary impurity need not be considered as forming a manganese ion-impurity ion complex, but act as two separate luminescent centers. The auxiliary impurity absorbs the exciting "short" ultraviolet radiation and emits as fluorescence longer wave ultraviolet or even visible radiation capable of exciting the manganese activator to its typical luminescence. This interpretation assumes, then, a greater or less degree of coincidence between the position of the manganese absorption band in $CaCO_3$:Mn and the emission bands of $CaCO_3$:Pb, $CaCO_3$:Tl, and $CaCO_3$:Ce. This interpretation is contradicted by simple experiments in which intimate mechanical mixtures of $CaCO_3$:Mn with $CaCO_3$:Pb, $CaCO_3$:Tl, and $CaCO_3$:Ce, respectively, were examined under 2537A excitation. In no case was luminescence observed.

The third interpretation of our results is that the $CaCO_3$:(Pb+Mn), $CaCO_3$:(Tl+Mn), and $CaCO_3$:(Ce+Mn) phosphors are cases of "sensitized luminescence," such as those first described by Rothschild[10] in the group of rare-earth activated alkaline earth sulfide phosphors. In this model it is assumed that (a) $CaCO_3$:Pb, $CaCO_3$:Tl, and $CaCO_3$:Ce have an absorption band in the short wave-length ultraviolet region in question; (b) $CaCO_3$:Mn does not have an absorption band in this region of the ultraviolet, but may have absorption bands in another spectral range; (c) the simultaneous incorporation of manganese and lead, thallium, or cerium in calcite leaves conditions (a) and (b) substantially unchanged; (d) energy absorbed in the lead, thallium, or cerium-induced absorption bands is transferred to the manganese by a process analagous to collisions of the second kind rather than by a radiative ("cascade") process; and (e) the luminescence emission is due to the $Mn^{++}$ ion alone and is independent in spectral characteristics of how the energy is imparted to this ion.

The fundamental lattice absorption of pure calcite lies at wave-lengths shorter than about

2250A.[11] The introduction of absorption bands at longer ultraviolet wave-lengths than the fundamental crystal absorption by the incorporation of lead, thallium, silver, and other heavy metal impurities in the alkali halides is well-known,[12] and a similar effect is to be expected in crystals with anions other than the halogens, although the position of the absorption peak produced by a given cation impurity will differ with the nature of the host crystal. The absorption produced by the impurity ion may be due to the excitation of this ion itself, as proposed by Seitz[13] for the alkali halide-thallium phosphors; or to the higher ionization potential of the substituting cation compared to that of the cation of the crystal itself[14]; or to a greater polarizing power of the impurity ion compared to the cation of the host crystal. In our manganese-activated calcites, the lead, thallium, and cerium impurities would act in this way as "absorbers" or "sensitizers," and this function would be performed whether the "sensitizers" themselves are capable of emitting luminescent radiation of their own or not. The manganese activator and the lead, thallium, or cerium "sensitizer" would have to be near neighbors in the calcite structure for the energy to be transferred from the sensitizer to the manganese, but this requirement is different from the concept of a $Mn^{++}-Pb^{++}$ (or $-Tl^{+}$ or $-Ce^{+++}$) complex as the luminescent center.

According to this picture of sensitized luminescence, no sensitizer should be required for the appearance of the manganese luminescence under cathode-ray bombardment. Under this type of excitation, energy is absorbed primarily by the atoms of the host crystal, the absorbed energy then being capable of transmission over large distances through the lattice to the site of the manganese activator by means of excitons or by the movement of electrons and positive holes through the crystal.[15]

The validity of the above interpretation of sensitized luminescence is supported by a more detailed study of the excitation and absorption (reflection method) of manganese-activated calcite phosphors being made by Mr. Elias Burstein and Mrs. Margaret White, Crystal Section, N.R.L., whom we thank for permission to present a summary of their preliminary results. Data on the excitation and reflection spectra of the lead, thallium, and cerium sensitized phosphors, as well as of calcites containing lead, thallium, cerium, and manganese separately, and of pure calcite are given in Figs. 6 and 7.

For the excitation studies, plaques of phosphor powder were irradiated with ultraviolet from a Beckman hydrogen discharge lamp, monochromatized by a Beckman quartz spectrophotometer, and the irradiated surface viewed by an RCA 1P21 multiplier photo-tube through a Corning 2418 filter. The design of the apparatus allowed the continuous automatic plotting of the photo-cell response *vs.* excitation wave-length in about 15 minutes over the range of 2000 to 3500A. The data are presented in Fig. 6 as cell response *vs.* wave-length instead of as a true excitation spectrum, since no means was provided for keeping constant ultraviolet energy incident on the phosphor at all wave-lengths or for measuring the intensity of the incident ultraviolet as a function of wave-length. Since the hydrogen lamp employed gives a continuous spectrum without sharp changes in output with wave-length, and the transmission of the monochroma-

tor likewise varies continuously, the data suffice to locate qualitatively, at least, the positions of excitation bands. Pure natural calcite (curve not shown in Fig. 6) gave no response over the whole range. Synthetic calcite, activated with manganese alone (dotted curve, Fig. 6) showed only a very faint luminescence under excitation near 2150A and again near 2450A. It is not yet known whether this very slight response is due to manganese alone or to traces of a sensitizing impurity which our purification method failed to remove. With $CaCO_3$:(Ce+Mn) (curve I) the 2450A excitation peak is somewhat higher, but a much more important effect is the far stronger excitation band created by the cerium at longer wave-lengths, peaking at about 3170A. $CaCO_3$:(Tl+Mn) (curve III) has a strong excitation region peaking at 2435A, while $CaCO_3$:(Pb+Mn) (curve II) shows a very intense excitation region with a peak at 2540A. This last band coincides almost exactly with the wave-length of mercury resonance radiation, which probably accounts for the much higher efficiency of luminescence of the $CaCO_3$:(Pb+Mn) phosphors under this excitation compared to that of $CaCO_3$:(Tl+Mn) and $CaCO_3$:(Ce+Mn) (*cf.* Table I).

In Fig. 7 are given the results of reflection measurements on the above materials. For these measurements the samples were illuminated with a Hanovia hydrogen-discharge lamp, and the reflected light analyzed by a Gaertner quartz monochromator, using a 1P28 multiplier phototube as a receiver. A plaque of magnesium carbonate[16] was used as a standard and the photocell response to the reflection from the samples was compared to the response from the standard. Absolute measurements cannot be made by this method, of course, since the reflectivity is a function of particle size, packing of the sample, angles of illumination and viewing. Comparison of the results obtained with this system with true absorption measurements on materials obtainable in the form of single plates or crystals has, however, given good agreement as to the location of absorption bands and qualitative information as to their intensity. The difference in reflection between different samples in regions where they are both quite transparent is not to be considered significant on account of the disturbing factors mentioned above; significance should be attached only to the shape of each curve and the structure or absence of structure found therein. The measurements were made point by point, with data being taken every 50A between 2000 and 3400A. The data indicate that the introduction of manganese into calcite does not introduce any pronounced absorption beyond that present in pure calcite in the wave-length range investigated except at wave-lengths shorter than about 2400A. The introduction of lead in the calcite calls forth two fairly sharp absorption bands, which persist when manganese is introduced in addition to the lead.††† The absorption band lying at the longer wave-lengths in $CaCO_3$:Pb and $CaCO_3$(Pb+Mn) coincides fairly well with the position of the excitation band of the latter phosphor. The same situation applies in the case of $CaCO_3$:Tl and $CaCO_3$:(Tl+Mn). The results with cerium are less satisfactory because there is no sharp peak in

---

[16] C. F. Goodeve, Trans. Faraday Soc. 34, 902 (1938).

††† The greater absorption and overlapping of the peaks in $CaCO_3$:(Pb+Mn) compared to $CaCO_3$:Pb is due to the higher Pb concentration in the former, 1.60 mole percent *vs.* 0.4 mole percent Pb in the latter.

the absorption coinciding with the peak of the excitation spectrum of $CaCO_3$:(Ce+Mn). However, even here a considerable increase in absorption over pure $CaCO_3$ is evident, there being a drop of approximately 20–30 percent in the reflection between 3400A and 3150A for both $CaCO_3$:Ce and $CaCO_3$:(Ce+Mn).

A study of the literature reveals a number of known phosphors which appear to be based upon the mechanism of sensitized luminescence outlined above. Among these are alkaline earth borates, phosphates, silicates, and silico-phosphates,[17,18] and the NaCl:(Pb+Mn) of Murata and Smith.[7] In principle it should be possible to introduce excitation bands for any desired ultraviolet spectral region by choice of the proper sensitizer for any phosphor showing response to cathode-ray or x-ray excitation but not to ultraviolet excitation. Investigations under way at the Naval Research Laboratory are concerned with further studies along these lines.

## SUMMARY

It is shown that synthetic preparations of calcite, with manganese as an activator, are luminescent under cathode-ray excitation, but are substantially non-luminescent under ultraviolet irradiation. By co-precipitation of small amounts of lead, thallium, or cerium with the manganese-activated calcium carbonate, there is produced no essential change in the cathode-ray luminescence spectrum, but the products are then strongly excited by ultraviolet radiation as well. Spectrographic analyses of natural calcites from a number of different localities show that in the strongly luminescent (2537A excitation) specimens of the natural mineral, lead accompanies the manganese activator, while in the non-luminescent (2537A excitation) specimens the manganese is present without lead. The near-ultraviolet excited luminescence of most natural calcites is not connected with the lead, and has not as yet been ascribed to the presence of any specific auxiliary impurity.

The interpretation of these results is shown to be most consistent with the concept of a "sensitized" luminescence, and the possible application of this viewpoint to known phosphors and to the synthesis of new phosphors having specific excitation bands is pointed out.

## ACKNOWLEDGMENT

We wish to express our thanks to Mrs. Esther Claffy for the chemical analyses of our synthetic calcites. The chemical analysis of the Langban calcite was obtained through the kindness of Professor C. Palache, Department of Mineralogy, Harvard University.

# Electron Beam Deflection

## Part I. Small-Angle Deflection Theory

R. G. E. HUTTER
*Sylvania Electric Products, Inc., Flushing, New York*

(Received February 26, 1947)

Two general mathematical methods are discussed which may be used to study the effects of electric and/or magnetic deflection fields on electron beams. The basic equations for the "path method" are the equations of motion of Newton or Euler-Lagrange. The "iconal method" makes use of certain properties of the Hamiltonian function.

These methods are then applied to describe the action of balanced, two-dimensional electric deflection fields on electron beams. It is shown that both methods yield essentially the same results. Expressions are derived describing the magnitude of deflection and the distortions of an electron beam.

Only the path method is used in a similar investigation of magnetic-type deflection fields.

## A. INTRODUCTION AND GENERAL OUTLINE OF THE THEORY

### 1. Introduction

THE problems of the formation and the control of electron beams are the concern of "Geometrical Electron Optics," a term chosen to imply the analogy which exists between the behavior of electron beams and light beams, and which manifests itself in the terminology and the fact that many light-optical instruments have an electron-optical equivalent. Electron beams may be focused, deflected, and reflected by electric or magnetic fields which are called electron lenses, deflection fields, and electron mirrors, respectively. The deflection fields might be termed electron prisms if it were not for the fact that deflection fields produce both prismatic *and* focusing effects on electron beams. A deflection field may be considered as a prism having a weak cylinder lens joined to each face.

If the deflection fields are classified as those making use of focusing effects and those for which these effects are undesirable, it is found that these two classes represent the deflection fields producing large-angle deflections and those producing small-angle deflections, respectively. Deflection fields of the former group are employed in mass spectrometers, cyclotrons, and microanalyzers, while fields of the latter group are used in cathode-ray and television tubes, ion traps, scanning-type electron microscopes, etc.

This paper will deal exclusively with small-angle deflection fields in the manner now used for the treatment of electron-optical phenomena; the terms "deflection field," and "deflection system" will hereafter be assumed to relate only to small-angle deflection fields or systems. Large-angle deflection fields have been discussed elsewhere [1-4]

It is the writer's purpose to provide certain mathematical tools which should be found useful in the design of improved deflection systems. In spite of the practical importance of an understanding of the problems of deflection, little attention has been paid to a systematic study of deflection fields. Approximate formulae are still used to determine the magnitude of deflection, and qualitative reasoning is applied to obtain information about the type of distortion of the deflected beam. Two exceptions exist: J. Picht and J. Himpan[5] have investigated single and crossed two-dimensional electric fields, and G. Wendt[6] has studied single and crossed magnetic deflection fields.

A thorough discussion of the subject is indicated for a number of reasons:

(1) Because of war conditions, the work of Picht, Himpan, and Wendt appears to have escaped the attention of the workers in the field of electron optics.

[6] G. Wendt, Die Telefunkenröhre **15**, 100 (1939); Zeits. f. Physik **118**, 593 (1942).

(2) These authors used a method of investigation which is known in electron optics as the "path method." It is of interest to show that another method, called the "iconal method," may also be employed.

(3) The method of Picht, Himpan, and Wendt, as well as the results, may be simplified. This simplification results in greater ease of application.

(4) The investigations may be generalized to include three-dimensional electric deflection fields.*

(5) A number of applications of the simplified and extended theory have now been made resulting in design charts for the determination of the magnitude of deflection, and in quantitative information on spot and pattern distortions of some of the commonly employed deflection fields.

The work is to be divided into two parts.** In Part I the general framework of the theory will be discussed, and the theory will be specialized for the case of single two-dimensional electric deflection fields, and single and crossed magnetic deflection fields. In Part II the magnitude of deflection and the distortion effects are computed for a number of typical electric and magnetic deflection fields.

## 2. General Outline of the Theory

Cathode-ray and television tubes are the most important devices employing the kinds of deflection fields to be investigated here. Although the theory to be developed may also be applied to small-angle deflection fields used in other devices, the terminology is that pertaining to cathode-ray tubes. The tube for which the theory will be developed is, however, an ideal rather than an actual cathode-ray tube. In order not to complicate the theory unduly, a number of assumptions had to be made chiefly concerning the electron beam and the focusing system.

The electron beam is assumed to be a rectilinear flow of electrons, homogeneous in velocity, and either conically or cylindrically shaped; space-charge effects are ignored. Such assumptions are not essential to the theory but were made to simplify its application. If it is necessary to explain the effects in an actual cathode-ray tube, such effects might have to be taken into account separately.

Furthermore, field distortions of the deflection fields due to the presence of other electrodes were not taken into account. This means that the deflection fields were taken as being determined solely by the current conductors and electrodes intended for the formation of the field.

These idealizations and approximations are permissible if one is interested in a comparative study of deflection fields, but not in an explanation of the performance of a particular cathode-ray tube which employs deflection fields.

The Cartesian system of coordinates will be used throughout this work. The $z$ axis is taken as the optical axis of the focusing system. If undeflected, the electrons of the beam will travel in the $+z$ direction. The $x$ direction is also called the "horizontal" direction while the $y$ direction is called the "vertical" direction.

The initial coordinates of an electron, whose path through the deflection field is to be deter-

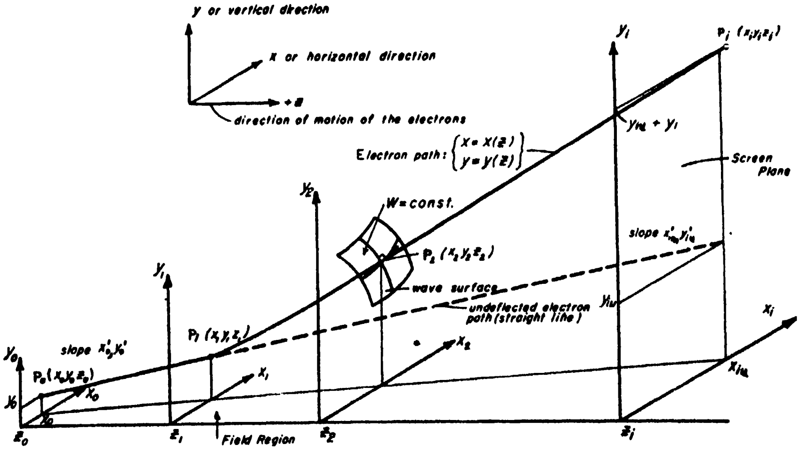

FIG. 1. The geometry of deflection.

---

* To be published at a later date.

** A part of the material presented in these papers was given in an abbreviated form at the National Electronics Conference in Chicago, October 3–5, 1946.

mined, are $z_0$, $x_0$, and $y_0$. The slope of the path at this point is given by $x_0'$, $y_0'$, the prime indicating the derivative of the quantity with respect to $z$. The position coordinates of an electron after deflection in a plane perpendicular to the $z$ axis at a point $z_t$ are given by $z_t$, $x_t$, and $y_t$. The coordinates $x_t$, $y_t$ at a specified coordinate $z_t$ are the quantities which ordinarily have to be determined. In cathode-ray and television tubes, $z_t$ is the axial coordinate of the plane of the fluorescent screen. For simplicity, it is assumed that the screen is flat, although in many tubes the screen is actually a curved surface. Since $z_t$ will remain a variable which may be chosen arbitrarily, it will also be possible to determine the position of the electron on a curved screen, in which case the calculations might be a little more cumbersome.

In most practical cases $z_0$ and $z_t$ are axial coordinates which are in regions where the influence of the deflection field is negligibly small. The deflection action of the field takes place between two $xy$ planes with axial coordinates $z_1$ and $z_2$, where $z_0<z_1<z_2<z_t$ (see Fig. 1).

There are four quantities—two coordinates and two slopes—which are of importance. If the deflecting field is zero, the electron with the above mentioned initial conditions $x_0$, $y_0$, $x_0'$, $y_0'$ at $z_0$, would proceed in a straight line from $x_0$, $y_0$, $z_0$ to the screen. Its coordinates at the screen are given by $x_{tu}$ and $y_{tu}$, where

$$x_{tu}=x_0+x_0'(z_t-z_0), \quad y_{tu}=y_0+y_0'(z_t-z_0). \tag{1}$$

Its slopes at that point are

$$x_{tu}'=x_0', \quad y_{tu}'=y_0'. \tag{2}$$

The second subscript $u$ indicates that $x_{tu}$, $y_{tu}$ are the coordinates of the undeflected electron at the screen. (See Fig. 1.)

Equations (1) and (2) may be used to express $x_0$, $y_0$ in terms of $x_{tu}$, $y_{tu}$, $x_{tu}'$, $y_{tu}'$ as follows:

$$x_0=x_{tu}-x_{tu}'(z_t-z_0), \quad y_0=y_{tu}-y_{tu}'(z_t-z_0). \tag{3}$$

The coordinates $x_t$, $y_t$ of the deflected electron at the axial coordinate $z_t$ may be expanded formally in power series of powers of $x_{tu}$, $y_{tu}$, and $x_{tu}'$, $y_{tu}'$:

$$\left.\begin{aligned} x_t &= \sum_{a,b,c,d} M_{a,b,c,d}\cdot x_{tu}^{a}\cdot y_{tu}^{b}\cdot x_{tu}'^{c}\cdot y_{tu}'^{d}, \\ y_t &= \sum_{a,b,c,d} N_{a,b,c,d}\cdot x_{tu}^{a}\cdot y_{tu}^{b}\cdot x_{tu}'^{c}\cdot y_{tu}'^{d}, \end{aligned}\right\} \tag{4}$$

where $a+b+c+d=n$ with $n=0, 1, 2, \cdots$. There are $[(n+1)(n+2)(n+3)]/6$ terms of degree $n$.

The coefficients $M_{a,b,c,d}$ and $N_{a,b,c,d}$ will, of course, be functions of $z_0$, $z_t$ and the field-strength parameters of the electric and magnetic deflection fields. The problem of determining $x_t$, $y_t$ reduces to one of determining these coefficients. It will be shown that the series, Eq. (4), are rapidly converging if small-angle deflections are considered only. In most practical cases, $n$ need not be taken as higher than three. The condition of smallness of the deflection angle will have to be stated mathematically.

Before going to the discussion of the two methods by which the coefficients $M_{a,b,c,d}$ and $N_{a,b,c,d}$ may be determined, a few remarks will be made concerning some general properties of these coefficients.

All electric and magnetic fields used as deflection fields are, strictly speaking, three-dimensional fields; i.e., the electrostatic potential function $\varphi$ and the magnetic field strength vector $\mathbf{H}$ will be functions of all three coordinates $x$, $y$, and $z$. However, certain fields employed in actual devices exhibit in certain regions the properties of two-dimensional fields. This is especially the case for some electric deflection fields. In this case the potential function $\varphi$ may be considered as depending only on $x$, $z$, or $y$, $z$. If the variation of $\varphi$ with the third coordinate is negligibly small in regions passed by the electron beam, a considerable simplification of the theory appears possible. This simplification finds its expression in the end result, Eq. (4), in which a number of the coefficients $M_{a,b,c,d}$ and $N_{a,b,c,d}$ will vanish. It is, however, unnecessary to prove which of the coefficients are zero, since the methods by which the coefficients are to be determined will automatically assign the value of zero to the proper coefficients.

Often, in practice, two deflection fields are used which are rotated 90 degrees about the $z$ axis with respect to each other. In this case only one set of coefficients $M_{a,b,c,d}$ or $N_{a,b,c,d}$ need be determined, the other set being obtained by interchanging $a$ and $b$ as well as $c$ and $d$, and interchanging the field quantities. In order to get $y_t$ from $x_t$, $x_{tu}$ must be replaced by $y_{tu}$, $x_{tu}'$ by $y_{tu}'$, and *vice versa*. It should be pointed out, however, that the numerical values of the corresponding coefficients will be different if different field functions are used for the two deflection fields.

The study of the motion of electrons in deflection fields requires a knowledge of the field distributions. An electric field may be given in terms of a potential distribution $\varphi=\varphi(x, y, z)$, while the magnetic field may be described by the magnetic vector potential distribution $\mathbf{A}=\mathbf{A}(x, y, z)$. It will be assumed that those functions are known.

Two essentially different methods are available to determine the position coordinates of an electron moving in the fields. (Both methods have been used to solve the analogous problem for focusing fields.)

If we consider electrons as small charged particles moving through electric and magnetic force fields, the concepts of electron ballistics can be applied. The Newton-Lorentz equations may be used as the basic set of equations. This method has been used by J. Picht and J. Himpan[5] for two-dimensional electrostatic deflection fields, and by G. Wendt[6] for a single magnetic deflection field. It is called the "path method."

If, on the other hand, waves are associated with a moving electron which travels through electric or magnetic fields of slowly-varying electron optical index of refraction, the wave approach to geometric optics can be applied. One of the basic concepts is that of the "point iconal." The method is based on the properties of the iconal function and is, therefore, called the "iconal method."

The common root of both methods is Hamilton's principle which states that the electron path,

$$x=x(s), \quad y=y(s), \quad z=z(s), \tag{5}$$

is such that

$$W=\int_{P_0(x_0,\,y_0,\,z_0)}^{P_i(x_i,\,y_i,\,z_i)} \left\{\left[\frac{2e}{m}\varphi(x, y, z)\right]^{\frac{1}{2}} - \frac{e}{m}(\mathbf{A}\cdot\mathbf{s})\right\} ds = \text{minimum}, \tag{6}$$

or with

$$\mathbf{s}=\frac{x'}{[1+x'^2+y'^2]^{\frac{1}{2}}}\mathbf{i}+\frac{y'}{[1+x'^2+y'^2]^{\frac{1}{2}}}\mathbf{j} +\frac{1}{[1+x'^2+y'^2]^{\frac{1}{2}}}\mathbf{k}, \tag{7}$$

and

$$ds=(1+x'^2+y'^2)^{\frac{1}{2}}dz, \tag{8}$$

that the electron path $x=x(z), y=y(z)$ is such that

$$W=\int_{z_0}^{z_i} F(x, y, z, x', y')dz =\int_{z_0}^{z_i} \left\{\left[\frac{2e}{m}\varphi(x, y, z)\right]^{\frac{1}{2}}\cdot[1+x'^2+y'^2]^{\frac{1}{2}} - \frac{e}{m}(A_x x'+A_y y'+A_z)\right\} dz=\text{minimum}, \tag{9}$$

where the primes indicate differentiation with respect to $z$.

The necessary conditions for the electron path Eq. (5) to satisfy Eq. (9) are certain differential equations. These equations are the Euler-Lagrange differential equations for the electron path obtained by carrying out the operations indicated by

$$\left.\begin{aligned}(d/dz)(\partial F/\partial x')-\partial F/\partial x=0,\\ (d/dz)(\partial F/\partial y')-\partial F/\partial y=0.\end{aligned}\right\} \tag{10}$$

These equations are equivalent to Newton's equations

$$m\frac{d^2\mathbf{r}}{dt^2}=e\mathbf{E}+e[\mathbf{v}\times\mathbf{H}], \tag{11}$$

with

$$\mathbf{r}\cdot\mathbf{i}+y\cdot\mathbf{j}+z\cdot\mathbf{k}. \tag{12}$$

The iconal method utilizes the properties of the function $W$. If $x(z)$ and $y(z)$ are taken as the functions describing the actual electron path, and if the initial point $P_0(x_0, y_0, z_0)$ is kept fixed, $W$ becomes a function of the end point $P_i(x_i, y_i, z_i)$. The equation $W=\text{const.}$ describes a surface about $P_0$. This is the wave surface of the electron radiation diverging from $P_0$. Assuming that we know the wave surface configuration in the space where electric and magnetic fields exist, the path of an electron beyond this space (with the boundary point $P_2(x_2, y_2, z_2)$) and into field-free regions to the point $P_i(x_i, y_i, z_i)$ is then given by[7] (see Fig. 1)

$$\left.\begin{aligned}x_i=x_2+(1/n_i)(\partial W/\partial x_2)[(x_i-x_2)^2\\ +(y_i-y_2)^2+(z_i-z_2)^2]^{\frac{1}{2}},\\ y_i=y_2+(1/n_i)(\partial W/\partial y_2)[(x_i-x_2)^2\\ +(y_i-y_2)^2+(z_i-z_2)^2]^{\frac{1}{2}}.\end{aligned}\right\} \tag{13}$$

---

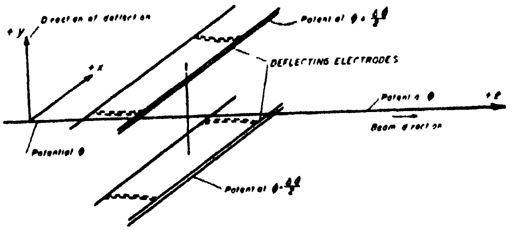

FIG. 2. The electrode geometry of a two-dimensional electric deflection field.

The slope of this straight line is that of the normal **n** to the wave surface at the point $P_2$, since **n** is given by

$$\mathbf{n}=\frac{1}{n_i}\frac{\partial W}{\partial x_2}\mathbf{i}+\frac{1}{n_i}\frac{\partial W}{\partial y_2}\mathbf{j}+\frac{1}{n_i}\frac{\partial W}{\partial z_2}\mathbf{k},$$
$$n_i=\phi_i^{\frac{1}{2}}=\left[(\partial W/\partial x_2)^2+(\partial W/\partial y_2)^2+(\partial W/\partial z_2)^2\right]^{\frac{1}{2}}. \tag{14}$$

It would appear that we have to know the electron path, i.e., the solution of the problem, in order to use the iconal method, since $W$ can only be determined if $x=x(z)$ and $y=y(z)$ are known. However, the restrictions on the magnitude of the deflection angle mentioned above, together with the property of $W$ as expressed by Eq. (9), eliminate the necessity of an exact knowledge of the path.

If the angle of deflection is small, the deflection itself must be small in the region where the field strengths are of appreciable magnitude. Large deflections are obtained by letting the beam travel in essentially field-free space before it reaches the screen; $x(z)$, $y(z)$, $x'(z)$, $y'(z)$ are, therefore, small quantities in regions of appreciable field strength. For their determination by means of Eq. (10), methods of successive approximations can be applied to yield electron paths of increasing accuracy. After the first-order approximation*** has been determined, either method may be used to find the higher order solutions.

In Part B, Section 2, the coordinates of the electron at the screen will be computed, including terms up to $n=2$ or $n=3$, which is, in general, sufficiently accurate to obtain quantitative information about the deflection, and the spot and pattern distortions occurring in common designs of cathode-ray and television tubes.

## B. TWO-DIMENSIONAL ELECTRIC DEFLECTION FIELDS

### 1. The Field Distribution

Electric fields which deflect the electron beam in cathode-ray and television tubes are ordinarily produced by metal electrodes connected to potential sources. The location of these electrodes with respect to the electron beam and the direction of deflection are shown in Fig. 2. The Cartesian system of coordinates is chosen so that $+z$ is in the direction of motion of the undeflected electrons, and $+y$ is in the direction of deflection. Two assumptions will be made about the shape and the potentials of the deflecting electrodes. These assumptions will be expressed in terms of the potential distribution $\varphi=\varphi(x, y, z)$ of the field produced by the deflecting system.

$$\varphi=\varphi(y, z)\quad \text{i.e., } \varphi \text{ is independent of } x, \tag{15}$$

$$\varphi(y, z)=\phi+\varphi^*(y, z),$$

where

$$-\varphi^*(+y, z)=\varphi^*(-y, z), \tag{16}$$

so that

$$\varphi(-y, z)=\phi-\varphi^*(+y, z)$$

where $\phi$ is the potential of the last anode of the electron gun.

The first assumption, Eq. (15), means that the electrodes producing $\varphi$ are considered to be of infinite extent in the $x$ direction, or, in other words, that the edge effects of the electrodes of finite extent in the $x$ direction are neglected. The error introduced by this assumption ordinarily is negligible, since most electrodes are of sufficient width in the $x$ direction. It follows from the assumption that the equipotential plots, as well as the cross section of the electrodes, are identical in all planes parallel to the $(y, z)$ plane.

The second assumption, Eq. (16), restricts the validity of the following investigations to so-called balanced fields.**** The electrodes are located symmetrically with respect to the center or $(x, z)$ plane. This center plane is at potential $\phi$. The potentials of the electrodes are $\phi+\frac{1}{2}\Delta\phi$ and $\phi-\frac{1}{2}\Delta\phi$, respectively; $\Delta\phi$ is the potential difference between the electrodes.

The potential function $\varphi$ must satisfy the

---

*** The first-order solution corresponds to the so-called "paraxial ray solution" of the focusing systems.

**** The theory of unbalanced deflection fields has also been worked out and will be published at a later date.

Laplace equation:

$$[\partial^2\varphi(y, z)/\partial y^2]+[\partial^2\varphi(y, z)/\partial z^2]\equiv 0. \tag{17}$$

Since $\varphi^*(y, z)=-\varphi^*(-y, z)$, the power series expansion of $\varphi^*$ in powers of $y$ can have only terms of odd power in $y$.

$$\begin{aligned}\varphi^*(y, z)&=a_1(z)\cdot y+a_3(z)\cdot y^3+\cdots\\&\quad+a_{2n+1}(z)\cdot y^{2n+1}+\cdots.\end{aligned} \tag{18}$$

Substituting Eq. (18) in Eq. (17), a recurrence formula for the coefficients is obtained, in which $a_1(z)$ remains arbitrary. With

$$a_1(z)=-E(z) \tag{19}$$

the following series is derived:

$$\begin{aligned}\varphi(y, z)&=\phi-E(z)\cdot y+\tfrac{1}{6}E''(z)y^3\\&\quad-(1/120)E^{(\mathrm{IV})}(z)y^5+\cdots(-1)^{n+1}\\&\quad\times[1/(2n+1)!]E^{(2n)}(z)\cdot y^{2n+1}+\cdots.\end{aligned} \tag{20}$$

It is seen that

$$E(z)=-\left.\frac{\partial\varphi(y, z)}{\partial y}\right|_{y=0}, \tag{21}$$

i.e., $E(z)$ is the axial field-strength distribution.

The electron-optical theory described below will be based on the general form of the potential distribution Eq. (20). It should be noted that edge effects of electrodes in the $z$ direction are not excluded, since $E(z)$ is left arbitrary. The axial field-strength distribution $E(z)$ determines, except for a constant, the equipotential distribution of deflection fields satisfying the condition expressed by Eq. (15).

Ordinarily, two fields of the type described by Eq. (20) are employed in cathode-ray and television tubes. The electrodes are rotated 90 degrees with respect to each other about the $z$ axis; one field deflects in the $y$ direction, the other in the $x$ direction. The two pairs of electrodes are generally spaced sufficiently far apart along the $z$ axis to prevent the distortion of the potential distribution of one field by the electrodes producing the other field. It is assumed here that a plane exists midway between the two fields where neither field has sufficient strength to affect the electrons. A study of crossed electric fields reduces, then, to a study of two single fields.

### 2. Path Method for a Single Two-Dimensional Electric Deflection Field

Integration of the path differential Eqs. (10) becomes possible if it is assumed that $x(z)$, $y(z)$, $x'(z)$, and $y'(z)$ are small quantities. The expressions $\varphi^{\frac{1}{2}}$ and $(1+x'^2+y'^2)^{\frac{1}{2}}$ of Eq. (9) may be written in series form

$$\varphi^{\frac{1}{2}}(y, z)=\phi^{\frac{1}{2}}\left(1-\frac{1}{2}\frac{E}{\phi}y+\frac{1}{12}\frac{E''}{\phi}y^3-\frac{1}{8}\frac{E^2}{\phi^2}y^2-\frac{1}{16}\frac{E^3}{\phi^3}y^3+\cdots\right), \tag{22}$$

and

$$(1+x'^2+y'^2)^{\frac{1}{2}}=1+\tfrac{1}{2}(x'^2+y'^2)-\tfrac{1}{8}(x'^2+y'^2)^2+\cdots. \tag{23}$$

The expression for $W$ then becomes

$$\left.\begin{aligned}W=\left(\frac{2e}{m}\phi\right)^{\frac{1}{2}}\int_{z_0}^{z_i}\Bigg\{&[1]-\left[\frac{1}{2}\frac{E}{\phi}y\right]+\left[\tfrac{1}{2}(x'^2+y'^2)-\frac{1}{8}\frac{E^2}{\phi^2}y^2\right]+\Bigg[-\tfrac{1}{4}(x'^2+y'^2)\frac{E}{\phi}y\\&+\left(\frac{1}{12}\frac{E''}{\phi}-\frac{1}{16}\frac{E^3}{\phi^3}\right)y^3\Bigg]+\Bigg[-\tfrac{1}{8}(x'^2+y'^2)^2-\tfrac{1}{16}(x'^2+y'^2)y^2\frac{E^2}{\phi^2}\\&-\left(-\frac{1}{24}\frac{EE''}{\phi^2}+\frac{5}{128}\frac{E^4}{\phi^4}\right)y^4\Bigg]+\text{higher order terms}\Bigg\}dz,\\&\text{or}\\W=\left(\frac{2e}{m}\phi\right)^{\frac{1}{2}}\int_{z_0}^{z_i}\{&F_0+F_1+F_2+F_3+F_4+\text{higher order terms}\}dz,\end{aligned}\right\} \tag{24}$$

if the bracketed expressions are called $F_0$, $F_1$, $F_2$, $F_3$, and $F_4$. The Euler-Lagrange differential equations

$$\left.\begin{aligned}(d/dz)[(\partial/\partial x')(F_1+F_2+F_3+F_4)]-0&=0,\\ (d/dz)[(\partial/\partial y')(F_1+F_2+F_3+F_4)]-(\partial/\partial y)(F_1+F_2+F_3+F_4)&=0,\end{aligned}\right\} \tag{25}$$

yield

$$\left.\begin{aligned}&\frac{d}{dz}\left[x'-\frac{1}{2}\frac{E}{\phi}yx'-\tfrac{1}{2}x'^3-\tfrac{1}{2}y'^2x'-\frac{1}{8}\frac{E^2}{\phi^2}y^2x'\right]=0,\\ &\frac{d}{dz}\left[y'-\frac{1}{2}\frac{E}{\phi}yy'-\tfrac{1}{2}y'^3-\tfrac{1}{2}x'^2y'-\frac{1}{8}\frac{E^2}{\phi^2}y^2y'\right]-\left[-\frac{1}{2}\frac{E}{\phi}-\frac{1}{4}\frac{E^2}{\phi^2}y-\frac{1}{4}\frac{E}{\phi}x'^2-\frac{1}{4}\frac{E}{\phi}y'^2\right.\\ &\qquad\left.-\frac{3}{16}\frac{E^3}{\phi^3}y^2+\frac{1}{4}\frac{E''}{\phi}y^2-\frac{1}{8}\frac{E^2}{\phi^2}x'^2y-\frac{1}{8}\frac{E^2}{\phi^2}y'^2y+\frac{1}{6}\frac{EE''}{\phi^2}y^3-\frac{5}{32}\frac{E^4}{\phi^4}y^3\right]=0.\end{aligned}\right\} \tag{26}$$

The restriction that the deflection be small where the field strength is of appreciable magnitude may be expressed mathematically as

$$\left|\frac{1}{2}\frac{E}{\phi}y\right|\ll 1. \tag{27}$$

Taking Eq. (27) and $|x'^2|\ll 1$ and $|y'^2|\ll 1$ into account, the approximate solution of Eq. (26) may then be obtained in two steps. To the first order of approximation, the electron path will be given by

$$(d/dz)(x')=0,\quad (d/dz)(y')=-\tfrac{1}{2}(E/\phi). \tag{28}$$

The solution of Eq. (28) is

$$\left.\begin{aligned}x_g(z)&=x_0+x_0'(z-z_0),\\ y_g(z)&=y_0+y_0'(z-z_0)+Y(z),\end{aligned}\right\}\dagger \tag{29}$$

where $x_0$, $x_0'$, $y_0$, and $y_0'$ are the initial conditions of the electron path. Here

$$Y(z)=-(1/2\phi)\int_{z_0}^{z}d\zeta\int_{z_0}^{\zeta}E(u)du, \tag{30}$$

is the deflection caused by the electrostatic field. If $z=z_1$ is the position coordinate of the screen, the deflection, $d$, at the screen for an electron with the initial conditions $x_0=y_0=x_0'=y_0'=0$ is given by

$$d=Y_1=Y(z_1)=-(1/2\phi)\int_{z_0}^{z_1}d\zeta\int_{z_0}^{\zeta}E(u)du. \tag{31}$$

Since $E(z)$ is proportional to the potential difference $\Delta\phi$ between the electrodes, it can be seen from Eq. (31) that $d$ is a linear function of $\Delta\phi$. This is a desirable property of a deflection field, but an actual field has this property only to the extent that it is permissible to neglect the higher order terms in Eq. (26). A more accurate solution of Eq. (26) will be given which shows the extent to which the actual paths deviate from the first-order paths.

The quantities $x'$, $y'$, $|\frac{1}{2}(E/\phi)y|$, are still assumed to be small, but not negligibly so. It may be expected that the actual solution of Eq. (26) will differ but little from the first-order solution Eq. (29). Only a small error will therefore be made if $y$ and $x$ of Eq. (29) are substituted in all terms of Eq. (26) which were previously neglected. The terms $x_0$, $x_0'$, $y_0$, and $y_0'$ would then appear in the new solutions for $x=x(z)$ and $y=y(z)$. It is, however, more convenient to use four other quantities, namely, the coordinates and slopes of the undeflected electron at the

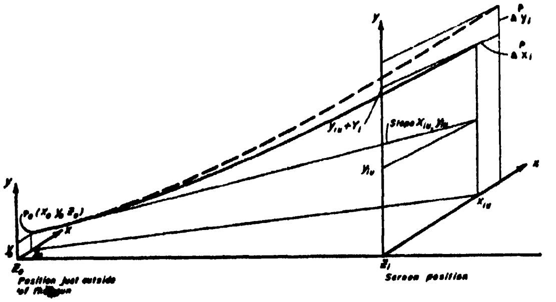

FIG. 3. The geometry of deflection (path method).

---

† This solution corresponds to the "paraxial ray" equation of the theory of focusing fields. In this theory the equation describes a path called the Gaussian path. It was for this reason that the subscript $g$ was chosen.

screen defined by Eq. (1). Replacing $x_0$, $y_0$, $x_0'$, and $y_0'$ in Eq. (29) by $x_{iu}$, $y_{iu}$, $x_{iu}'$, and $y_{iu}'$ (using Eqs. (2), (3)), the following equations are obtained for $x_g$ and $y_g$:

$$\left.\begin{aligned} x_g(z) &= x_{iu}+x_{iu}'(z-z_i), \\ y_g(z) &= y_{iu}+y_{iu}'(z-z_i)+Y(z). \end{aligned}\right\} \tag{32}$$

Substituting Eq. (32) in Eq. (26), the solutions $x(z)$ and $y(z)$ of the resulting differential equations are obtained by simple integrations. The terms of this solution may be arranged in powers of $x_{iu}$, $y_{iu}$, $x_{iu}'$, $y_{iu}'$. If the difference between the new and the former solution is taken and the integrals are extended from $z_0$ to $z_i$, two quantities $\Delta^P x_i$, $\Delta^P y_i$ are derived which describe the deviations at the screen of the actual electron path from the first-order path given by Eq. (29). (See Fig. 3.) These quantities $\Delta^P x_i$ and $\Delta^P y_i$ may be written as

$$\left.\begin{aligned} \Delta^P x_i &= \alpha_{0010}x_{iu}'+\alpha_{0110}x_{iu}'y_{iu}+\alpha_{0011}x_{iu}'y_{iu}'+\alpha_{0210}x_{iu}'y_{iu}^2+\alpha_{0111}x_{iu}'y_{iu}'y_{iu}+\alpha_{0012}x_{iu}'y_{iu}'^2, \\ \Delta^P y_i &= \beta_{0000}+\beta_{0100}y_{iu}+\beta_{0001}y_{iu}'+\beta_{0200}y_{iu}^2+\beta_{0020}x_{iu}'^2+\beta_{0002}y_{iu}'^2+\beta_{0101}y_{iu}'y_{iu} \\ &\quad +\beta_{0300}y_{iu}^3+\beta_{0120}x_{iu}'^2y_{iu}+\beta_{0102}y_{iu}y_{iu}'^2+\beta_{0021}x_{iu}'^2y_{iu}'+\beta_{0201}y_{iu}^2y_{iu}'+\beta_{0003}y_{iu}'^3. \end{aligned}\right\} \tag{33}$$

Here the notation, similar to that for the expressions $x_i$ and $y_i$, Eqs. (4), has been used to describe the expansion of the additional deflections $\Delta^P x_i$ and $\Delta^P y_i$. Since

$$x_i \cong x_g(z_i)+\Delta^P x_i = x_{iu}+\Delta^P x_i,$$

$$y_i \cong y_g(z_i)+\Delta^P y_i = y_{iu}+Y_i+\Delta^P y_i.$$

Then, to the degree of approximation considered here

$$M_{1000}=1+\alpha_{1000}, \quad \text{otherwise} \quad M_{a,b,c,d}\equiv\alpha_{a,b,c,d}$$

and

$$N_{0000}=\beta_{0000}+Y_i, \quad N_{0100}=1+\beta_{0100}, \quad \text{otherwise} \quad N_{a,b,c,d}\equiv\beta_{a,b,c,d}.$$

The coefficients $\alpha_{a,b,c,d}$ and $\beta_{a,b,c,d}$ are certain definite integrals from $z_0$ to $z_i$ which can be written in various forms. After carrying out the operations mentioned above, some of these coefficients contain double integrals which can be changed to single integrals by the use of the formula

$$\int_{z_0}^{z_i} d\zeta \int_{z_0}^{\zeta} F(u)du = -\int_{z_0}^{z_i} F(u)(u-z_i)du. \tag{34}$$

Some integrands have the second derivative of the axial field distribution $E''(z)$ as a factor. In general, $E(z)$ is known from experiment and $E''(z)$ can then only be obtained by numerical differentiation. This leads to inaccuracies which can be avoided by eliminating $E''(z)$ from all integrands employing the method of partial integration. This method and the equations

$$Y''(z) = -\frac{1}{2\phi}E(z), \tag{35}$$

and

$$Y_i = Y(z_i) = (1/2\phi)\int_{z_0}^{z_i}(\alpha-z_i)E(\alpha)d\alpha \tag{36}$$

were used to simplify the coefficients $\alpha_{a,b,c,d}$ and $\beta_{a,b,c,d}$ which were first derived by J. Picht and

J. Himpan[6] in a different form. They may be written as follows:

$$
\left.\begin{aligned}
\alpha_{0100} &= \tfrac{1}{2} Y_i Y_i' + \frac{3}{4\phi}\int_{z0}^{z_i} EY\,dz + \frac{1}{8\phi^2}\int_{z0}^{z_i} E^2 Y^2 dz, \\
\alpha_{0110} &= -\frac{1}{2\phi}E_0(z_i - z_0) - Y_i' + \frac{1}{4\phi^2}\int_{z0}^{z_i} E^2 Y dz, \\
\alpha_{0011} &= 2Y_i + \frac{1}{2\phi}E_0(z_i - z_0)^2 + \frac{1}{4\phi^2}\int_{z0}^{z_i} E^2 Y(z - z_i)dz, \\
\alpha_{0210} &= -\frac{1}{8\phi^2}E_0^2(z_i - z_0) + \frac{1}{8\phi^2}\int_{z0}^{z_i} E^2 dz, \\
\alpha_{0012} &= -\frac{1}{8\phi^2}E_0^2(z_i - z_0)^3 + \frac{1}{8\phi^2}\int_{z0}^{z_i} E^2 (z - z_i)^2 dz, \\
\alpha_{0111} &= \frac{1}{4\phi^2}E_0^2(z_i - z_0)^2 + \frac{1}{4\phi^2}\int_{z0}^{z_i} E^2 (z - z_i)dz;
\end{aligned}\right| \qquad (37)
$$

$$
\left.\begin{aligned}
\beta_{0000} = {} & \tfrac{1}{3} Y_i Y_i'^2 + \frac{1}{4\phi}E_i Y_i^2 - \frac{1}{6\phi}\int_{z0}^{z_i} EYY'dz + \frac{1}{2\phi^2}\int_{z0}^{z_i} E^2 Y(z - z_i)dz \\
& + \frac{1}{12\phi^2}E_i^2 Y_i^3 - \frac{3}{8\phi^2}\int_{z0}^{z_i} E^2 YY'^2(z - z_i)dz - \frac{3}{8\phi^2}\int_{z0}^{z_i} E^2 Y^2 Y'dz + \frac{1}{6\phi^2}\int_{z0}^{z_i} E'^2 Y^3(z - z_i)dz \\
& + \frac{5}{16\phi^3}\int_{z0}^{z_i} E^3 Y^2(z - z_i)dz + \frac{5}{32\phi^4}\int_{z0}^{z_i} E^1 Y^3(z - z_i)dz, \\
\beta_{0100} = {} & \tfrac{1}{2} Y_i'^2 + \frac{1}{2\phi}E_i Y_i + \frac{1}{4\phi^2}E_i^2 Y_i^2 + \frac{1}{2\phi^2}\int_{z0}^{z_i} E^2(z - z_i)dz - \frac{3}{8\phi^2}\int_{z0}^{z_i} E^2 Y'^2(z - z_i)dz \\
& + \frac{1}{2\phi^2}\int_{z0}^{z_i} E'^2 Y^2(z - z_i)dz - \frac{3}{4\phi^2}\int_{z0}^{z_i} E^2 YY'dz + \frac{5}{8\phi^3}\int_{z0}^{z_i} E^3 Y(z - z_i)dz \\
& + \frac{15}{32\phi^1}\int_{z0}^{z_i} E^1 Y^2(z - z_i)dz, \\
\beta_{0001} = {} & \tfrac{1}{2} Y_i Y_i' - \frac{1}{4\phi}\int_{z0}^{z_i} EY\,dz + \frac{1}{2\phi^2}\int_{z0}^{z_i} E^2(z - z_i)^2 dz - \frac{3}{8\phi^2}\int_{z0}^{z_i} E^2 Y^2 dz \\
& - \frac{3}{2\phi^2}\int_{z0}^{z_i} E^2 YY'(z - z_i)dz - \frac{3}{8\phi^2}\int_{z0}^{z_i} E^2 Y'^2(z - z_i)^2 dz + \frac{1}{2\phi^2}\int_{z0}^{z_i} E'^2 Y^2(z - z_i)^2 dz \\

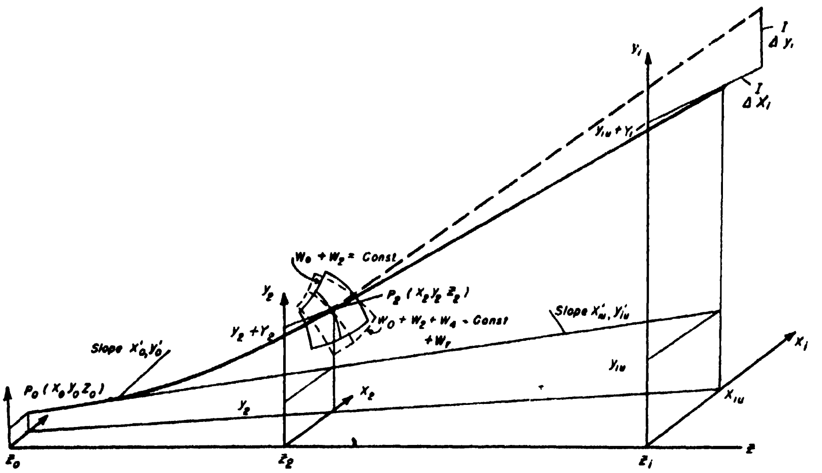

FIG. 4. The geometry of deflection (iconal method).

## 3. Iconal Method for a Single Electrostatic Deflection Field

Essentially the same coefficients can also be obtained by the use of the iconal method, as will now be shown. The point iconal function will be written in the form

$$W=\left(\phi\frac{2e}{m}\right)^{\frac{1}{2}}\int_{z_0}^{z_2}\left\{[1]+\left[-\frac{1}{2}\frac{E}{\phi}y+\tfrac{1}{2}(x'^2+y'^2)\right]+\left[-\frac{1}{8}\frac{E^2}{\phi^2}y^2-\tfrac{1}{8}(x'^2+y'^2)^2-\tfrac{1}{4}(x'^2+y'^2)y\frac{E}{\phi}\right.\right.$$
$$\left.+\frac{1}{12}\frac{E''}{\phi}y^3\right]+\left[-\frac{1}{16}\frac{E^3}{\phi^3}y^3-\tfrac{1}{16}(x'^2+y'^2)y^2\frac{E^2}{\phi^2}+\frac{1}{24}\frac{EE''}{\phi^2}y^4-\frac{5}{128}\frac{E^4}{\phi^4}y^4\right]$$
$$\left.+\text{higher order terms}\right\}dz, \tag{39}$$

or

$$W=W_0'+W_2+W_4+W_r+\text{higher order terms.}$$

If $P_0(x_0, y_0, z_0)$ remains fixed, $W=\text{const.}$ is the wave surface of electron radiation diverging from $P_0(x_0, y_0, z_0)$ and passing through the point $P_2(x_2, y_2, z_2)$. It is assumed that the space between the plane of the screen and the plane through $z_2$ parallel to the screen plane is field-free.†† (See Fig. 4.) The coordinates $x_i^{(1)}$ and $y_i^{(1)}$ of the electron path at the screen will then be given to the first degree approximation by

$$\left.\begin{aligned}x_i^{(1)}&=x_2+[(z_i-z_2)/\phi_i^{\frac{1}{2}}][\partial W_2/\partial x_2],\\ y_i^{(1)}&=y_2+[(z_i-z_2)/\phi_i^{\frac{1}{2}}][\partial W_2/\partial y_2].\end{aligned}\right\} \tag{40}$$

Equation (40) is derived from Eq. (13) by admitting only first-order terms. The expression $W_2$ has been determined by using the electron path equation in the form

$$\left.\begin{aligned}x_g(z)&=x_0[(z_2-z)/(z_2-z_0)]+x_2[(z-z_0)/(z_2-z_0)],\\ y_g(z)&=y_0[(z_2-z)/(z_2-z_0)]+y_2[(z-z_0)/(z_2-z_0)]-Y_2[(z-z_0)/(z_2-z_0)]+Y(z),\end{aligned}\right\} \tag{41}$$

with

$$Y(z)=-\frac{1}{2\phi}\int_{z_0}^{z}d\zeta\int_{z_0}^{\zeta}E(u)du. \tag{42}$$

The wave surface through the point $P_2(x_2, y_2, z_2)$, to a first approximation, is given by $W_0+W_2=\text{const.}$ More accurately, this surface will be given by $W_0+W_2+W_4+W_r=\text{const.}$ A new solution

---

†† This assumption can be discarded by an argument similar to that presented for focusing fields in the book by Zworykin, reference 7, p. 563.

for the coordinates of the electron path at the screen may be obtained in the form

$$\left.\begin{aligned} x_i^{(3)} &= x_2+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial W_2}{\partial x_2}\left[1+\frac{1}{2}\left(\frac{x_i^{(1)}-x_2}{z_i-z_2}\right)^2+\frac{1}{2}\left(\frac{y_i^{(1)}-y_2}{z_i-z_2}\right)^2\right]+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial(W_4+W_r)}{\partial x_2}, \\ y_i^{(3)} &= y_2+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial W_2}{\partial y_2}\left[1+\frac{1}{2}\left(\frac{x_i^{(1)}-x_2}{z_i-z_2}\right)^2+\frac{1}{2}\left(\frac{y_i^{(1)}-y_2}{z_i-z_2}\right)^2\right]+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial(W_4+W_r)}{\partial y_2}. \end{aligned}\right\} \quad (43)$$

The differences between the new and the former values of the coordinates are

$$\left.\begin{aligned} \Delta^I x_i &= x_i^{(3)}-x_i^{(1)}=\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial(W_4+W_r)}{\partial x_2}+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\left[\frac{1}{2}\left(\frac{x_i^{(1)}-x_2}{z_i-z_2}\right)^2+\frac{1}{2}\left(\frac{y_i^{(1)}-y_2}{z_i-z_2}\right)^2\right]\frac{\partial W_2}{\partial x_2}, \\ \Delta^I y_i &= y_i^{(3)}-y_i^{(1)}=\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\frac{\partial(W_4+W_r)}{\partial y_2}+\frac{z_i-z_2}{\phi_i^{\frac{1}{2}}}\left[\frac{1}{2}\left(\frac{x_i^{(1)}-x_2}{z_i-z_2}\right)^2+\frac{1}{2}\left(\frac{y_i^{(1)}-y_2}{z_i-z_2}\right)^2\right]\frac{\partial W_2}{\partial y_2}. \end{aligned}\right\} \quad (44)$$

Carrying out the indicated differentiations, the additional deflections $\Delta^I x_i$ and $\Delta^I y_i$ may be compared with the values $\Delta^P x_i$ and $\Delta^P y_i$ of the path method. The result of such a comparison is expressed by the following relations:

$$\left.\begin{aligned} \Delta^I x_i &= \Delta^P x_i-[(z_i-z_0)/(z_2-z_0)]\Delta^P x_2, \\ \Delta^I y_2 &= \Delta^P y_i-[(z_i-z_0)/(z_2-z_0)]\Delta^P y_2. \end{aligned}\right\} \quad (45)$$

Both methods give essentially the same result if the plane through $z_2$ terminates the deflection field where the deflection itself is still very small; then $\Delta^P x_2$ and $\Delta^P y_2$ will be small compared with $\Delta^P x_i$ and $\Delta^P y_i$, respectively.

The small difference between the results obtained by the two methods arises mainly from the fact that the path method corrects the first-order approximation path through the whole region from $z_0$ to $z_i$, while the iconal method corrects essentially only for the difference in slope at $z_2$, i.e., at the end of the field.

### 4. Some Remarks Concerning Applications

There are three problems which can be solved with the aid of the theory here presented. These are: (1) the determination of the "deflection" of the electron beam by any electric deflection system when the dimensions of the deflecting electrodes and their potentials are known; (2) the computation of the defocusing effects by a deflection system; and (3) the determination of deflection fields having less defocusing and distortion effects than those in common use.

The solution of the deflection problem requires a knowledge of the axial field-strength distribution $E(z)$. If the electrode shapes and potentials are known, $E(z)$ may, in some cases, be determined mathematically. In general, however, an experimental method must be used. The deflection may then be computed by means of Eq. (31). The problem of computing the defocusing and distortion effects requires a knowledge of $E(z)$, $E'(z)$, $Y(z)$, and $Y'(z)$. The defects of the deflection system are described by Eq. (33), the coefficients $\alpha_{a,b,c,d}$ and $\beta_{a,b,c,d}$ of Eqs. (37) and (38), ordinarily being determined by means of a planimeter. The coordinate $z_0$ is chosen to be outside the deflection field; $\alpha_{a,b,c,d}$ and $\beta_{a,b,c,d}$ are determined for any given screen position $z_i$ and any given potentials $\phi$ and $\Delta\phi$. Since $E(z)$ is proportional to $\Delta\phi$, the various terms in the coefficients may be arranged in powers of $\Delta\phi/\phi$. Terms other than the lowest in each coefficient may ordinarily be neglected, reducing the amount of work involved in making computations. In order to compute the spot distortion, $x_{iu}$, $y_{iu}$, and $x_{iu}'$, $y_{iu}'$ are chosen to be the coordinates and slopes, respectively, of an electron in the undeflected beam. It should be noted that if the electron beam is considered to be a rectilinear flow of electrons with sharp boundaries, either cylindrically or conically shaped, the computations need only be applied to a number of electrons on the circumference of the beam.

Equation (33) can also be used to determine pattern distortion. It has been pointed out that crossed electrostatic fields, necessary to obtain a

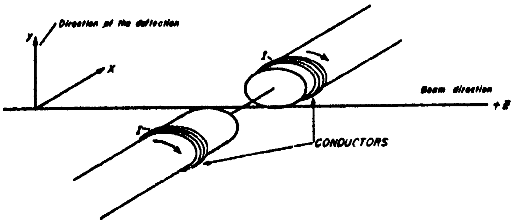

FIG. 5. Conductors and pole pieces producing a magnetic deflection field.

pattern, are arranged successively along the optical axis of the tube; it is assumed that a field-free plane exists between the two deflecting fields. The effects of both fields can then be superimposed linearly upon each other. An electron moving along the axis of the focusing system is deflected first by the vertical deflection system by the amount $Y(z_i)+\Delta^P y_i$ in the $y$ direction, and zero in the $x$ direction. Shortly after passing the vertical deflection field it passes through the horizontal deflection field, the effect of which is computed by replacing $x$ by $y$, and $y$ by $x$ in all equations written so far. The horizontal deflection will be

$$x_i=-\frac{1}{2\phi}\int_{z_0}^{z_i}d\zeta\int_{z_0}^{\zeta}E_h(u)du,$$

where $E_h(z)$ symbolizes the axial field-strength distribution of the horizontal deflection field. The quantities $\Delta^P y_i$ and $\Delta^P x_i$ determine the additional deflections when $x$ and $y$ are interchanged in Eq. (33). The "initial conditions" $x_{iu}$, $y_{iu}$, $x_{iu}'$, $y_{iu}'$ are given by

$$x_{iu}=0,\quad y_{iu}=Y_i,\quad x_{iu}'=0,\quad y_{iu}'=Y_i'.$$

Spot and pattern distortions were computed for a number of deflection systems and will be presented in Part II.

The third problem, namely, that of determining deflection fields having smaller defocusing and distortion effects than those ordinarily encountered, means, mathematically, to find a function $E(z)$ such that $Y_i$ has a prescribed value and yields coefficients $\alpha_{a,b,c,d}$ and $\beta_{a,b,c,d}$ smaller than those of known systems for the same value of $Y_i$. Various auxiliary conditions may be imposed such as those of constant electrode-to-screen distance, "reasonable" physical size of deflecting electrodes, etc. Solutions of these problems by mathematical procedures such as those used in the calculus of variations appear extremely difficult. It is more likely that trial and error methods, guided by the theory as expressed by Eqs. (31), (33), (37), and (38), will lead to improved deflection fields.

## C. MAGNETIC DEFLECTION FIELDS

### 1. The Field Distribution

Magnetic deflection fields of cathode-ray and television tubes are produced by a pair of iron or air-cored electromagnets placed in "ear-muff" position on the outside of the tube. This is illustrated in Fig. 5 by a single deflection field. In order to obtain a pattern on the screen of the tube, two such fields are needed, rotated 90 degrees about the optical axis with respect to each other. Ordinarily these two fields exist over the same interval along the axis. Electrostatic deflection fields were arranged one after the other along the axis. This difference between the arrangements necessitates a difference in theoretical treatment. The effects of the crossed magnetic fields can only be described by treating them as a single field obtained by superposition of the two fields, since both magnetic fields act simultaneously on the electron beam.

Series expressions for magnetic field distributions will now be derived in a manner similar to that used for electrostatic fields. Fields of the type pictured in Fig. 5 show a certain kind of symmetry. Again using Cartesian coordinates $x$, $y$, and $z$, with $+z$ in the direction of the original motion of the electrons, and with $y$ and $x$ in the direction of vertical and horizontal deflections, respectively, a mirror-type symmetry of the fields exists with respect to the $(x, z)$ and $(y, z)$ planes. The lines of force are mirror-symmetrical with respect to these planes. This condition may be expressed mathematically for the two fields by the following two sets of equations.

(1) Horizontal deflection field:

$$\left.\begin{aligned}H_x^h(x,y,z)&=-H_x^h(-x,y,z)\\&=-H_x^h(x,-y,z),\\H_y^h(x,y,z)&=+H_y^h(-x,y,z)\\&=+H_y^h(x,-y,z),\\H_z^h(x,y,z)&=+H_z^h(-x,y,z)\\&=-H_z^h(x,-y,z).\end{aligned}\right\}\quad(46)$$

(2) Vertical deflection field:

$$\left.\begin{aligned} H_x^v(x, y, z) &= +H_x^v(-x, y, z) \\ &= +H_x^v(x, -y, z), \\ H_y^v(x, y, z) &= -H_y^v(-x, y, z) \\ &= -H_y^v(x, -y, z), \\ H_z^v(x, y, z) &= -H_z^v(-x, y, z) \\ &= +H_z^v(x, -y, z), \end{aligned}\right\} \quad (47)$$

where $H_x^h$, $H_y^h$, $H_z^h$, and $H_x^v$, $H_y^v$, $H_z^v$ are the components of the magnetic field-strength vectors $\mathbf{H}^h$ and $\mathbf{H}^v$, respectively.

In current-free regions the relations

$$\operatorname{div}\mathbf{A}=0, \quad \nabla^2\mathbf{A}\equiv 0 \quad (48)$$

must hold for the magnetic vector potential $\mathbf{A}$, which is related to the magnetic field strength $\mathbf{H}$ by

$$\mathbf{H}=\operatorname{curl}\mathbf{A}. \quad (49)$$

The functions describing the components of the magnetic field strength may be expanded in power series of powers in $x$ and $y$ in which the coefficients are functions of $z$. Hence for the vertical deflection field one may write

$$\left.\begin{aligned} H_x^v &= p_{00}+p_{20}x^2+p_{02}y^2+p_{22}x^2y^2+p_{40}x^4+p_{04}y^4+p_{44}x^4y^4+p_{24}x^2y^4+p_{42}x^4y^2+\cdots, \\ H_y^v &= q_{11}xy+q_{13}xy^3+q_{31}x^3y+q_{33}x^3y^3+\cdots, \\ H_z^v &= r_{10}x+r_{12}xy^2+r_{32}x^3y^2+r_{14}xy^4+r_{34}x^3y^4+r_{30}x^3+\cdots. \end{aligned}\right\} \quad (50)$$

The procedure for the horizontal deflection field is the same.

In Eq. (50) use was made of the symmetry relations expressed by Eq. (47). The series for the components of the magnetic vector potential must then be (to give a relation expressed by (49)) of the form

$$\left.\begin{aligned} A_x^v &= a_{11}xy+a_{31}x^3y+a_{13}xy^3+a_{33}x^3y^3+a_{15}xy^5+\cdots, \\ A_y^v &= b_{00}+b_{20}x^2+b_{02}y^2+b_{22}x^2y^2+b_{40}x^4+b_{04}y^4+b_{24}x^2y^4+\cdots, \\ A_z^v &= c_{01}y+c_{21}x^2y+c_{03}y^3+c_{41}x^4y+c_{23}x^2y^3+c_{05}y^5+c_{43}x^4y^3+c_{25}x^2y^5+\cdots. \end{aligned}\right\} \quad (51)$$

The relations between the two sets of coefficients ($p_{\alpha\beta}$, $q_{\alpha\beta}$, $r_{\alpha\beta}$) and ($a_{\alpha\beta}$, $b_{\alpha\beta}$, $c_{\alpha\beta}$) may be found by the use of Eq. (49). Two more sets of relations between the coefficients of the set ($a_{\alpha\beta}$, $b_{\alpha\beta}$, $c_{\alpha\beta}$) may be found by use of the Eq. (48).

Redefining these coefficients $p_{00}$, $p_{02}$, and $p_{04}$ by

$$p_{00}\equiv -V_0(z), \quad p_{02}\equiv -V_2(z), \quad p_{04}\equiv -V_4(z), \quad (52)$$

the following series for the components $H_x^v$, $H_y^v$, and $H_z^v$ are obtained:

$$\left.\begin{aligned} H_x^v &= -V_0+(V_2+\tfrac{1}{2}V_0'')x^2-V_2y^2-[V_4+\tfrac{1}{6}V_2''+(1/24)V_0^{(\mathrm{IV})}]x^4 \\ &\qquad +(6V_4+\tfrac{1}{2}V_2'')x^2y^2-V_4y^4+\cdots, \\ H_y^v &= -2V_2xy-4V_4xy^3+(4V_4+\tfrac{1}{3}V_2'')x^3y+\cdots, \\ H_z^v &= -V_0'x-V_2'xy^2+(\tfrac{1}{3}V_2'+\tfrac{1}{6}V_0''')x^3+\cdots. \end{aligned}\right\} \quad (53)$$

The series for the components of the horizontal deflection field may be obtained by interchanging $x$ and $y$ in Eq. (53) and replacing $V_0$ by $-H_0$, $V_2$ by $-H_2$, and $V_4$ by $-H_4$. This yields

$$\left.\begin{aligned} H_x^h &= 2H_2xy+4H_4x^3y-(4H_4+\tfrac{1}{3}H_2'')xy^3+\cdots, \\ H_y^h &= H_0-(H_2+\tfrac{1}{2}H_0'')y^2+H_2x^2+[H_4+\tfrac{1}{6}H_2''+(1/24)H_0^{(\mathrm{IV})}]y^4 \\ &\qquad -(6H_4+\tfrac{1}{2}H_2'')x^2y^2+H_4x^4+\cdots, \\ H_z^h &= H_0'y+H_2'x^2y-(\tfrac{1}{3}H_2'+\tfrac{1}{6}H_0''')y^3+\cdots. \end{aligned}\right\} \quad (54)$$

The field strength of the combined fields is then given by

$$\left.\begin{aligned}
H_x &= -V_0+(V_2+\tfrac{1}{2}V_0'')x^2+2H_2xy-V_2y^2-[V_4+\tfrac{1}{6}V_2''+(1/24)V_0^{(\mathrm{IV})}]x^4+4H_4x^3y \\
&\qquad +(6V_4+\tfrac{1}{2}V_2'')x^2y^2-(4H_4+\tfrac{1}{3}H_2'')xy^3-V_4y^4+\cdots, \\
H_y &= H_0+H_2x^2-2V_2xy-(H_2+\tfrac{1}{2}H_0'')y^2+H_4x^4+(4V_4+\tfrac{1}{3}V_2'')x^3y \\
&\qquad -(6H_4+\tfrac{1}{2}H_2'')x^2y^2-4V_4xy^3+[H_4+\tfrac{1}{6}H_2''+(1/24)H_0^{(\mathrm{IV})}]y^4+\cdots, \\
H_z &= -V_0'x+H_0'y-V_2'xy^2+H_2'x^2y+(\tfrac{1}{3}V_2'+\tfrac{1}{6}V_0''')x^3-(\tfrac{1}{3}H_2'+\tfrac{1}{6}H_0''')y^3+\cdots.
\end{aligned}\right\} \tag{55}$$

The functions $-V_0$ and $+H_0$ are the axial field-strength distributions of the vertical and horizontal field strengths, respectively.

## 2. Theory of Magnetic Deflection

Either the path method or the iconal method may be used to describe the deflection and deflection defocusing effects of magnetic fields. Only the path method will be presented here; both methods give substantially the same result.

The equations of motion of an electron through any magnetic field are

$$\left.\begin{aligned}
\sqrt{\phi}(d/dz)[x'\ (1+x'^2+y'^2)^{\frac{1}{2}}] &= \eta[-y'H_z+H_y], \\
\sqrt{\phi}(d/dz)[y'/(1+x'^2+y'^2)^{\frac{1}{2}}] &= \eta[x'H_z-H_x],
\end{aligned}\right\} \tag{56}$$

where $\phi$ is the potential of the space in which the electrons are moving and $\eta=(e/2m)^{\frac{1}{2}}$, where $e$ and $m$ are charge and mass, respectively, of the electron. Equations (56) may be obtained either from

$$\delta\int_{P_0}^{P_1}\{[2(e/m)\phi]^{\frac{1}{2}}-e/m(\mathbf{A}\cdot\mathbf{s})\}ds=0, \tag{57}$$

with $\mathbf{H}=\mathrm{curl}\mathbf{A}$, or from Newton's equations of motion, written

$$m\frac{d^2\mathbf{r}}{dt^2}=-e[\mathbf{v}\times\mathbf{H}],\quad \text{with}\quad \mathbf{r}=x\mathbf{i}+y\mathbf{j}+z\mathbf{k}. \tag{58}$$

If the magnetic field is that given by Eqs. (55), the Eqs. (56) become

$$\left.\begin{aligned}
(d/dz)[x'-\tfrac{1}{2}x'^3-\tfrac{1}{2}x'y'^2] &= (\eta/\sqrt{\phi})[V_0'y'x-H_0'y'y+H_0+H_2x^2-2V_2xy-(H_2+\tfrac{1}{2}H_0'')y^2], \\
(d/dz)[y'-\tfrac{1}{2}y'^3-\tfrac{1}{2}y'x'^2] &= (\eta/\sqrt{\phi})[-V_0'x'x+H_0'x'y+V_0-(V_2+\tfrac{1}{2}V_0'')x^2-2H_2xy+V_2y^2],
\end{aligned}\right\} \tag{59}$$

where only terms of zero, first and second order of $x$, $x'$, $y$, and $y'$ are considered. To a first approximation, the equations of motion are

$$x''=(\eta/\sqrt{\phi})H_0,\quad y''=(\eta/\sqrt{\phi})V_0. \tag{60}$$

The solution of these equations is

$$x_g(z)=x_0+x_0'(z-z_0)+X(z),\quad y_g(z)=y_0+y_0'(z-z_0)+Y(z), \tag{61}$$ †††

where

$$X(z)=\frac{\eta}{\sqrt{\phi}}\int_{z0}^{z}d\zeta\int_{z0}^{\zeta}H_0(u)du,\quad Y(z)=\frac{\eta}{\sqrt{\phi}}\int_{z0}^{z}d\zeta\int_{z0}^{\zeta}V_0(u)du. \tag{62}$$

The quantities $X=X(z)$ and $Y=Y(z)$ at $z=z_s$ (the screen position) are the deflections at the screen.

---

††† This solution corresponds to the paraxial ray equation of the theory of focusing fields.

The deflections in the two directions $x$ and $y$ are independent of each other in this first-order approximation.

It was assumed that the quadratic terms in Eq. (59) were negligibly small. They are still assumed to be small, but will now be taken into account. Following the procedure used for electric deflection fields, $x$, $x'$, $y$, and $y'$ of Eq. (59) will be replaced by $x_0$, $x_0'$, $y_0$, and $y_0'$ of Eq. (61). This yields

$$\left.\begin{aligned}
(d/dz)[x'-\tfrac{1}{2}x_0'^3-\tfrac{1}{2}x_0'y_0'^2]=(\eta/\sqrt{\phi})\{&V_0'[y_0'+Y'][x_0+x_0'(z-z_0)+X]\\
&-H_0'[y_0'+Y'][y_0+y_0'(z-z_0)+Y]+H_0+H_2[x_0^2+x_0'^2(z-z_0^2)+X^2+2x_0x_0'(z-z_0)\\
&+2x_0X+2x_0'(z-z_0)X]-2V_2[x_0y_0+x_0'y_0(z-z_0)+y_0X+x_0y_0'(z-z_0)\\
&+x_0'y_0'(z-z_0)^2+y_0'(z-z_0)X+x_0Y+x_0'(z-z_0)Y+XY]\\
&-(H_2+\tfrac{1}{2}H_0'')[y_0^2+y_0'^2(z-z_0)^2+Y^2+2y_0y_0'(z-z_0)+2y_0Y+2y_0'(z-z_0)Y]\},\\
(d/dz)[y'-\tfrac{1}{2}y_0'^3-\tfrac{1}{2}y_0'x_0'^2]=(\eta/\sqrt{\phi})\{&-V_0'[x_0'+X'][x_0+x_0'(z-z_0)+X]\\
&+H_0'[x_0'+X'][y_0+y_0'(z-z_0)+Y]+V_0-(V_2+\tfrac{1}{2}V_0'')[x_0^2+x_0'^2(z-z_0)^2+X^2\\
&+2x_0x_0'(z-z_0)+2x_0X+2x_0'(z-z_0)X]-2H_2[x_0y_0+x_0'y_0(z-z_0)+y_0X\\
&+x_0y_0'(z-z_0)+x_0'y_0'(z-z_0)^2+y_0'(z-z_0)X+x_0Y+x_0'(z-z_0)Y+XY]\\
&+V_2[y_0^2+y_0'^2(z-z_0)^2+Y^2+2y_0y_0'(z-z_0)+2y_0Y+2y_0'(z-z_0)Y]\}.
\end{aligned}\right\}\quad(63)$$

The initial conditions $x_0$, $x_0'$, $y_0$, and $y_0'$ may be replaced by $x_{iu}$, $x_{iu}'$, $y_{iu}$, and $y_{iu}'$ of the undeflected electron. The relation between these quantities is

$$x_0=x_{iu}+x_{iu}'(z_0-z_i),\quad y_0=y_{iu}+y_{iu}'(z_0-z_i),\quad x_0'=x_{iu}',\quad y_0'=y_{iu}'.\quad(64)$$

The solution of the differential equations, Eqs. (63) can be obtained by simple integrations. If the differences $\Delta^M x_i$ and $\Delta^M y_i$ between the new solution and that given by Eqs. (61) are taken, one obtains

$$\left.\begin{aligned}
\Delta^M x_i=\gamma_{0000}&+\gamma_{1000}x_{iu}+\gamma_{0100}y_{iu}+\gamma_{0010}x_{iu}'+\gamma_{0001}y_{iu}'+\gamma_{2000}x_{iu}^2\\
&+\gamma_{1100}x_{iu}y_{iu}+\gamma_{0200}y_{iu}^2+\gamma_{0020}x_{iu}'^2+\gamma_{0011}x_{iu}'y_{iu}'+\gamma_{0110}x_{iu}'y_{iu}\\
&+\gamma_{1001}x_{iu}y_{iu}'+\gamma_{1010}x_{iu}x_{iu}'+\gamma_{0101}y_{iu}y_{iu}'+\gamma_{0002}y_{iu}'^2,\\
\Delta^M y_i=\delta_{0000}&+\delta_{1000}x_{iu}+\delta_{0100}y_{iu}+\delta_{0010}x_{iu}'+\delta_{0001}y_{iu}'+\delta_{2000}x_{iu}^2\\
&+\delta_{1100}x_{iu}y_{iu}+\delta_{0200}y_{iu}^2+\delta_{0020}x_{iu}'^2+\delta_{0011}x_{iu}'y_{iu}'+\delta_{0110}x_{iu}'y_{iu}\\
&+\delta_{1001}x_{iu}y_{iu}'+\delta_{1010}x_{iu}x_{iu}'+\delta_{0101}y_{iu}y_{iu}'+\delta_{0002}y_{iu}'^2.
\end{aligned}\right\}\quad(65)$$

The coefficients $\gamma_{a,b,c,d}$ and $\delta_{a,b,c,d}$ in Eq. (65) are

$$\begin{aligned}
\gamma_{0000}=\tfrac{1}{2}\int X'^3dz+\tfrac{1}{2}\int X'Y'^2dz-(\eta/\sqrt{\phi})\int Y'XV_0'(z-z_i)dz&\\

The path method was applied by G. Wendt[6] to obtain expressions $\Delta^M x_s$ and $\Delta^M y_s$ for a single magnetic field. His equations may be obtained from Eqs. (65)–(67) by letting either $H_0$, $H_2$, and $H_4$, or $V_0$, $V_2$, and $V_4$ be identically equal to zero.

The two crossed magnetic deflection fields of actual cathode-ray tubes are ordinarily superimposed. The simultaneous deflecting action finds its expression in the existence of cross-terms with integrals of the type

$$\int X'Y'dz,\quad \int XV_2(z-z')dz,$$

$$\int YH_2(z-z_s)dz \quad \text{etc.}$$

### 3. Some Remarks Concerning Applications

The solution of the deflection problem requires a knowledge of the axial field-strength distributions $V_0(z)$ and $H_0(z)$. Experimental methods are ordinarily the only means to determine these functions. It is rarely possible to compute them from the shapes of current conductors or pole pieces. The axial field strengths $V_0$ and $H_0$ could be measured by means of a number of methods described in the literature.[7]

In order to compute the distortion and defocusing effects, two other functions are required, namely $V_2(z)$ and $H_2(z)$. From Eq. (55) it can be seen that

$$(\partial^2 H_x/\partial y^2)\big|_{\substack{x=0\\y=0}}=-2V_2(z).$$

A similar equation holds for $H_2(z)$:

$$(\partial^2 H_y/\partial x^2)\big|_{\substack{x=0\\y=0}}=2H_2(z).$$

These relations provide the means to determine $V_2$ and $H_2$ experimentally. $H_x$ is measured in the $y$, $z$ plane at $z$ for a number of values of $y$ in the neighborhood of $y=0$. It is then possible to determine for each $z$ the quantity $(\partial^2 H_x/\partial y^2)|_{x=0,\,y=0}$ and hence $V_2(z)$. A similar procedure for $H_y$ will give $H_2(z)$. The measurements are made for each field alone.

The coefficients may be determined for any screen position coordinate $z_s$. Pattern and spot distortions are computed in a manner similar to that described for electrostatic fields.

Comparing the two sets of coefficients, a remark made above can now be verified easily. The set of coefficients $\gamma_{a,b,c,d}$ goes over into the set $\delta_{b,a,d,c}$ if $H_0$ is replaced by $V_0$, $H_2$ by $V_2$ and $x_{su}$ by $y_{su}$, and $x_{su}'$ by $y_{su}'$. If the functional dependency of the field-strength functions $H_0$, $H_2$ is the same as those of $V_0$, $V_2$, corresponding coefficients will also be alike numerically and only one set of coefficients need be calculated.

# Electrostatic Dischargers for Aircraft

WAYNE C. HALL
*Naval Research Laboratory, Washington, D. C.*

(Received February 27, 1947)

Methods of discharging static electricity from aircraft in flight so as to reduce or eliminate corona interference, commonly known as precipitation static, are discussed. These methods have been classified into those employing either gaseous ions (high mobility), or those employing charge carriers such as water spray or dust particles (low mobility). Devices within the first classification offer the better solution to the problem from a practical standpoint. A discharger invented and developed at the Naval Research Laboratory is described.

## INTRODUCTION

AIRCRAFT flying in stormy weather, at a time when radio communication becomes particularly important, often encounter a severe form of radio interference sufficient to prevent all reception.[1] The interference, which is commonly known as "precipitation static," results when the aircraft, acting as an isolated conductor, becomes electrically charged. When the charging is caused by rain, snow, ice particles, or dust, that is, by friction with atmospheric particles, it is found[2] that the charging is roughly proportional to the cube of the air speed and to the frontal area of the aircraft. Consequently, this effect may be expected to increase on the larger, higher speed aircraft of the future.

The reason for precipitation static may be seen from the following. Charging the aircraft results in generating a potential gradient between the aircraft and its surroundings sufficiently large to cause a corona discharge. Corona discharges on aircraft are also caused by electrical fields existing around the aircraft in the vicinity of highly charged clouds. The corona will occur from the regions of high electrical field surrounding sharp projections on the plane, such as the antennae, antenna masts, and propellers. Ordinarily, a corona discharge creates steep wave front impulses which will induce transient voltages of considerable magnitude in the antenna circuit of a radio receiver nearby. This results because the usual corona discharge occurs in the form of bursts which are cut off in a quasi-periodic fashion by accumulations of space charge about the discharge point. In exceptional cases, as from a very sharp point, non-pulsating corona currents causing no radio interference may be observed; however, the equilibrium which permits this type of discharge is unstable and is quickly destroyed by any effect which dulls the point. If the point of discharge is on the antenna itself, a corona current as small as one microampere may cause severe static.[3]

The radio interference resulting from corona can occasionally be removed by noise suppressor circuits. Usually, however, the interference created is continuous and covers so broad a frequency range that noise reduction circuits have little or no beneficial effects. In general, precipitation static—that is, radio interference induced by corona, is best prevented by removing the cause: that is, by preventing the formation of corona on the aircraft.

An interfering corona will be prevented or reduced only if the electrical charge is drained off from the aircraft so rapidly that a potential gradient sufficient to cause corona does not develop. Evidently, any modification of the aircraft which will raise the minimum potential gradient required to cause corona will be very beneficial. It can be accomplished by the use of electrostatic shielding, or by dielectric treatment, which will tend to prevent corona discharge from the antenna or the aircraft itself. Discussion of such treatments, however, is beyond the scope of this article, which is limited to the description of discharge devices capable of removing electrostatic charge from the aircraft.

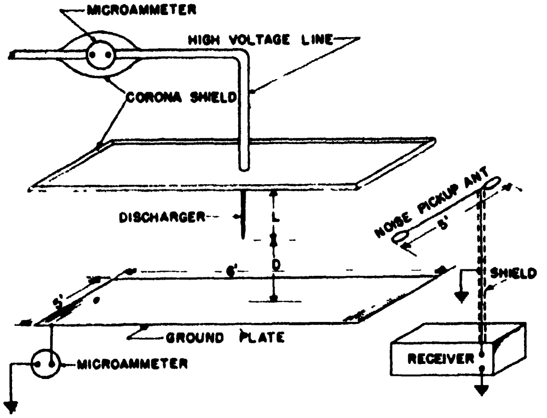

FIG. 1. Laboratory set-up to obtain discharger characteristics.

Electrostatic dischargers have the function of removing electric charge from the aircraft at a rate which substantially equals the rate of accumulation, and/or permitting the passage of electrical current to or from the aircraft when it is in the vicinity of charged clouds. Such dischargers may be classified into those using ions of high mobility (mobilities of 1.2 centimeters/second per volt/centimeter, or greater) and those using charge carriers, such as water particles or dust particles (mobilities varying from 0.002 to 0.01 centimeter/second per volt/centimeter). In the first classification are those dischargers involving the use of discharge wires or discharge points, while in the second classification are those involving the use of water spray or dust particles charged by induction or triboelectric processes.

## GASEOUS-ION DISCHARGERS

Consider, first, the static dischargers which involve the highly mobile gaseous ions and electrons. Steps involved in operating these dischargers are: (1) the production of ions, and (2) the subsequent removal of ions with one sign only from the charged aircraft by the surrounding electric field. The discharge current resulting will remove charge of the same sign as that on the aircraft, and will be limited primarily by the space charge that forms about the discharge points. An example of a discharger in this class is the so-called trailing wire discharger, which consists of a five-foot strand of small wire extending in flight from the tail of the aircraft. This discharger has had some use and does help. Another example of this class of discharger is one using needle points located on the extremities of the aircraft, or on the propellers. In these examples, the electric field causing separation of charge is fixed largely by the potential of the aircraft, a factor which may not be increased greatly without causing interfering corona on the aircraft. Hence, in an investigation of possible increased output for this class of dischargers, it is sufficient to consider only whether the discharger will benefit from more profuse generation of ions, and whether the number of dischargers to be used may be increased with beneficial effects.

For a laboratory study of the static discharger, an experimental arrangement was constructed consisting of two parallel plates, between which a d.c. potential difference of up to 60,000 volts could be established. The discharger under investigation was attached to one of these plates. Nearby, a short antenna attached to an aircraft type receiver was arranged so as to pick up the radiated interference created by the discharger; then simultaneous measurements of the potential difference between the plates, current from the discharger, and radio noise picked up by the antenna were taken. All noise measurements were made in terms of the equivalent signal required from a signal generator coupled to the

TABLE I. Characteristics of sharp point dischargers.

| Type of discharger | Distance $D$ to plate | Voltage | Discharge (micro-amperes) | Radio noise at 300 kc |
|---|---|---|---|---|

* Using blunt points, it was observed that discharge currents were reduced and noise signals up to 400 μv were obtained.

** Estimated r-f dissipation in arc = 5 to 10 watts.

*** See Table 3. Presented here for comparison purposes.

receiver through a 100-micromicrofarad condenser to cause a receiver output, as measured by an averaging meter, equal to that from the noise signal. Measurements were taken at two frequencies, 300 kilocycles and 4000 kilocycles. Since those at 300 kilocycles were always larger, for the sake of brevity only they will be given. The laboratory set-up is shown in Fig. 1.

Using sharp needle points about 10 centimeters long, with a separation of 40 centimeters between point and plate, results were obtained which are given in Table I. When dull or damaged needles were tried, noise measurements as great as 400 microvolts were observed.[4] Next, the experiment was repeated with short lengths of wire parallel to the plate, so as to duplicate, roughly, the trailing wire discharger. The results obtained are not given, because they are comparable to those obtained with the sharp needle points, except that the radio noise was much greater. In supplementary flight experiments, it was found that if very long lengths of wire, say 400 feet in length, were trailed behind an aircraft in flight, the entire wire exhibited corona and maintained the aircraft at a low potential. Although effective in some respects, such a discharger is not practical because of the radio noise generated, the difficulty of handling such a long wire, the undesirable alteration of the radio transmission characteristics of the aircraft, and the lightning hazard involved. The short trailing wire and the blunted needle point are practical but suffer from the defect, already explained, that the corona discharge from them causes noise in nearby radio receivers. In fact, it is possible to use either type of discharger with some degree of success only when it is suitably attached to the aircraft by a series decoupling resistor of about ½ megohm or more, and when it is properly installed on the tail of the aircraft, where the interference radiated will be shielded as much as possible from the overhead antennae. This means that trailing wire dischargers or needle points (whose sharp points soon become dull or damaged) should not be installed on the wings where good inductive coupling with the antennae exists. Such dischargers, therefore, are undesirably limited in use.

TABLE II. Characteristics of dischargers with thermal ions.

| Source of thermal ions | Distance $D$ to plate | Voltage | Discharge (microamperes) | Radio noise at 300 kc** |
|---|---|---|---|---|
| Acetylene flame* (blue cone—1 cm long) | 60 cm from flame to plate | +30,000 | 6 | <3 μv |
| | | +45,000 | 16 | <3 μv |
| | | +60,000 | 28 | <3 μv |
| | | −30,000 | −12 | <3 μv |
| | | −45,000 | −26 | 3 μv |
| | | −60,000 | −44 | 4 μv |
| Gasoline blowtorch (flame length—13 cm) | 54 cm from flame to plate | +45,000 | 14 | Radio noise input less than 3 μv |
| | | +60,000 | 20 | |
| | | −45,000 | −27 | |
| | | −60,000 | −43 | |
| Manufactured gas flame from Mecca burner (flame, 15 cm long) | 45 cm | +45,000 | 19 | <3 μv |
| | | +60,000 | 35 | <3 μv |
| | | −45,000 | −28 | <3 μv |
| | | −60,000 | −53 | 4 μv |
| Signal flare (flame—10 cm long) | 60 cm | +60,000 | 10 | <3 μv |
| | | −60,000 | −20 | <3 μv |

* Flame consumes about 225 cc acetylene (N.T.P.) per minute.
** Noise measurements are uncertain and may show large values for changing electric fields.

The problem remains of devising a discharger without such limitations and of investigating whether or not profuse generation of ions will improve the output of the discharger. Taking the second part of the problem first, several possible ion sources must be reviewed. Of these, the electric arc appears to be quite promising because of the known high ionization intensity existing in the arc. Also, it is known[5] that the superposition of a high frequency field upon a d.c. field at a point can be made to prevent discharge bursts causing interference. Based on this knowledge, experiments intended to measure the effectiveness of the electric arc as a static discharger have been carried out at several laboratories, including the Naval Research Laboratory. The discharger investigated at this Laboratory consisted of a blunt tungsten point supplied with radiofrequency energy from a resonant circuit and mounted on one of the two parallel plates in the d.c. field previously described. The discharge currents for an arc of about ½ inch length, requiring some 50 watts of oscillator power at a frequency of 8.0 megacycles, are given in Table I. With the receiver tuned to 300 kilocycles, the radio interference from the arc discharge was negligible; at 5 megacycles, it was serious. Evidently, therefore, the arc frequency should be several times that of the receiver frequency

---

[4] Needles employed in these experiments were common polished steel sewing needles of various sizes, the size having negligible effect upon the results. However, even a barely visible deformation of the point was sufficient to make the discharge from the point become noisy.

TABLE III. Characteristics of wick* dischargers.

| Type | Distance $D$ to plate | Voltage | Discharge (microamperes) | Radio noise at 300 kc |
|---|---|---|---|---|
| Glycerol impregnated (after 25 hours flight time on aircraft) | 30 cm | +40,000 | 13 | Less than 3 $\mu$v |
| | | +60,000 | 36 | Less than 3 $\mu$v |
| | | −40,000 | −18 | Less than 3 $\mu$v |
| | | −60,000 | −48 | Less than 3 $\mu$v |
| Metallized (with silver) | 30 cm | +30,000 | 12 | Less than 3 $\mu$v |
| | | +45,000 | 25 | Less than 3 $\mu$v |
| | | +60,000 | 44 | Less than 3 $\mu$v |
| | | −30 000 | −11 | Less than 3 $\mu$v |
| | | −45,000 | −26 | Less than 3 $\mu$v |
| | | −60,000 | −50 | Less than 3 $\mu$v |
| Metallized (with silver) | 2.5 cm | +15,000 | 20 | Less than 3 $\mu$v |
| | | +30,000 | 125 | Less than 3 $\mu$v |
| | | +53,000 | 350 | Sparkover above this |
| | | −30,000 | −130 | Radio noise less than 3 $\mu$v |
| | | −45,000 | −350 | |
| | | −60,000 | −620 | |

* Each wick of cotton fibers, over-all diameter ¼ inch, length approximately 6 inches.

for noise-free operation of the discharger. Results were disappointing, in that the amount of r-f power dissipated in the arc, provided it was large enough to reduce corona static, had only a small effect on the discharger current. This was determined by varying the oscillator power over the range from 50 to 150 watts; the arc length varied from ½ to 1½ inches over this range.

Parallel experiments seeking the effect of thermal ions on discharge characteristics were conducted in the apparatus already described, using flames in place of the r-f arcs previously used. It had been observed before that a flame could be made to ignite and burn in a slipstream by using a specially designed nozzle, and by using a fuel, such as acetylene, with a high heat of combustion. In the laboratory experiments, much radio noise resulted if any metallic projections having high field intensities sufficient to cause corona were present in the flame itself; however, flames could be made to discharge with no measurable radio noise. The results obtained in the laboratory using acetylene flames, gasoline, and solid fuel are given in Table II.

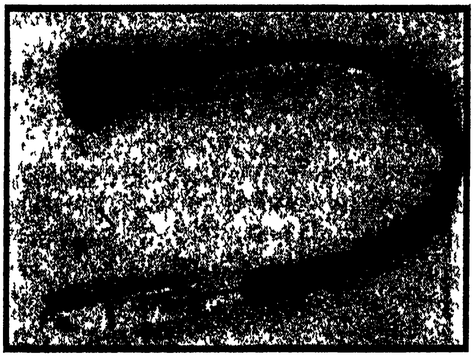

FIG. 2A. Wick type static discharger.

Next, exhaust gases from the aircraft reciprocating engines were considered for use in the discharge process; however, the low temperature, relatively speaking, of exhaust gases as they leave the exhaust pipe of this type of engine, results in ion densities too small to be of any real help. For example, calculations based on exhaust gas conductivity of eight electrostatic units (obtained from other data) indicate currents from the exhaust will be of the order of 10 to 20 microamperes per 1000 horsepower engine. This approximate result has been checked by experiment.[6] Discharge possibilities using the exhaust from jet type engines have not been investigated.

Certain observations may now be made, based on the data of Tables I and II. These data show that the point discharger, the arc discharger, and the flame discharger have roughly the same discharge current. The major part of the differences in discharge current which exist may be ascribed to differing geometries at the discharger, or to different separations between the parallel plates across which the d.c. test voltage was maintained. Neither the relatively diffuse ionized region of the flame, nor the intense ionization of the high frequency arc significantly increased the output of the discharger. The only conclusion which can be drawn is that all of these dischargers are space-charge limited and, therefore, are unavoidably limited in output.[7,8] With this

---

[6] R. G. Stimmel, E. H. Rogers, F. E. Waterfall, and R. Gunn, Proc. I.R.E. **34**, 175 (April, 1946).

[7] During discharge there is about any of the dischargers a narrow region or layer of intense ionization; the rest of the space between the plates is free from the action of the ionizing agent. Also, the discharge current to the opposite plate is only a small fraction of the maximum corresponding to the ionization. Hence, the situation is quite analogous to that discussed by J. J. Thomson, reference 8, for the case where ionization is confined to a thin layer between parallel plates. Thomson shows that in this case, the discharge current, $i$, is given by

$$i = A(V^2k/l^3)$$

where $A$ is a constant, $V$ is the potential difference between the plates, $l$ is the separation, and $k$ is the mobility of the ion carrying the charge. It is apparent that the current, $i$, is in mind, it becomes evident that improvements in the static discharger of this type can be realized only by making the discharger noise-free, cheap, easy to install, and capable of being attached at a number of points on the aircraft. The last improvement is the only one which can be expected to drain off larger and larger amounts of electric charge from the aircraft.

In the search for improvements along these lines, a "wick" discharger was developed by the author at the Naval Research Laboratory. It is essentially a small, flexible, treated cotton wick enclosed in a plastic tube, with many conducting fibers exposed at the end to serve as discharge points (see Fig. 2). The multitude of points in the wick have high resistance paths back to the aircraft, a negligible capacity, and provide a completely noise-free discharger of this type. Other fibers than cotton may be used, obviously, but none have been found more satisfactory. The cotton wick is treated to make it conducting, either by soaking the wick in an aqueous glycerol solution, chosen because it provides the desired low conductivity and has a very low rate of evaporation, or by metallizing the wicks with very thin deposits of metal. Either treatment is satisfactory, except that the glycerol treated wick is subject to a diminution in effectiveness as the glycerol evaporates or is diluted with rain water, and is more prone to become dirty in use on aircraft. The latter point is important, because wicks that are dirty may become noise. Metallized wicks using silver were found to have an indefinite life, except for mechanical wear. The discharge characteristics of some wicks made by the author are shown in Table III. These wicks generated no radio noise whatever at normal frequencies when properly made (so as to be free of metal flakes or bulky metal deposits), up to the limit of discharge which could be taken from the wicks before spark breakdown of the surrounding air occurred.

The "wick" discharger, or any discharger of this class, has limitations of the following nature. First, it must be placed on the aircraft in an exposed position where it will begin to discharge before other parts of the aircraft exhibit interfering corona. For best performance of these dischargers, therefore, they must be placed at the points of maximum electric field about the aircraft, as shown in Fig. 3. Two dischargers on each wing tip, and two to four on the empennage, represent a practical installation, though more could be used for improved performance. Second, no matter how many "wick" dischargers are used, precipitation static will occasionally be observed. This occurs when the charging current to the aircraft becomes significantly greater than the discharge current from the wicks. In such

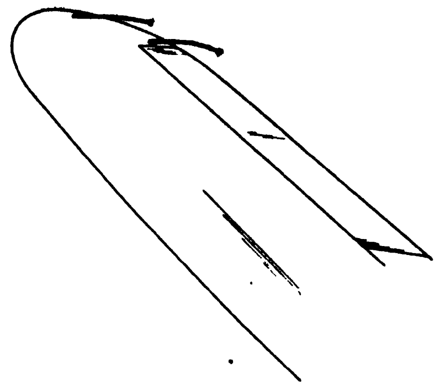

Fig. 2B. Wick type static discharger sample installation on wing.

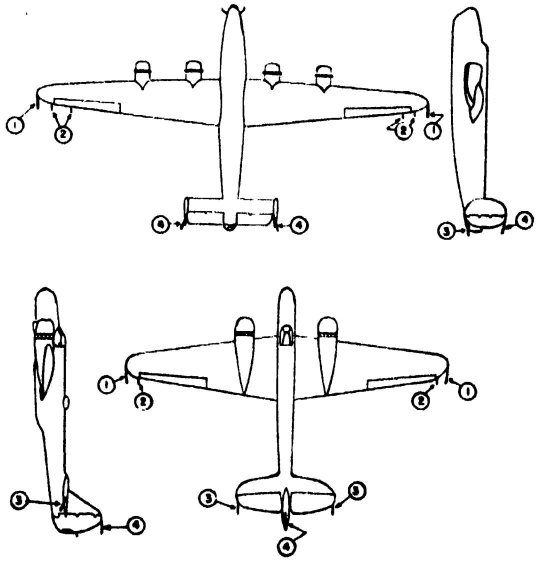

Fig. 3. Preferred localities for dischargers.

---

independent of the intensity or amount of ionization, and is thus space-charge limited.

[8] J. J. Thomson, *Conduction of Electricity through Gases* (Cambridge University Press) third edition, p. 206.

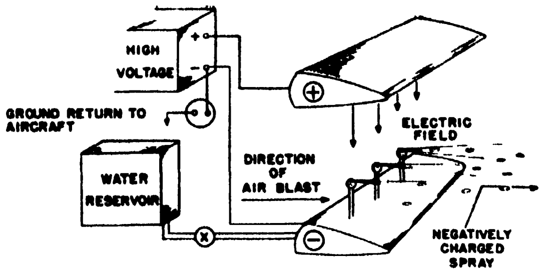

FIG. 4. Schematic of a water spray discharger.

cases, observed in severe atmospheric conditions, the aircraft will experience precipitation static, though usually for brief periods of time. For example, in the case of heavy rain, when precipitation static is heard, it will be difficult to remove. In this case, the streamers of water from the trailing edges of the airplane or other projections, such as the antenna, become, effectively, blunt points subject to corona discharge. Such streamers of water in an electric field under laboratory conditions are observed to cause intense radio static.

Another important point with regard to dischargers of this class should be made. It is known that atmospheric electrification of the aircraft may raise it to an extremely high potential with respect to its surroundings; for example, to a potential of one-half million volts. Consideration of this fact will lead to a realization that boosting the potential of a discharger relative to the aircraft by some 20,000 volts, such as may be obtained by a high voltage rectifier on the plane, will have little effect on the discharge current. Experimental results confirm this conclusion.

## HEAVY PARTICLE DISCHARGERS

The second class of electrostic dischargers involves heavy particles, such as charged water droplets, as charge carriers. Charged particles like these are produced, for example, in a liquid spray exposed to a strong electric field. Alternatively, these charge carriers are produced by a triboelectric process where certain finely divided materials, such as powdered quartz, flowing through friction tubes take on one sign of charge, leaving the other charge on the friction tube. Such particles have mobilities of the order of 0.002 centimeter/second per volt/centimeter.

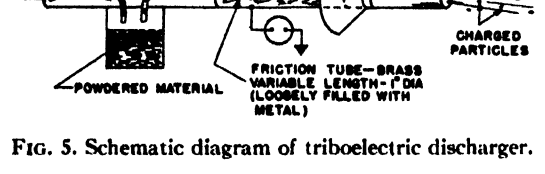

FIG. 5. Schematic diagram of triboelectric discharger.

Dischargers of this class have some advantages, in that:

(1) The external electric field about the aircraft does not necessarily affect the amount of charge induced upon the particles sprayed from the discharger; hence, the discharge currents are relatively unlimited, and the point of attachment is unimportant.

(2) The aircraft's external field does not necessarily determine the induced charge; therefore, discharge current of either sign may be obtained.

The induction type of discharger, using a water spray, is illustrated by Fig. 4. It exposes water droplets to a strong electric field as the water droplets are removed from a nozzle by a high speed blast of air. This discharger has been used very successfully to charge aircraft in flight under fair weather conditions for the purpose of simulating precipitation static conditions.[9] In flight tests using a large number of spray nozzles, discharge currents of 250 microamperes have been measured for a water discharge of approximately 75 grams/second. By stepping up the rate of flow of the water through the spray nozzle, this discharger could be made to discharge quite an appreciable current. If the auxiliary electric field that is established at the spray nozzle to charge the droplets is maintained slightly below a value sufficient to cause corona, there will be little radio noise generated. There are engineering drawbacks to such a discharger, however; for example, the discharger requires an auxiliary high voltage of some 20,000 volts, a bulky and heavy tank of non-freezing liquid such as alcohol, and it increases the aerodynamic losses of the aircraft.

The triboelectric discharger, on the other hand, is illustrated in one form that it takes in Fig. 5. Here the friction between the tube and particles moving through affects the amount of charge carried away by the particle. Since the friction

---

[9] R. C. Waddel, R. C. Drutowski, and W. N. Blatt, Proc. I.R.E. 34, 161–166 (April, 1946).

is partially determined by the velocity of the air blast through the tube, the data to be reported on the triboelectric discharger are for one air velocity only, namely, 250 miles per hour at the inlet tube. Table IV has been prepared to show the performance characteristics of this discharger under the given conditions. As high as 84 microcoulombs of charge per gram of material was obtained when using finely divided quartz (Santocel). Making the reasonable assumption that the average radius of the particles of the diatomaceous earth used (largely silica) was $10^{-4}$ centimeter, the theoretical limit of charge which could be carried by the powdered material per cubic centimeter of solid material (before pulverization) becomes $3E/4\pi R$, where $E$ is the electric field at breakdown of the surrounding air. This corresponds roughly to a figure of 80 microcoulombs per cubic centimeter, or 30 microcoulombs per gram.

With this type of discharge, the substance of the powdered material usually determines whether the sign of charge will be positive or negative. Many materials, when blown through the friction tube, came out with a negative sign. This would be desirable, because in nearly all cases of charging by atmospheric particles, the airplane became negatively charged and would require a discharger of negative electricity. Noise measurements on the triboelectric discharger gave erratic results; at times a high level of noise intensity was observed. These and other drawbacks, of an engineering and practical nature, are believed to be sufficiently important to prevent any commercial use of this discharger.

TABLE IV. Characteristics of triboelectric dischargers using powdered materials.

| Material | Discharge current (micro-amperes) | Discharge of material (grams/second) | Remarks | Efficiency micro-coulombs per gram of material |
|---|---|---|---|---|

## SUMMARY

To summarize, it appears that static dischargers are a practical necessity on aircraft using present-day methods of radio communication. Wicks or trailing wires, being simple and having relatively good performance, are to be preferred over other types. The wick discharger, if properly made, is completely noise-free and is applicable to the airplane at a number of points; hence, it appears to be the best available discharger. No discharger, alone, however, offers a complete solution to the problem.

# Slow Transverse Magnetic Waves in Cylindrical Guides

G. G. Bruck and E. R. Wicher
*Specialties, Inc., Syosset, Long Island, New York*

(Received March 24, 1947)

The fundamental physical phenomenon upon which linear electron accelerators and traveling beam tubes depend is the fact that the phase velocity of guided *TM* waves can be reduced to a fraction of the velocity of light. There are various practical ways of achieving these reduced velocities, such as diaphragms or spiral grooves in the guide wall. An open helix has been used by Pierce.

An accurate knowledge of the field pattern would greatly facilitate an understanding of these devices. It is of particular importance to have exact information about the field in the region in which the charge actually travels, namely, in a region located at least a considerable fraction of a wave-length from the guide walls. Because of the complex shapes assumed by actual guide walls calculations of the field are inevitably somewhat inexact and complicated.

The authors propose that, for the purposes of theory, the well-established proposition concerning the equivalence of true and simulated dielectrics in producing a slow field be used. We propose to think of slowing down the phase velocity by lining the guide walls with a natural dielectric. The essential properties of the slow field, particularly in the important region referred to above, will not be affected by this method of obtaining it while, on the other hand, the field calculation becomes quite easy and exact.

Although this procedure is intended in the main as a device to facilitate the theoretical calculation of the field, the authors believe that such a step—replacement of periodic metallic structures by dielectrics—might prove useful in some actual applications.

---

The solutions of Maxwell's equations appropriate to the description of a $TM_{01}$ mode propagated axially in a cylindrical tube, may be written

$$
\begin{aligned}
&E_z = AJ_0(\kappa\rho)+BN_0(\kappa\rho)\\
&E_r = (2\pi i/\kappa s)[AJ_1(\kappa\rho)+BN_1(\kappa\rho)]\\
&E_\varphi=0,\ H_z=0,\ H_r=0\\
&H_\varphi=(2\pi ic\epsilon/\kappa)[AJ_1(\kappa\rho)+BN_1(\kappa\rho)]
\end{aligned}
\tag{1}
$$

where $\rho=r/\lambda$, $s=v/c$, $\lambda$ = free space wave-length, $c$ = velocity of light, $v$ = phase velocity actually present in tube, $(z, r, \varphi)$ are standard cylindrical coordinates, $\kappa=2\pi c(\mu\epsilon-1/v^2)^{\frac{1}{2}}$, $\epsilon$ = inductive capacity of medium, $\mu$ = permeability, $(E_z, E_r, E_\varphi)$, are components of electric field strength, $(H_z, H_r, H_\varphi)$, are components of magnetic field strength, $A$, $B$ are arbitrary constants to be adjusted to fit assigned boundary conditions.

Georgi rationalized units are used. It is understood that the factor $\exp(i\omega t-\gamma z)$ has been omitted from the right members of all of (1). Here $\omega$ is the angular frequency, equal to $2\pi c/\lambda$, and $\gamma$ is the propagation constant. We neglect conductivity so that $\gamma=i\omega/v=2\pi i/s\lambda$.

Table I.

| $\rho_2$ | $\rho_2-\rho_1$ | $\epsilon_2/\epsilon_1$ |
|---|---|---|
| 0.9564 | 0.00064 | 154000.0 |
| 0.05530 | 0.00530 | 2499.0 |
| 0.05943 | 0.00943 | 774.4 |
| 0.06164 | 0.01164 | 524.3 |
| 0.07187 | 0.02187 | 174.4 |
| 0.08958 | 0.03958 | 74.44 |
| 0.10000 | 0.05000 | 57.25 |
| 0.1500 | 0.1000 | 34.27 |
| 0.4897 | 0.4397 | 25.63 |

We apply the solutions (1) to the case of a pair of infinitely long coaxial cylinders with radii $r_1=\rho_1\lambda$ and $r_2=\rho_2\lambda$, $\rho_1<\rho_2$. The inner cylinder is evacuated and the region $\rho_1<\rho<\rho_2$ is filled with a dielectric of inductive capacity $\epsilon_2$. The outer cylinder is bounded by a perfect conductor. In the following we call the region $\rho<\rho_1$, region I, and the region $\rho_1<\rho<\rho_2$, region II. Parameters referring explicitly to these regions are distinguished by the use of subscripts 1 and 2.

In medium *I*, $B_1=0$ because the *N* functions are infinite at $\rho=0$. Hence,

$$
\begin{aligned}
&E_{z1}=A_1J_0(\kappa_1\rho),\quad E_{r1}=(2\pi i/\kappa_1 s)A_1J_1(\kappa_1\rho),\\
&E_{\varphi1}=0,\quad H_{z1}=0,\quad H_{r1}=0,\\
&H_{\varphi1}=(2\pi ic\epsilon_1/\kappa_1)A_1J_1(\kappa\rho),
\end{aligned}
\tag{2}
$$

$$\kappa_1=2\pi(1-1/s^2)^{\frac{1}{2}}. \tag{3}$$

We now examine three cases.

Case *I*. $\kappa_1$ is real. Then by (3), $s>1$ and $v>c$. The $z$ component of the electric field is described by the function $J_0(\kappa_1\rho)$ which is unity at $\rho=0$, and which tapers off to a zero at $\kappa_1\rho=2.4048$. In general, the fact that $J_0(\kappa_1\rho)$ is a decreasing

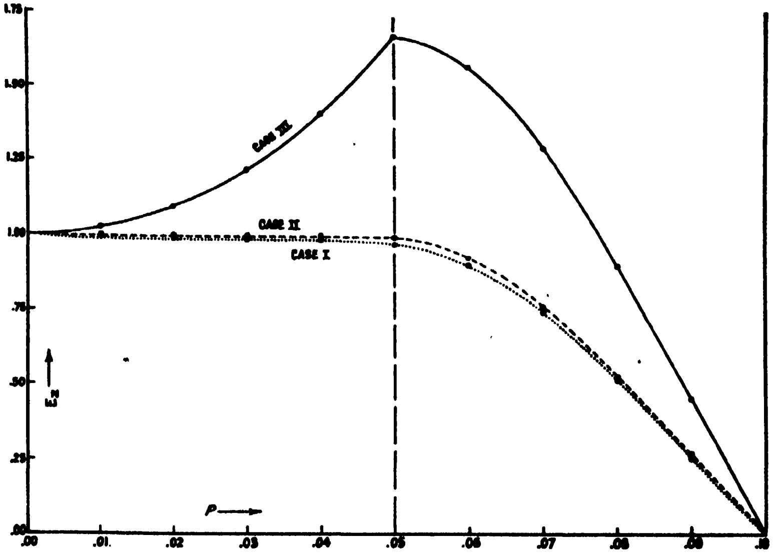

FIG. 1. Distribution of the longitudinal component of electric field strength through a cross section of the tube.

function for real $\kappa_1$ makes it usable in any case where $v>c$.

Case *II*. $\kappa_1$ is zero. Then by (3), $s=1$ and $v=c$. This gives $E_{z1}=A_1$, a constant. If region *I* were bounded by a conductor, this result would be trivial since all field components would have to vanish. Here, the result will have application to cases of electron accelerators, or traveling wave tubes in which the electrons have an energy of more than $10^6$ electron volts.

Case *III*. $\kappa_1$ is imaginary. In this case $s<1$ and $v>c$. This gives an $E_{z1}$ distribution described by $J_0(i|\kappa_1|\rho)=I_0(|\kappa_1|\rho)$, an increasing function of $\rho$. This type of distribution is of particular interest because it permits slowing down the phase velocity of the field to any desired value.

In region *II* the fields will be given by

$$\begin{aligned}
&E_{z2}=A_2J_0(\kappa_2\rho)+B_2N_0(\kappa_2\rho)\\
&E_{r2}=(2\pi i/\kappa_2 s)[A_2J_1(\kappa_2\rho)+B_2N_1(\kappa_2\rho)] \qquad (4)\\
&E_{\varphi 2}=0,\ H_{z2}=0,\ H_{r2}=0
\end{aligned}$$

$$\left.\begin{aligned}
&H_{\varphi 2}=(2\pi ic\epsilon_2/\kappa_2)[A_2J_1(\kappa_2\rho)+B_2N_1(\kappa_2\rho)]\\
&\kappa_2=2\pi[(\epsilon_2\mu_2/\epsilon_1\mu_1)-(1/s^2)]^{\frac{1}{2}}.
\end{aligned}\right\} \quad (5)$$

The boundary conditions may be written

$$\begin{aligned}
&E_{z2}(\kappa_2\rho_2)=0,\\
&E_{z1}(\kappa_1\rho_1)=E_{z2}(\kappa_2\rho_1), \qquad (6)\\
&\epsilon_1E_{r1}(\kappa_1\rho_1)=\epsilon_2E_{r2}(\kappa_2\rho_1).
\end{aligned}$$

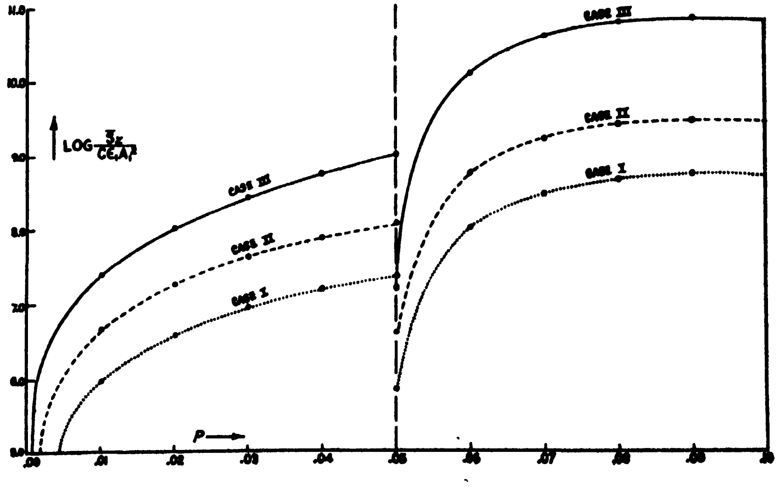

FIG. 2. Energy distribution. The logarithm of the real part of the complex Poynting vector plotted against the radial coordinate of the tube. The logarithm has been used to obtain a convenient scale.

From (2), (4), and (6) we get

$$A_2/A_1=(\pi\kappa_2\rho_1/2)\big[(\epsilon_1/\epsilon_2)(\kappa_2/\kappa_1)N_0(\kappa_2\rho_1)J_1(\kappa_1\rho_1)-N_1(\kappa_2\rho_1)J_0(\kappa_1\rho_1)\big],$$
$$B_2/A_1=(\pi\kappa_2\rho_1/2)\big[J_0(\kappa_1\rho_1)J_1(\kappa_2\rho_1)-(\epsilon_1/\epsilon_2)(\kappa_2/\kappa_1)J_0(\kappa_2\rho_1)J_1(\kappa_1\rho_1)\big]. \tag{7}$$

In these formulas $A_1$ is simply the amplitude of the $z$ component of the electric field along the axis. From (6) and (7) we obtain

$$\frac{\epsilon_1}{\epsilon_2}\frac{\kappa_2}{\kappa_1}\frac{J_1(\kappa_1\rho_1)}{J_0(\kappa_1\rho_1)}=\frac{N_0(\kappa_2\rho_2)J_1(\kappa_2\rho_1)-J_0(\kappa_2\rho_2)N_1(\kappa_2\rho_1)}{N_0(\kappa_2\rho_2)J_0(\kappa_2\rho_1)-J_0(\kappa_2\rho_2)N_0(\kappa_2\rho_1)}. \tag{8}$$

This formula, taken with the definitions of $\kappa_1$ and $\kappa_2$, is a relation between field velocity, tube radii, and the dielectric constant of region *II*. In order to have a definite Case *III* to discuss, we chose $s=v/c=0.2$ and let $\rho_1=0.05$. These choices are arbitrary, and are simply meant to be illustrative. Having made this selection, (8) can be solved by a combination of patience with a variety of numerical procedures. The result is shown in Table I.

One particularly useful device in obtaining these points is to select the product $\kappa_2\rho_2$ to be a zero of either $J_0(\kappa_2\rho_2)$ or $N_0(\kappa_2\rho_2)$. For general points, (8) may be transformed to read

$$\frac{\epsilon_1}{\epsilon_2}\frac{\kappa_2}{\kappa_1}\frac{J_1(\kappa_1\rho_1)}{J_0(\kappa_1\rho_1)}=\frac{|H_1^{(1)}(\kappa_2\rho_1)|\sin(\psi-\theta_1)}{|H_0^{(1)}(\kappa_2\rho_1)|\sin(\psi-\theta_0)}, \tag{9}$$

where $\psi=\arg H_0^{(1)}(\kappa_2\rho_2)$, $\theta=\arg H_0^{(1)}(\kappa_2\rho_1)$, $\theta_1=\arg H_1^{(1)}(\kappa_2\rho_1)$.

The tables in Watson† are simply applicable to this form. We did the calculations from (9) to four significant figures and checked the results by substitution into (8). It will be noticed that for a given $\epsilon_2/\epsilon_1$, a denumerable set of numbers $\rho_2$ exists; we tabulate only the lowest $\rho_2$.

To compare field strength distributions, energy distributions, and field patterns in the three cases, we selected $v=0.2c$ (Case *III*), $v=c$ (Case *II*), and $v=5c$ (Case *I*), and fixed $\rho_1=0.05$ and

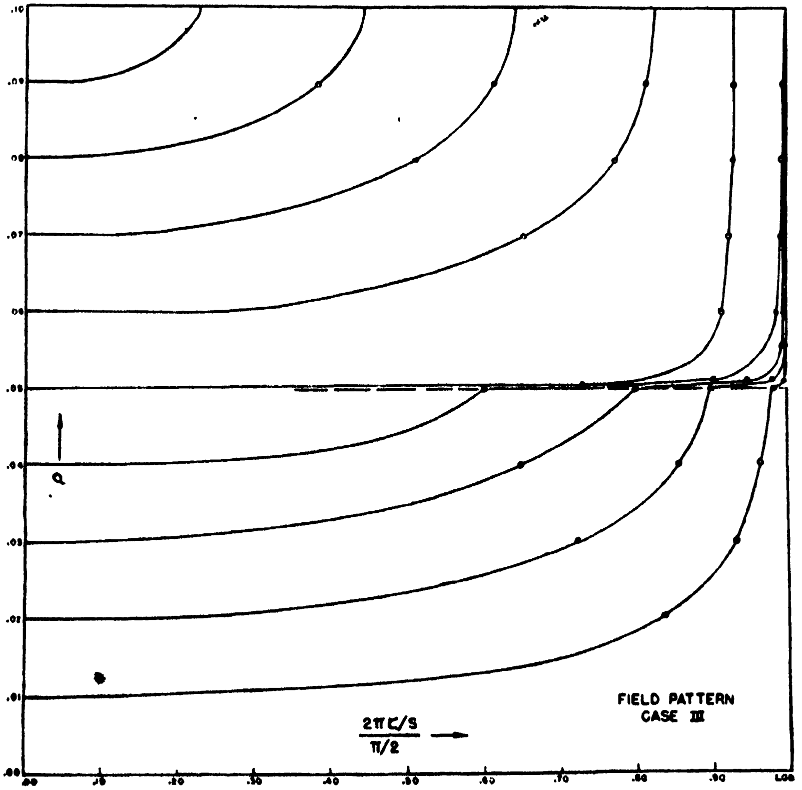

FIG. 3. Longitudinal field pattern, showing lines connecting points of equal electric field strength along a longitudinal cross section of the tube. The slope of the lines gives the direction of the field. $\zeta=z/\lambda$, and $s=v/c=2/10$.

---

† G. N. Watson, *Theory of Bessel Functions* (The Macmillan Company, New York, 1945), Chapter XX.

$\rho=0.10$ in all cases. This gives $\epsilon_2/\epsilon_1=57.25$ (Case *III*), $\epsilon_2/\epsilon_1=32.80$ (Case *II*), $\epsilon_2/\epsilon_1=31.82$ (Case *I*).

The results of this comparison for the distribution of the $z$ component of the electric field are seen in Fig. 1.

The real part of the complex Poynting vector is given by

$$\bar{S}_{z1}/c\epsilon_1 A_1^2=(2\pi^2/\kappa_1^2 s)[J_1(\kappa_1\rho)]^2,$$

$$\bar{S}_{z2}/c\epsilon_1 A_1^2=\frac{2\pi^2}{\kappa_2^2 s}\frac{\epsilon_2}{\epsilon_1}\left[\frac{A_2}{A_1}J_1(\kappa_2\rho)+\frac{B_2}{A_1}N_1(\kappa_2\rho)\right]^2. \tag{10}$$

Figure 2 shows the logarithm of this quantity as a function of $\rho$ for the three cases. It is obvious that practically all the energy is carried in region *II* in each case.

The field pattern is given by integrating the relation

$$dz/dr=ReE_z/ReE_r. \tag{11}$$

Letting

$$\zeta=z/\lambda, \tag{12}$$

(11) yields

$$\begin{aligned}\kappa_1\rho J_1(\kappa_1\rho)&=C_1\sec(2\pi\zeta/s)\\ \kappa_2\rho[A_2J_1(\kappa_2\rho)+B_2N_1(\kappa_2\rho)]&=C_2\sec(2\pi\zeta/s),\end{aligned} \tag{13}$$

where $C_1$ and $C_2$ are integration constants. The obvious requirement on these constants is

$$\frac{C_1}{C_2}=\frac{\kappa_1\rho_1J_1(\kappa_1\rho_1)}{\kappa_2\rho_1[A_2J_1(\kappa_2\rho_1)+B_2N_1(\kappa_2\rho_1)]}. \tag{14}$$

In Case *II* the first of Eqs. (13) may be replaced by

$$\rho^2=C_1\sec 2\pi\zeta, \tag{15}$$

so that (14) becomes, for this case

$$\frac{C_1}{C_2}=\frac{\rho_1^2}{\kappa_2\rho_1[A_2J_1(\kappa_2\rho_1)+B_2N_1(\kappa_2\rho_1)]}. \tag{16}$$

It develops that if the pattern be drawn by plotting $\rho$ against $2\pi\zeta/s$, there is no appreciable difference between the three cases. This means that the effect of decreasing the field velocity is simply to compress the pattern in the direction of propagation. Figure 3 shows the pattern for Case *III*.

# Incandescent Lamps as Electrical Load for Testing

S. Keilien
*Pass and Seymour, Inc., Syracuse, New York*

(Received March 25, 1947)

Because of the positive coefficient of resistivity of tungsten, incandescent lamps permit a current considerably greater than the normal lamp current to flow for a short initial period. When lamps are used as load for testing electrical apparatus, the factors affecting this inrush must be considered. Size of power source, its distance from the load (lamps), and frequency of switching the lamps (employing repetitive operations for endurance testing) are evaluated.

From the given curve the necessary cooling time for the desired current inrush may be determined, and thus the frequency with which the lamps could be switched "on" and "off" may be calculated. Practical means for obtaining the required cooling time are described.

ONE of an electric control device's usual function is switching. In this operation the electrical load is either connected to or disconnected from the source of power supply and, to be acceptable, the switching element should be capable of performing with least deterioration.

There are 3 basic types of loads, and their characteristics affecting the performance of switching devices may be summed up as follows:

Non-inductive-resistance load-current rise to reach the Ohm's-law value and its fall to zero (when disconnected) is instantaneous; the values of steady-state conditions are not exceeded.

Inductive load-current rise is gradual, depending on the rate of magnetic flux build-up; on disconnection of this load the stored electromagnetic energy is dissipated quickly, causing momentarily a high voltage, frequently far above that of the supply.

Tungsten-filament lamp load-current rise is very rapid and the maximum exceeds that of the steady-state value; current decay to normal value, following its reaching the peak, is relatively slow; upon the disconnection the fall of current to zero is instantaneous.

TABLE I.* Ratio *R* for various size lamps.

| Size of lamp watts | Ratio *R* |
|---|---|
| 100 | 9.1 |
| 500 | 8.7 |
| 1000 | 6.8 |

* R. W. Gillette, "Control of Multiple Street Lighting," Elec. World **94**, 419 (1929).

From the above grouping it will be seen that the inductive and the tungsten-filament lamp loads call for special precautions to be taken: the former upon interruption of the circuit (because of presence of high voltage) and the latter at completion of the circuit (because of current inrush).

In practice, the usual non-inductive-resistance loads are heating appliances of various kinds; the inductive load is typified by magnets and motors; the lamp-load characteristics are present in tungsten-filament lamps and condensers. For determination of suitability of a switching device, it is usually tested under various load conditions, and it is important to give proper consideration to these loads if the results of tests are to be used as criteria.

Tungsten filament lamps are employed extensively for testing the devices which are designed for such loads, or which are intended for loads with initial inrush of current. It is important, therefore, to have a clear conception of lamp characteristics and of limitations to assure their proper application as loads for testing.

TABLE II. Ratio *R* for various size lamp loads and their distance from busbars.

Notes: 1. All lamps—115 volts.
2. Power derived from specially designed 125 volts d.c. generator.
3. Values of "length" in first column—length of conductors between load and busbars.
4. Plus sign (+) in first column indicates series connections.

Because of the positive temperature coefficient of resistivity of the metal, the tungsten-filament lamps possess low resistance when cold and higher resistance when heated. It must be noted that carbon-filament lamps have the reverse characteristics because of the negative coefficient of resistivity of carbon. For regular 115- or 120-volt tungsten-filament lamps, sizes 40 to 1500 watts, the operating temperature of the filament varies between 4400°F and 4900°F, and the resistance of a hot lamp is 15 to 17 times that of a cold lamp. Consequently, if a cold lamp is connected to a source of supply, a current considerably greater than the normal lamp current will flow for a short time. Because of heating by the passing current, the temperature of the filament will rise and so will its resistance, thus causing a corresponding decrease in current. It would appear that the ratio of inrush current to the normal lamp current would be also 15 or 17 to 1. However, these values are not attained usually, for the inrush current also depends on such factors as the capacity of the current source, impedance of the circuit, and voltage stability, all of these tending to reduce the magnitude of the peak.

It is difficult to determine quantitatively the effect of some of the above factors, but definite conclusions may be drawn on the basis of experimental data.

The source of power should be of ample capacity to furnish the necessary inrush current. It is apparent that the source should not be the limiting factor, since the characteristics of the filament determine these inrush values. The ratio *R* of the peak current to nominal current of the lamp may be used as the criterion in evaluating the suitability of the generator.

A small generator having a relatively slow current response and a small amount of available power will give a smaller value of *R*, for the same lamp load, than would a larger machine. A 5-kw, 125 volt, direct-current generator controlling tungsten-filament lamps gave the current ratios *R* shown in Table I. A generator used for routine and experimental testing of switches produced considerably greater values of $R$, as shown in Table II. It will be observed that such generator permits a current inrush to produce a value of $R$ as high as 10.3, for 1200-watt load (compare a corresponding value of 6.8 for 1000-watt load with a smaller generator).

A generator for testing switching devices with lamps as load must be properly designed, for its rated capacity is not the only consideration. Factors like armature reaction, commutation, and voltage stability for a specific load will affect the values of $R$. The Underwriters' Laboratories, Inc., standard for switches specifies a generator capable of producing a current inrush of eight times the normal value of current, using a 20-ampere (normal) lamp load. Values of $R$ considerably in excess of this can be obtained with specially designed generators.[1]

Size of conductors and distance between the lamp and the generator affect the resistance of the circuit. Since the current inrush is of transient nature, the impedance of this circuit must also be considered. The last four columns of Table II give values of the ratio $R$ for various conductor sizes and their lengths. From this table it may also be observed that, for the same wattage, the larger the number of lamps in the circuit, the lower is the value of $R$ (compare last two columns). This may be explained as follows: The rate of heating of a small lamp is considerably higher than that of a large lamp.[2] Because of this, with smaller lamps there will be considerably greater overlapping of the initial period when the current is limited by the circuit inductance and of the period when resistance of filament has risen sufficiently to reduce the current. Therefore, with same current, inductance and resistance of the circuit, smaller lamps would produce a lower value of $R$ than would one large lamp of the same wattage. The $R$ in the case of smaller lamps is further diminished by their lower final filament temperature, as compared with that of the larger lamp.

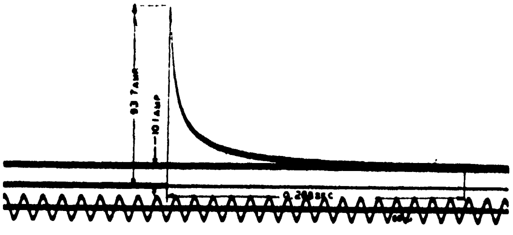

FIG. 1. Oscillogram showing current rise and decay in 1200-watt lamp circuit (2–500-w and 1–200-w lamps) upon its connection to 125-volt d.c. generator.

The use of tungsten-filament lamps for repetitive operations (connecting to and disconnecting from power source) should be conducted with discretion because of the time required to bring the filament to final temperature and the time needed for cooling it to the ambient temperature. The filament-heating time is relatively short. From oscillogram, Fig. 1, it will be seen that normal current was reached within 0.268 second. For lamps of lower rating this time is correspondingly shorter. Since the current decay in the lamp after reaching inrush peak is exponential, it is difficult to determine with a great degree of precision the exact point where the current curve reaches its normal value. However, for practical purposes, the oscillographic determination is sufficiently accurate.

The rate of cooling of the lamp is important in the calculation of the frequency with which the device under test may be operated. The value of $R$ (ratio of inrush peak current to normal lamp current) may be used as basis for the determination. Should a lamp be reconnected to the power source while the filament is still hot, the ratio $R$ would not be as great as that for a completely cooled lamp. This is apparent,

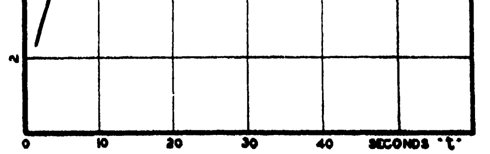

FIG. 2. Relation between cooling time $t$ of tungsten-filament lamps and ratio $R$ (ratio of initial peak current to normal current) for 1200-watt lamp load at 125-v d.c.

[2] W. E. Forsythe, M. A. Easley, and D. D. Hinman, "Time constants of incandescent lamps," J. App. Phys. 9, 209 (1938).

for under such a condition the differential in temperature would be lower. Results of experiments conducted with lamps which were cooled for varying intervals are represented by a curve, Fig. 2. In order to obtain stable data the readings of current inrush (from oscillograms) were obtained after constant ambient temperature had been established.

The curve is particularly valuable when rhythmic operation of switching *on* and *off* of lamps is to be employed. In testing current-interrupting devices for endurance, it is important to have a specific current inrush. From Fig. 2, it is possible to determine the cooling time (duration of the *off* period) for the desired current inrush, and then the frequency with which the testing is to be conducted may be readily calculated.

If, for endurance testing, only one lamp (or one bank of lamps) were used, it would be necessary to allow considerable time for its cooling in order to obtain the desired current peak on the subsequent *on* operation. Such procedure would be quite lengthy and would impede testing, especially if a large number of specimens is to be tested to keep up with production schedules.

To facilitate testing, a number of lamps (or banks of lamps) may be employed, so arranged that while one is being used (*on*) the others are cooling (*off*). This method makes possible any desired rate of specimen operation, the limitations being only those of the specimen itself, such as heat dissipation of its current carrying parts, velocity of its moving system, etc., and the time required to bring the filament to maximum temperature.

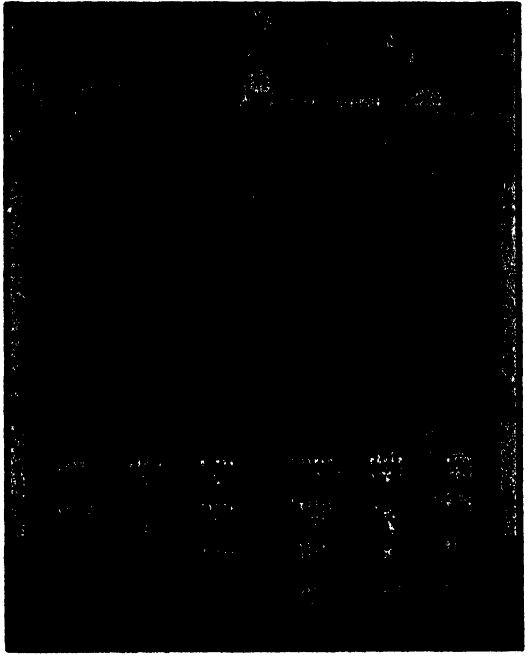

FIG. 3. View of switchboard with equipment for automatic selection of lamp circuits.

For repetitive operation of switches at a uniform rate, the number of lamps required to produce a desired cooling time may be calculated from Eq. (1),

$$N=\frac{t+a}{b+a} \tag{1}$$

where:

$N$—number of lamps (or banks of lamps),

$t$—lamp-cooling time to produce the desired value of $R$ in seconds (obtainable from curve Fig. 2, for specific load),

$a$—time, per cycle of operation, during which the switch is *on*, in seconds,

$b$—time, per cycle of operation, during which the switch is *off*, in seconds.

If the *on* and the *off* periods of switch operation are equal, then Eq. (1) becomes

$$N=\frac{1}{60}(t\times f+30) \tag{2}$$

where $f$ = rate of switch operation, in cycles per minute.

In testing switches, $a$ is usually greater than the time required to heat the lamp and since the heating time is quite negligible in comparison with that needed for cooling the lamp, it was not considered in the formulae.

A very satisfactory scheme for the simultaneous testing of a number of switches is to connect the cold lamp in the circuit containing the specimen under test while this specimen is *off*, and to disconnect the lamp while the specimen is in the succeeding *off* position. Thus, the lamp-selecting device does not ***make*** nor ***break*** the circuit while it is alive; it is done by the device undergoing the test. The actual equipment for accomplishing such selection is shown in Fig. 3, which is a part of an installation for simultaneous testing of 10 switches, each with a 1200-watt lamp load, or a smaller number of switches with a proportionately greater load.

The cool lamps are connected in the test circuits by means of a magnetically-operated, step-by-step selector, which is driven in synchronism with the switches under test. The selector actually controls the coils of heavy-duty contactors, the contacts of which introduce into or remove from circuits the lamps for loading the switches. Other means of selection of cool lamps, such as continuously or intermittently-operated commutators, or cam-operated contacts of either spring or mercury type may be employed.

In some cases it is desired to obtain the inrush current with lesser equipment, or at quite rapid rate. Then, it is possible to connect resistance loads in such a way that the low resistance (allowing high current inrush) is removed from the circuit a short time after the switch under test has established the contact, leaving a higher resistance in the circuit (corresponding to normal current of lamp), thus permitting only normal current interruption by the switch. This arrangement does not duplicate actual lamp operation, because if current equivalent to inrush value is *on* for a considerable time the contacts are subjected to excessive heating. Furthermore, in the event of contact vibrations the contact erosion and welding are aggravated. Consequently, such testing may become unduly severe. In this scheme, shown in Fig. 4, the normal current is determined by resistance $R_a$, while the inrush current is limited by resistance $R_b$. After a predetermined interval following the closure of switch $S$, the timing contacts $T$ open, thus permitting the switch $S$ to break only the normal current, as determined by $R_a$. The current rises and decays abruptly since non-inductive resistances are used. Contacts $T$ are synchronized with $S$ so that they *close* and *open* before $S$ is subjected to respective operations.

Another method is based on the characteristic curve of charging a condenser. A condenser of suitable capacity is connected in the test circuit before the switch is *closed;* this produces the necessary current inrush and decay. The condenser is then disconnected by a relay after a desired lapse of time, restoring the circuit containing a resistance to a current equal to that of normal value of the lamp. Essentially this arrangement is a modification of that shown in Fig. 4, the difference being in the introduction of capacitance $C$ (not shown in diagram) in series with resistance $R_b$. As in the previous scheme, the resistance $R_a$ determines the final value of current flowing through switch (normal lamp current), resistance $R_b$ determines the peak current, while condenser $C$ defines the rate of current decay during the transient period upon closure of switch $S$. Contacts $T$ disconnect the condenser $C$ (and resistance $R_b$) when the current through this path has decayed to a desired magnitude (near zero). This is done before $S$ is opened. The operation of the timing contacts $T$ may be accomplished either electrically or mechanically. Provision must be made for discharging the condenser $C$ prior to its reconnecting into the circuit.

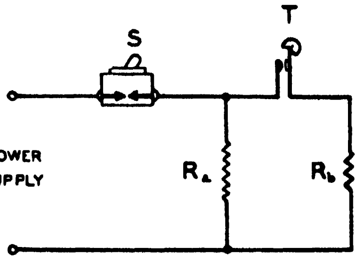

FIG. 4. Schematic wiring diagram of connections for producing initial current inrush.

Because of presence of some inductance in the circuit, it is difficult to predict by calculation the initial peak current that would result. It is, therefore, necessary to adjust the parameter of the circuit until the desired values are obtained. These constants will differ from the calculated values.

While it is possible to duplicate relatively closely a current rise and decay of a tungsten-filament lamp, such synthetic-load testing equipment has been found less desirable from the standpoint of stability, reliability, and maintenance for large scale testing.

The tungsten-filament lamps should be employed as electrical load with due consideration given to their characteristics. Particular attention should be given to the frequency of operation of specimens under test, in order to obtain the desired current inrush during the *on* period. The source of power supply and the impedance of the circuit must also be evaluated if it is planned to duplicate the conditions to which the switching device would be subjected under actual field operations.

# The Capacity per Unit Length and Characteristic Impedance of Coaxial Cables with One Slightly Non-Circular Conductor

PHILIP PARZEN*
*New York, New York*

(Received April 9, 1947)

It is possible to calculate approximately the electrostatic field in a coaxial line with one slightly non-circular conductor as a perturbation of that existing in the usual coaxial line. General expressions are then derived for the capacity per unit length and the characteristic impedance of such lines. In particular, these results are applied to the coaxial line with outer square conductor.

## INTRODUCTION

THE calculation of the capacity per unit length, $C$, of a coaxial line depends upon the derivation of a potential distribution function, $V$, which satisfies $\nabla^2 V=0$, with the boundary conditions: $V=0$ on inner conductor, $V=V_1$ =constant on outer conductor. Thus,

$$C=-K\int \frac{\partial V}{\partial n} ds/V_1 \quad \text{(m.k.s. units)} \qquad (1)$$

where the numerator is the total charge per unit length which is given by the line integral of the normal derivative of the potential along either conductor, and $K$ is the dielectric constant of the medium.

The characteristic impedance, $Z_0$, of a resistanceless line is:

$$Z_0=1/Cv,\ v=\text{velocity of light in medium.} \qquad (2)$$

This may be seen physically as follows: an outgoing progressive wave will advance a distance $vdt$ in time $dt$, during which an amount of charge $dq=CvVdt$ will appear across that portion of the line. Hence the current $I=CvV$ and $Z_0=V/I=1/Cv$. A rigorous proof may be found in Smythe.[1]

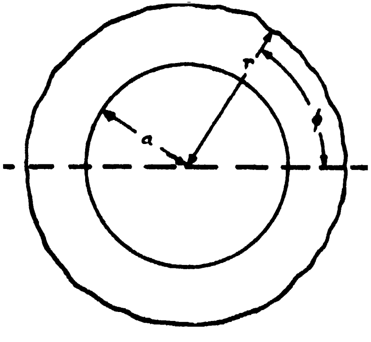

FIG. 1.

While the solution for concentric circles is quite easily obtained, only approximately correct solutions are obtainable for non-circular cables. In this paper we shall consider lines wherein one conductor is circular and the other slightly non-circular. The potential distribution is then calculated as a perturbation of that due to concentric circles. Finally we shall apply these results to the case where one conductor is square.

## CALCULATION OF $C$ AND $Z_0$

In Fig. 1 the inner conductor is a circle of radius $a$ and the outer conductor is specified by its polar equation, $r=f(\phi)$, which can be sufficiently approximated by a Fourier series with $p$ harmonics. Thus,

$$r=f(\phi)=A_0\left(1+\sum_1^p A_j\cos j\phi\right) \qquad (3)$$

with

$$\sum_2^p A_j^2 \ll 1. \qquad (4)$$

The inclusion of sine terms in the Fourier series will not add anything of general value to the discussion. Moreover, most conductors in practice are symmetrical about an axis. Hence we seek a potential distribution $V(r\ \phi)$ such that,

$$\nabla^2 V=0 \qquad (5)$$

with boundary conditions,

$$V=0 \text{ on } r=a \qquad (6)$$

$$=V_1 \text{ on curve (3).} \qquad (7)$$

---

*Consulting Engineering Mathematician.

[1] W. R. Smythe, *Static and Dynamic Electricity* (McGraw-Hill Book Company, Inc., New York, 1939), p. 471.

Let

$$V=L\log r+M+\sum(E_nr^n+F_nr^{-n})\cos n\phi. \tag{8}$$

This expansion[2] will automatically satisfy (5), and to satisfy (6)

$$0=L\log a+M \tag{9}$$

$$0=E_na^n+F_na^{-n}\quad n=1,2,\cdots \tag{10}$$

To satisfy (7), we have after expanding $\log r$, $r^n$, and $r^{-n}$ in Taylor series about $r=A_0$,

$$\begin{aligned}V_1=&L\log A_0+M+L\\&\times[\Sigma A_j\cos j\phi-\tfrac{1}{2}(\Sigma A_j\cos j\phi)^2+\cdots]\\&+\Sigma E_mA_0^m[1+m\Sigma A_j\cos j\phi\\&+\tfrac{1}{2}m(m-1)(\Sigma A_j\cos j\phi)^2+\cdots]\cos m\phi\\&+\Sigma F_mA_0^{-m}[1-m\Sigma A_j\cos j\phi\\&+\tfrac{1}{2}m(m+1)(\Sigma A_j\cos j\phi)^2+\cdots]\cos m\phi,\end{aligned} \tag{11}$$

where . . . denotes higher powers of $A_j$. Now equating coefficients of $\cos n\phi$ in (11),

$$\begin{aligned}-LA_n=&E_nA_0^n+F_nA_0^{-n}\\&+\tfrac{1}{2}\Sigma\Sigma m(E_mA_0^m-F_mA_0^{-m})A_j+\cdots\\&n=1,2,\cdots\end{aligned} \tag{12}$$

and the double summation is taken over $m+j=n$, $m-j=\pm n$.
For $n=0$,

$$\begin{aligned}V_1=&L(\log A_0-\tfrac{1}{4}\Sigma A_j^2+\cdots)+M\\&+\tfrac{1}{2}\Sigma j(E_jA_0^j-F_jA_0^{-j})A_j+\cdots\end{aligned} \tag{13}$$

We now have the linear set of Eqs. (9), (10), (12), and (13) to solve for $L$, $M$, $E_n$, and $F_n$. We should, however, point out that $C$ depends upon $L$ only, since by applying (1) to the inner circle, the line integral of the cosine terms in (8) vanish; thus

$$C=2\pi KL/V_1. \tag{14}$$

We now solve Eqs. (10) and (12) for $E_n$ and $F_n$ by successive approximations. For a first approximation, we neglect the double summation and higher order terms in (12) and solving, we have,

$$E_n=-\frac{A_nL}{a^n[(A_0/a)^n-(a/A_0)^n]}, \tag{15}$$

$$F_n=-\frac{a^nA_nL}{(A_0/a)^n-(a/A_0)^n}. \tag{16}$$

Substituting these expressions in (13) and subtracting (9) from (13), we have to a first approximation,

$$C=\frac{2\pi K}{\log A_0/a-\sum_1 A_j^2(\frac{1}{4}+\frac{1}{2}jR_j)}\quad\text{farads/meter} \tag{17}$$

$$R_j=\frac{(A_0/a)^j+(a/A_0)^j}{(A_0/a)^j-(a/A_0)^j}. \tag{18}$$

Thus we have an approximation which is of the order of $jA_j^2$. We can now obtain further approximations by substituting (15) and (16) in the neglected part of (12) and resolving for $E_n$ and $F_n$, and so forth. This, however, will result in corrections to $C$ which are of higher powers in $jA_j^2$ and hence may be neglected because of (4). It should also be noted that $A_0$ is always greater than $a$; otherwise there would be points on the outer conductor for which $r$ is less than $a$, which is impossible.
Also, by (2),

$$Z_0\text{ in air}=60[\log A_0/a-\sum_1 A_j^2(\tfrac{1}{4}+\tfrac{1}{2}jR_j)]\text{ ohms} \tag{19}$$

since $v=3\times10^8$ meters/sec., and $K=8.85\times10^{-12}$ farads/meter.

A case of interest is where $A_0/a$ is of the order of 3 or greater. Then $R_j$ is approximately 1 and

$$Z_0=60[\log A_0/a+d] \tag{20}$$

$$d=-\sum_1 A_j^2(\tfrac{1}{4}+\tfrac{1}{2}j). \tag{21}$$

Since $d$ is at most of the order of a few percent, we may replace $d$ by

$$\log(1+d)\text{ and }Z_0=60\log A^*/a \tag{22}$$

and $A^*$, which is $A_0/1+d$, may be considered as the outer radius of an equivalent coaxial (concentric lines) line, with the same characteristic impedance.

### APPLICATION OF RESULTS TO SQUARE OUTER CONDUCTOR

For a square of side $2b$, the polar equation is,

$$\begin{aligned}&r=b\sec\phi\quad 0\le\phi\le\pi/4\\&r=b\csc\phi;\ \pi/4\le\phi\le\pi/2\end{aligned} \tag{23}$$

---

[2] See reference 1, p. 63.

with a periodicity of $\pi/2$. Hence only $\cos 4j\phi$ terms will appear in the Fourier series, and

$$A_0=\frac{4b}{\pi}p_0$$
$$A_0A_{4j}=\frac{8b}{\pi}p_j;\quad p_j=\int_0^{\pi/4}\sec\phi\,\cos 4j\phi d\phi. \tag{24}$$

Now,

$$p_{j-1}-p_j=2\int_0^{\pi/4}[\cos(4j-3)\phi-\cos(4j-1)\phi]d\phi$$
$$=(-1)^{j+1}2.828/(4j-3)(4j-1).$$

Thus knowing $p_0$, $p_j$ is easily calculated; and $p_0=.881$, $p_1=-.062$, $p_2=.019$, $p_3=-.010$, $p_4=.005$, $A_0=1.12b$; $A_4=-.14$, $A_8=.044$, $A_{12}=-.021$, $A_{16}=.012$. Thus condition (4) is approximately satisfied with $p$ equal to 12. Thus,

$$Z_0=60[\log b/a+.108 - 039R_4-.008R_8-.002R_{12}], \tag{25}$$

with

$$R_4=\frac{1.570(b/a)^4+.636(a/b)^4}{1.570(b/a)^4-.636(a/b)^4}, \tag{26}$$

and $R_8$ and $R_{12}$ are given by similar expressions, with the constants replaced by (2.480, .403) and (3.870, .258), and the exponents by 8 and 12, respectively.

For $b/a$ of the order of 2, the equivalent outer radius defined by (22) is $1.06b$. This value compares more or less favorably with $1.08b$, obtained by Frankel.[3] For $b/a$ less than 2, Frankel's derivation does not apply, and the correct $Z_0$ is given by (25).

For $b/a$ equal to 1, $Z_0$ from (25) is .06 ohms, which is fairly close to the actual value of $Z_0$, namely, 0. This constitutes a partial check upon the accuracy of this formula.

Finally I wish to thank Mr. Benjamin Parzen for suggesting the problem.

# Thermal Conductivity of Aluminum; Solid and Liquid States

C. C. Bidwell and C. L. Hogan
*Lehigh University, Bethlehem, Pennsylvania*

(Received April 9, 1947)

Thermal conductivity measurements on lead, tin, and zinc extending over the liquid as well as the solid states were reported by one of the authors in 1940. The present report extends this work to cover aluminum in both the liquid and solid phases. An improved technique is described. The law $k/\rho C=K(1/T)+K'$ is found to hold for aluminum also, with the intercept, $K'$, the same for both states. The thermal conductivity ($k$) decreases with rise of temperature as it does for lead, tin, and zinc. On this point previous workers have published very conflicting data.

## INTRODUCTION

Data on the thermal conductivity of aluminum in the handbooks, the critical tables, and as collected and published in *The Aluminum Industry*[1] are conflicting particularly as to the change with temperature. No data for the liquid state are reported. Several observers report a rise of thermal conductivity with temperature; only one, Konno,[2] reports a decrease. The present data on a specimen of purity 99.20 percent is in exact agreement with Konno's values (0.50 at 0°C; 0.36 at 600°C). A specimen of purity 99.95 percent is found to have a higher conductivity, *viz.*, 0.54 at 25°C, decreasing to 0.44 at 657°C. On this specimen, measurements were extended into the liquid state at points 740°C and 900°C.

## THE METHOD

The Forbes bar method previously used was further modified and adapted to high temperature work. A cylinder of the material under study, 25 cm long, 2.5 cm in diameter, was

---

[1] Edwards, Frary, and Jeffries, *The Aluminum Industry* (McGraw-Hill Book Company, New York, 1930).
[2] S. Konno, Phil. Mag. **40**, 542 (1920).

centered vertically in a tubular furnace and surrounded with finely screened silocel. Thermojunctions were previously fastened to the rod every 3 cm by insertion into small holes drilled about 1.5 mm deep, and the junctions peened in. At the upper end, just above the top junction, was placed a heater coil of about 10 turns of B & S No. 26 nichrome wire, insulated from the bar by mica or asbestos. The junction wires, encased in fine quartz tubes, were led down and out the bottom of the furnace tube, the heater wires going out the top. A reference junction was inserted into the furnace from below to a point just below the bottom of the test rod but not touching it. Another reference junction, as a spare, was inserted from above to a point about half-way down the specimen but placed near the furnace tube so as not to be affected by the heater at the top of the rod. The junctions could be connected in turn differentially with either of the reference junctions and led directly to the galvanometer (Leeds and Northrup Type R 2500 a). At any particular temperature steady conditions were indicated by the galvanometer readings. (The zero was adjusted to the right hand end of the scale at 30, thus making the whole scale available.) Deflections were differentials between the given junction and the reference. At room temperatures all junctions would read alike at 30. At higher temperatures there was always a residual temperature difference, and initial readings for each junction had to be taken and the heater turned on only when steady readings were obtained. A deflection of 60 divisions meant approximately 6°C. At upper temperatures the deflection for the bottom junction was very small, while that for the top junction (No. 1) might be as much as 20 divisions. The elimination of this gradient while desirable was not necessary. Also a slight drift of all junction readings due to temperature drift had to be tolerated and corrected for.

## PROCEDURE

When all junctions show fairly steady condition, the time is noted, and the readings from top to bottom of the specimen and back again are recorded and again the time noted. This is repeated several times in order to determine the drift. Then the time is again noted, the heater turned on and, after about three minutes, the readings again taken from top to bottom and back and the time noted before and after. This is immediately repeated, and then the switch is opened. The cooling data are immediately obtained, using the top junction and taking readings every half minute. The readings should all be taken within about ten minutes from the time of closing the heater switch, otherwise the reference points become uncertain. Only the cooling data from the top junction are significant, the other junctions indicating too low a rate because of the inflow of heat from the upper part of the bar. The cooling rate for the top junction (which is about 4 cm from the top of rod) is approximately corrected with respect to the heat flow down the rod although for the first minute even this rate is low. This shows up on the $dT/dt$, $T$ curve which is a straight line except possibly for the first few points. We have now two sets of data, the gradient data and the cooling data. The actual temperature is observed by connecting one of the reference junctions (or any junction) to a potentiometer. The gradient data and the cooling data are now plotted. First the temperatures (galvanometer deflections) are plotted for the gradient data, the deflections as ordinates, the distances down the rod as abscissa, taking the position of the top junction as $x=0$. This is the $T$, $x$ curve. Slopes of this curve are measured graphically and the $dT/dx$, $x$ curve plotted. Then the slopes of this curve are measured and the $d^2T/dx^2$, $x$ curve plotted. The cooling data are plotted giving the $T$, $t$ curve ($T$ as ordinates and $t$ (time) as abscissa). The slopes of this curve are measured and plotted, $dT/dt$ as abscissa, $T$ as ordinates. Corresponding* values of $dT/dt$ and $d^2T/dx^2$ for the various values of $T$ are plotted, $d^2T/dx^2$ as ordinates, $dT/dt$ as abscissa. The straight lines usually go through the origin but not always. The constant value of $dT/dt/d^2T/dx^2$ is called $m$ (actually the reciprocal of the slope considering the way the curves are plotted), and $m=k/\sigma\rho$, where $k$ is the thermal conductivity, $\sigma$ the specific heat, $\rho$ the density. $k$ is thus determined if $\sigma$ and $\rho$ are

---

* Corresponding values are values for the same temperature $T$. $dT/dt$ values are read directly, but $d^2T/dx^2$ is found by finding the value of $x$ for the given $T$ (on the $T$, $x$ curve) and for this value of $x$ moving vertically to the value of $d^2T/dx^2$.

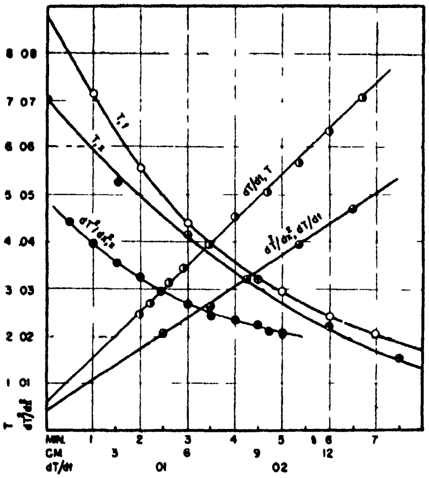

FIG. 1. Sample set of data for thermal conductivity of aluminum at 650°C.

known. Figure 1 is a sample of the plots. A similar set of curves is obtained for each value of $k$ determined.

## THEORY

This is the old Forbes method described by Forbes in 1868. The difference in the heat flowing down the rod at one level and out at a slightly lower level is $kA(dT/dx)_1 - kA(dT/dx)_2$, and this difference is $\sigma\rho Al dT/dt$. $A$, the cross section cancels, $l$ is the difference between the two levels, and

$$\frac{(dT/dx)_1 - (dT/dx)_2}{l} = d^2T/dx^2.$$

The equation is

$$\sigma\rho dT/dt = kd^2T/dx^2$$

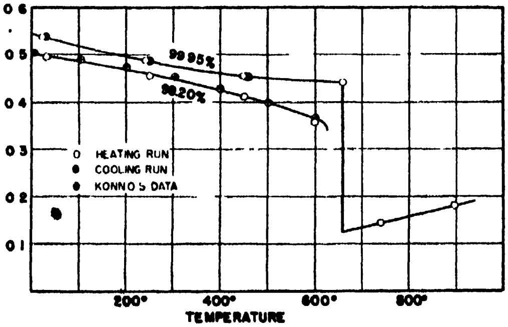

FIG. 2. Thermal conductivity and temperature of aluminum.

or

$$dT/dt = \frac{k}{\sigma\rho} d^2T/dx^2.$$

This calls for a straight line through the origin. Often the curve does not go through the origin. In taking the data one has to compromise—one cannot wait until conditions are completely steady. The reference junction readings are slowly changing, and hence one must be satisfied even though the temperatures are still slightly rising. This introduces a term $\sigma\rho dT/dt_H$ on the left side of the above leading to the equation

$$\frac{dT}{dt_C} = \frac{k}{\sigma\rho}\frac{d^2T}{dx^2} - \frac{dT}{dt_H}.$$

$\sigma\rho dT/dt_H$ is the residual heating, $\sigma\rho dT/dt_C$ is the observed cooling. Careful study of the data shows that the intercept is thus accounted for.

When measurements in the liquid state are desired the specimen must be contained in some inert container. In this work graphite was used—a long cylindrical crucible being bored out of a graphite electrode. The walls were about 3 mm thick, and the junctions were placed in small holes drilled into these walls but not clear through. The wires encased in quartz tubes were tied on with threads, the silocel packing holding them in place when the threads burned away. The heater was wound on the graphite cylinder (insulated with mica) and measurements made as before. The equation now is

$$\sigma_a\rho_a A_a dT/dt + \sigma_g\rho_g A_g dT/dt = k_a A_a d^2T/dx^2 + k_g A_g d^2T/dx^2$$

or

$$\frac{dT}{dt} = \left[\frac{k_a A_a + k_g A_g}{\sigma_a\rho_a A_a + \sigma_g\rho_g A_g}\right]\frac{d^2T}{dx^2}.$$

If one takes account of the slight heating, the term $dT/dt_H$ is to be subtracted from the right side as above. The subscripts refer to aluminum and graphite. Values of $\sigma_a\rho_a$ were obtained from *The Aluminum Industry* or determined experimentally. The latter was necessary for the graphite. For this purpose observations were made as above on a graphite rod at room temperature and at 700°C. This gave values of $k_g/\sigma_g\rho_g$. $\sigma_g\rho_g$ was obtained by an auxiliary experiment in which a graphite rod with an axial heater was held at various temperatures and the watts input noted. Later cooling curves were taken through these temperatures. The equation $\sigma_g\rho_g A l dT/dt = VI/4.18$ permits the computation of $\sigma_g\rho_g$.

## RESULTS

The values of the thermal conductivity of aluminum (99.95 percent) are as follows: at 25°C, 0.538; at 240°C, 0.486; at 250°C, 0.486; at 450°C, 0.452, 0.456; at 650°C, 0.445; at 740°C (liquid), 0.143; at 900°C (liquid), 0.180. For the aluminum (99.2 percent**) the values are: at 25°C, 0.500; at 245°C, 0.457; at 450°C, 0.414; at 590°C, 0.365. These values are shown graphically in Fig. 2, together with Konno's points. The error in these values does not exceed ±.005, assuming the accuracy of the values of $\sigma\rho$ (taken from *The Aluminum Industry*). The 99.95 specimen shows higher conductivity throughout, and the change with temperature is a decrease paralleling the change for the commercial specimen. Figure 3 shows the data for the c.p. specimen plotted to test the relation $k/\rho C = K(1/T) + K'$. This relation is found to hold with the intercept, $K'$, the same for the solid and liquid phase, exactly as was found for tin, lead, and zinc.[3] ($C$ in this equation is the atomic heat.) Since only two points were found for the liquid state it probably is more proper to state that the data are at least consistent with this equation.

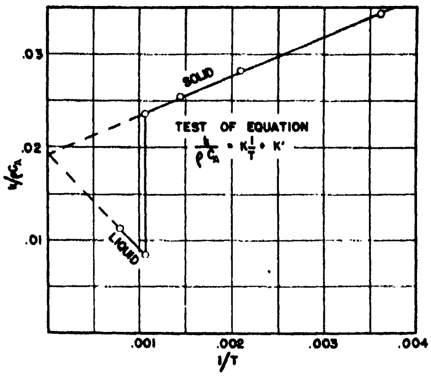

FIG. 3.

## THERMAL CONDUCTIVITY OF GRAPHITE

The thermal conductivity of graphite as here determined was found as 0.30 at 25°C. Buerschaper[4] finds 0.26 for radial and 0.40 for longitudinal, while Powell and Schofield[5] find 0.34 at this temperature. The value here found for 700°C, 0.123, is consistent with an extrapolation of the data of the above observers.

## ACKNOWLEDGMENT

The aluminum specimens and the analyses were furnished by The Aluminum Company of America together with a grant of funds to facilitate this work. For this help the authors express their appreciation to this Company.

## Stabilization, Tempering, and Relaxation in the Austenite-Martensite Transformation *

J. H. HOLLOMON,† L. D. JAFFE, AND D. C. BUFFUM
*Watertown Arsenal Laboratory, Watertown, Massachusetts*

Received May 12, 1947

TRANSFORMATION in steels of the face-centered cubic phase, austenite, to the body-centered tetragonal phase, martensite, ordinarily takes place only during cooling. The temperature (*Ms*) at which the transformation begins is independent of the cooling rate. The extent of transformation at any temperature below *Ms* is less, the lower the cooling rate.[1] Moreover, holding at a constant temperature below *Ms* decreases the extent of transformation on subsequent cooling to a fixed lower temperature.[2] This phenomenon, termed stabilization, is believed to arise from a change in microstresses with time. This change might result from (*a*) decomposition of the metastable martensite (tempering) and consequent dimensional change, or (*b*) stress relaxation (viscous flow) of microscopic regions.

Specimens of a quenched steel containing 1 percent C, 1.5 percent Cr, were stabilized at various temperatures and times. The specific volume at room temperature (*R.T.*) was then determined before and after cooling to −196°C. The results (Fig. 1) indicate that the time and temperature for a fixed degree of stabilization are related through an activation energy of about 21,500 cal./mole.

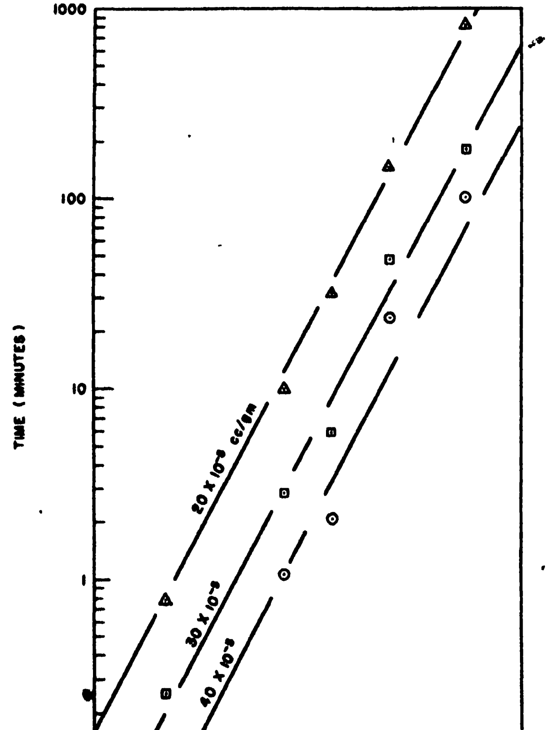

FIG. 1. Relation between time and temperature of stabilization for a fixed change of specific volume upon subatmospheric cooling.

Specimens of a quenched plain-carbon, 0.95 percent C, steel were cooled to −196°C, then tempered at various temperatures and times. The tetragonality, $c/a-1$, of the martensite lattice at *R.T.* was determined by x-ray diffraction methods. The results (Fig. 2) indicate an activation energy of 34,000 cal./mole for the first stage of tempering.

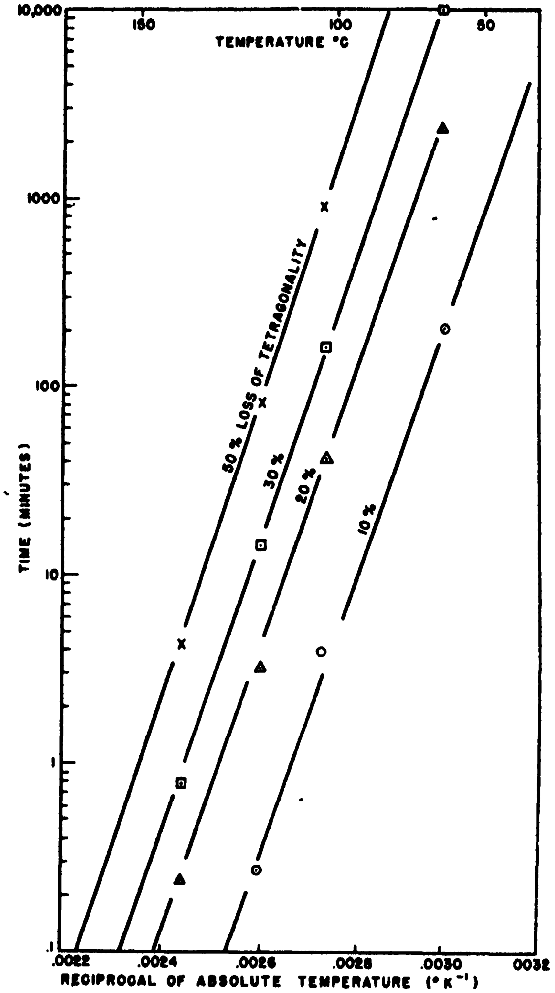

FIG. 2. Relation between time and temperature for fixed loss of tetragonality.

Rods of quenched plain-carbon steel, 1.25 percent C, were heated to 100°C and twisted a fixed amount, not enough to cause permanent set. After holding 30 min., the specimens were cooled to lower temperatures and released. The anelastic twisting, measured as a function of time

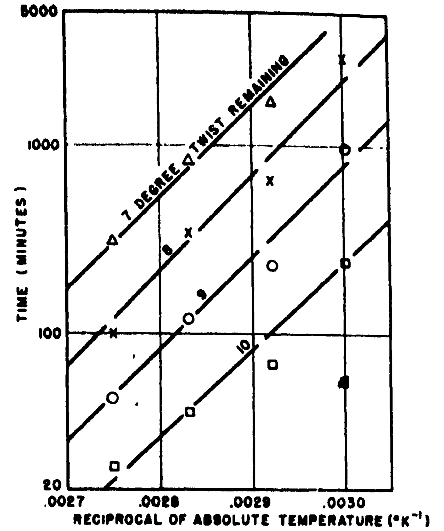

FIG. 3. Relation between time and temperature of untwisting for a fixed amount of untwisting. Twisted 30 degrees at 100°C. Held 30 minutes.

(Fig. 3), corresponds to an energy of about 22,500 cal./mole for stress relaxation. The energies observed for stabilization and relaxation are approximately equal to that reported [3] for stress relaxation in plastically deformed iron (ferrite).

Different steels were used for the different tests to obtain the required accuracy. However, changes in steel composition are unlikely to affect the activation energies materially, particularly in the light of the above agreement between the heats of activation for stress relaxation. It is concluded that stabilization in the austenite-martensite reaction does not arise from tempering of martensite, and probably arises from stress relaxation. Apparently, the relaxation centers responsible for stabilization are produced by local plastic flow caused by austenite-martensite transformation and perhaps by non-uniform thermal contraction.

This work will be discussed in detail elsewhere.

## Remarks on Compressive and Tensile Strengths

Concerning a Paper by P. W. Bridgman

STANLEY THOMPSON
*North American Aviation, Inc., Los Angeles, California*

April 9, 1947

IN a recent paper[1] Bridgman has discussed a series of tests on the effect of hydrostatic pressure on the fracture of brittle materials. The remarks of this letter are considered pertinent to Bridgman's paper, since they explain some of the anomalies mentioned.

Tests to failure in compression by Föppl[2] indicate that the magnitude of the compressive strength, as well as the type of failure observed, depends markedly on the end conditions of loading. Föppl tested his specimens under two end conditions of loading, lubricated and unlubricated loading faces; and with two types of compressive loading, one-dimensional and two-dimensional. With a specimen of concrete, the compressive strengths in the four cases were related as shown in Fig. 1.

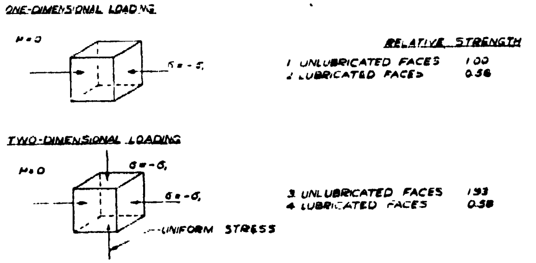

FIG. 1.

With the surfaces unlubricated, failure occurred by breaking off wedge-shaped pieces, while with lubricated surfaces failure occurred in planes parallel to the direction of compression—as if a tension existed at right angles to the direction of compression—with almost the same load for the one-dimensional case as for the two dimensional. The variation between lubricated and unlubricated surfaces is attributed by Föppl to the effect of shear stress across the loading faces. Since a compressive specimen must be comparatively short to prevent buckling, the end conditions are rarely negligible.

For an analysis of the type of failure produced and a prediction of the comparison between compressive and tensile strengths, it is desirable to consider the load systems shown in Fig. 2. Figure 2(a) shows a two-dimensional compressive loading $(-\sigma_1)$; Fig. 2(b) shows a hydrostatic pressure, numerically equal to the compressive loading of Fig. 2(a) on which is superimposed a one-dimensional tensile loading numerically equal to the hydrostatic pressure. Neither the theory of elasticity, nor any test, can differentiate between these two loading systems, since they are physically identical.

In that which follows, aside from the entire equivalence of load systems (a) and (b) in Fig. 2, one assumption is made: the equivalence of breaking stress under one- and two-dimensional loading, as found experimentally by Föppl for lubricated loading faces, and as predicted by the

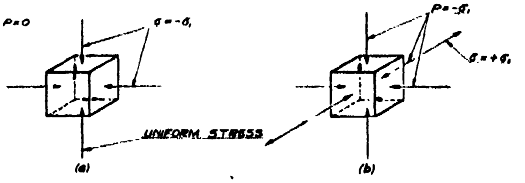

FIG. 2.

semi-empirical shear and octahedral-stress theories. As a result any given one-dimensional compressive breaking stress ($-\sigma_1$) superimposed on a given hydrostatic pressure ($-P_1$) is equivalent to a one-dimensional tensile breaking stress ($+\sigma_1$) of equal magnitude superimposed on a hydrostatic pressure ($-P_1-\sigma_1$). A plot satisfying this condition of breaking stress $\sigma(P)$ against hydrostatic stress $P$ is shown schematically in Fig. 3. Positions above the horizontal axis represent tensile breaking stresses, those below compressive breaking stresses; positions to the right of the vertical axis represent hydrostatic tensions (triaxial tension), those to the left, hydrostatic pressure (triaxial compression). Tensions are considered positive, compressions negative. It should be noted that $\sigma_P$ is zero when $P$ is positive, which corresponds to failure under hydrostatic (triaxial) tension only.

The relationship shown in Fig. 3 can be expressed mathematically by the equation

$$f(P) = -g(P+f), \tag{1}$$

where $f(P)$ represents either branch of the curve for breaking stress $\sigma_P$, and $g(P+f)$ represents the other branch.

It is interesting to compare the slope $df(P)/dP$ of the branch $f(P)$ at any abscissa $P$ with the slope $dg(P+f)/d(P+f)$ of the branch $g(P+f)$ at the corresponding $(P+f)$. From Eq. (1):

$$\frac{dg(P+f)}{d(P+f)} = -\frac{\dfrac{df(P)}{dP}}{1+\dfrac{df(P)}{dP}}. \tag{2}$$

These slopes correspond to the pressure coefficients of stress for the two branches of the curve. It can be concluded from Eq. (2) that a pressure coefficient of tensile strength at $P$ between 0 and 1 corresponds to a pressure coefficient of compressive strength at $(P+f)$ between 0 and $\infty$, and the coefficient for compressive strength is always the larger.

Bridgman reports that "the effect of hydrostatic pressure is markedly greater in increasing the compressive strength of glass than in increasing its tensile strength." Equation (2) and Fig. 3 give a measure of this effect for any function $f(P)$. If either the compressive or tensile breaking stress is known experimentally as a function of hydrostatic stress, the other may be obtained without experiment by use of Eq. (1) or Fig. 3.

Since actual compressive failures of homogeneous materials under hydrostatic pressure cannot occur, it is concluded that failure of a material under compressive loading, in one or two directions, will occur in a manner typical of tensile failures for that material under corresponding hydrostatic pressure. Any departure from this type of failure, or from behavior predicted by a plot similar to Fig. 3, is a measure of the experimental departure from idealized end conditions or inhomogeneity of material. It is believed that the angular fracture of glass in simple compression when supported by hydrostatic pressure, shown in Bridgman's Fig. 3, may be due to the end effects investigated by Föppl and that the numerical results thus obtained for compressive strength are unreliable.

# Reply to "Remarks on Compressive and Tensile Strengths"

P. W. Bridgman
*Harvard University, Cambridge, Massachusetts*

April 22, 1947

THANK you for letting me see the remarks by Stanley Thompson on my paper on brittle fracture under pressure. These remarks are interesting as showing the consequences of carrying through to a mathematical conclusion the implications of a literal acceptance of the results of the equivalence of one and two dimensional loading in compression. I think, however, that one would not expect the bearing on the experimental situation to be any too close. Föppl's results were obtained only for a single material of not very typical properties, namely, cement and furthermore were obtained only at atmospheric pressure. In developing his mathematics Thompson had to make an additional assumption not covered by the experiments of Föppl, namely, that the equivalence of one and two dimensional compression would continue to hold if the experiment were performed in a medium to which any hydrostatic pressure whatever is applied in addition to the compressions. I very much question whether this is legitimate. One of the conclusions that could be drawn is that when the effects of terminal friction are eliminated, only one type of fracture occurs, the same under simple tension as under simple compression. It is tacitly assumed that this type of fracture is the simple tension type, but I can see no intrinsic reason in the argument for preferring this to the ordinary simple compression type except the highly special experiments of Föppl. The point of view of Thompson also commits him to the position that the same type of fracture will prevail along the entire course of both the upper and lower branches of the curves in his Fig. 3. This seems to me highly improbable.

Of course I will have to admit that there is some justice to his last sentence, namely, that terminal friction modifies the figures for the fracture stresses that would be given by using only the figures for hydrostatic pressure and compressive stress. But, I think the modification would not be large, and I think the effect is in the wrong direction. The most complete fracture experimentally was obtained near the ends, where the effect of friction in fictitiously raising the strength is the greatest according to Thompson's suggestion. If this is correct it seems to me that fracture should have occurred first at the center and should have been most complete there. Furthermore, I think substitution of the numerical values into a diagram like his Fig. 3, both for glass and Carboloy, would show that a rather improbable state of affairs is demanded.

Certain aspects of Thompson's analysis of the stress system into hydrostatic pressure and superposed simple stresses are much like my analysis in Mechanical Engineering, February 1939, in which similar questions are discussed.

## European Induction Accelerators

Rolf Wideröe
*Zürich, Switzerland*

(April 21, 1947)

I have read with interest in the January number of this journal H. F. Kaiser's account concerning "European Induction Accelerators" and should be grateful if you would allow me to augment and also to correct some of the statements contained therein.

First of all, as regards the historical data concerning the development of the betatron: in the autumn of 1922 I had already invented the "ray transformer" (my own designation for the electron induction accelerator) in Karlsruhe during my studies there, quite independently of Slepian. In 1925 I applied for a German Patent on this invention, but this patent application was subsequently abandoned. After the completion of my experimental work under Professor Rogowsky in Aachen (1925–1927),[1] it was only in the autumn of 1942 that I learned of the work done by Kerst and other investigators in the meantime.[2] Subsequently, up to June 1943 I was able to make a number[3] of inventions during my work at the Norsk Elektrisk Brown Boveri in Oslo, these inventions being confiscated in the autumn of 1943, however, by the German authorities. Slepian's U. S. Patent, which had not been mentioned by Kerst in his first publication, only came to my knowledge accidentally some time later, so that it appears to me that Slepian's proposals can only have been of slight importance as regards the development of the induction accelerator.[4]

In Kaiser's account it is stated that the formula for the average electron ray current was found by me. This is an error, and in my work[5] it is clearly stated that this formula and its derivation originate from Kerst. According to this formula it should not be possible to obtain an appreciable amount of $\gamma$-rays with a 15-mv transformer at such a low frequency as 50 cycles. With $\Delta r=2$ cm and $dr=0.1$ cm, for instance, the formula gives an injection voltage of about 170 v and an average current strength of only about 0.0085 $\mu$A. Compared with this we used an optimum injection voltage of 7–10 kv and attained an average current of about 0.03 $\mu$A, the maximum obtainable current strength for this injection voltage being probably about 10 times higher. The remarkable fact that small ray transformers can still be operated to advantage with such a low frequency as 50 cycles was entirely novel in 1944 and certainly represents the most important result obtained from the work performed in Hamburg.

Our experimental results obtained with the 15-mv transformer can, as shown by Touschek and myself, be explained by elaborating the original Kerst-Serber assumptions.[6] When in accordance with our theory the electron source is placed inside the potential channel of the stabilizing forces, the efficiency of the electron injection can be calculated approximately from:

$$\eta=\mathrm{Eksp}\left(\frac{-16\sqrt{2}}{3\pi^2}\,\frac{Ui}{\Delta U}\left(\frac{b}{2\Delta r}\right)^{\frac{1}{2}}\arcsin\frac{h}{2\Delta z}\right),$$

where

$Ui$ = injection voltage
$\Delta U$ = induced voltage per turn
$b$ = width of electron source
$h$ = height of electron source
$\Delta r$ = radial oscillation amplitude of electrons
$\Delta z$ = axial oscillation amplitude of electrons.

If the electron gun is located outside the potential channel ("injection from outside"), the efficiency of the electron injection will depend on the divergency of the injected electron beam, because only very small deviations from the optimum direction of injection are permissible for catching the electrons. With the 15-mv transformer, the angular deviation for $Ui=10$ kv may for instance only amount to about 0.16°–0.32°. It can be shown that in this case the efficiency of the injection in first approximation will be proportional to:

$$\left(\frac{\Delta U}{U_i}\right)^x \text{ where } \tfrac{1}{3}\leqq x\leqq\tfrac{3}{4}.$$

In conclusion I should like to state that our work in Hamburg was performed quite independently and without knowledge of that done by Siemens-Reiniger and other investigators. An account given at a mutual discussion in Erlangen (Nov. 1944) concerning the favorable results obtained by us with the 50-cycle ray transformer probably may have given the impetus for the later construction of corresponding 50-cycle apparatus by Siemens.

## Direction of Maximum Crystal Elongation during Metal Cutting*

G. H. TOWNEND
*Metropolitan-Vickers Electrical Company, Ltd., Manchester, England*
March 17, 1947

IN an interesting paper by Dr. M. E. Merchant on "Mechanics of the Metal Cutting Process,"[1] an error was made in the expression connecting shear angle, rake angle, and direction of maximum crystal elongation (Eq. (1), page 269). I have written to Dr. Merchant and he confirms the new expression derived below.

Let $\alpha$ = rake angle,

$\phi$ = the angle between the shear plane and the surface of the workpiece.

Consider a section of the workpiece $ABCD$ such that $< CBD = 90°$. Then after shearing this section will become the parallelogram $BFEC$. The dimension perpendicular to the shear plane must be unchanged during shearing.

$$\therefore\quad BD = BH = a.$$

Consider a line $CG$ in the chip making an angle $\psi$ with the plane of shear. Then the corresponding line in the workpiece is $DJ$. The condition that $CG$ shall be the direction of maximum crystal elongation is that $CG/DJ$ is a maximum.

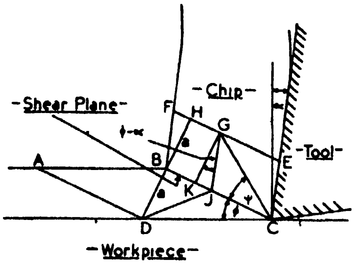

FIG. 1.

$$CG = a\ \mathrm{cosec}\psi,$$
$$DJ = \{a^2 + (a\cot\phi - a\cot\psi + a\tan(\phi-\alpha)^2)^2\}^{\frac{1}{2}}.$$

The condition is that

$$\{\sin^2\psi + (\cot\phi\sin\psi - \cos\psi + \tan(\phi-\alpha)\sin\psi)^2\}^{\frac{1}{2}}$$

is a maximum. That is,

$$\sin^2\psi + \{\sin\psi(\cot\phi + \tan(\phi-\alpha) - \cos\psi)\}^2$$

is a minimum. Let

$$\cot\phi + \tan(\phi-\alpha) = \epsilon,$$
$$\epsilon^2\sin 2\psi - 2\epsilon\cos 2\psi = 0.$$

If $\epsilon \neq 0$

$$2\cot 2\psi = \epsilon,$$
$$2\cot 2\psi = \cot\phi + \tan(\phi-\alpha).$$

Alternatively it is easily shown that a circle on the workpiece becomes an ellipse on the chip and that the principal axes of the ellipse make an angle $\psi$ with the shear plane, where

$$2\cot 2\psi = \cot\phi + \tan(\phi-\alpha).$$

---

* This letter was published in the May issue of the Journal of Applied Physics, but through an error Fig. 1 was omitted.

# Here and There

### New Appointments

A recent issue of *Science* reported the following new affiliations:

E. C. Watson, Professor of Physics at California Institute of Technology, has been appointed chairman of the Division of Physics, Mathematics, and Electrical Engineering.

C. J. Gorter, Professor of Physics and Co-Director, Physical Institute, University of Leiden, and formerly Zeeman Professor of Physics, University of Amsterdam, is a visiting lecturer at Harvard University for the 1947 summer term. He is conducting one course in advanced dynamics and one in relaxation phenomena. The latter treats magnetic and dielectric absorption and dispersion in alternating fields, a subject in which Professor Gorter has made outstanding contributions.

H. P. Robertson, a member of the faculty of Princeton University since 1928, has been appointed Professor of Mathematical Physics, California Institute of Technology, effective July 1.

### Distribution of Concentrated Boron 10

Concentrated isotope boron 10, which enables scientists to make more sensitive neutron-detection tubes and thereby speed up results in atomic research problems, is now available, the Isotopes Branch of the Atomic Energy Commission has announced. However, only a limited quantity is ready for general distribution. Requests will be carefully reviewed and allocations will be restricted to reasonable quantities for the proposed investigation.

Boron 10 atoms are normally quite stable. They have, however, a great affinity for neutrons. When a boron 10 atom captures a neutron it is transmuted into two energetic nuclear particles, one lithium and the other helium. The latter is the well-known alpha-particle. Either particle serves as an excellent trigger for a tube designed to count neutrons. Boron found in nature contains only 20 percent boron 10. Hence a neutron-detection tube five times more sensitive can be made by employing nearly pure boron 10 rather than an equal quantity of ordinary boron. The boron 10 was produced by concentrating the isotope from natural boron in studies of isotope concentration.

Boron 10 will be packaged for shipment in the form of the solid complex boron trifluoride-calcium fluoride. The complex contains 6.9 percent elemental boron, of which 96 percent is B 10. Approximately 6.5 grams of $BF_3 \cdot CaF_2$ are needed to obtain one liter of $BF_3$ at normal temperature and pressure (assuming 100 percent liberation). The boron trifluoride may easily be released as a gas by heating to temperatures above 260°C in a vacuum.

The price of $BF_3 \cdot CaF_2$ complex is $2 per gram, independent of quantity. Shipping charges will be added to the invoice. There is no additional handling fee per shipment. Standard units of 1, 5, 10, and 50 grams have been packaged in glass containers with moisture-proof plastic screwtops. Requirements will be filled in single units or multiples of these standard sizes. Clinton Laboratories, Oak Ridge, Tennessee, will act as the supplier.

### Exhibit of Technical Photographs

A special section devoted to photographs of technical and scientific subjects will be included again this year in the annual exhibition of the Photographic Society of America. The exhibition will be hung at the Oklahoma Art Center, Oklahoma City, and contributors are invited to submit prints for the technical section prior to September 8. Prints should be mailed to W. F Swann, 343 State Street, Rochester 4, New York

Subject matter may cover any phase of technical photography save pictorial photographs of technical or mechanical operations. Scientific and industrial photographs illustrating original and novel photographic techniques may be submitted. These include photographs in such fields as astronomy, geology, medicine (except diagnostic radiographs), metallography, mineralogy, and physics. Both black-and-white or color photographs are acceptable. Technical data pertaining to each photograph should be lettered neatly in the lower left-hand corner of each mount, if possible, and the maker's name should appear on the face of the mount. There is no limit to the number of prints which may be submitted by a competitor.

### Brookhaven Advisory Committee

Dr. Edward U. Condon, Director of the National Bureau of Standards, and Dr. Detlev W. Bronk, Chairman of the National Research Council, have accepted appointments as members of the Scientific Advisory Committee of Brookhaven National Laboratory, Long Island, New York.

### Louisville Research Institute Dedicated

The University of Louisville Institute of Industrial Research (affiliated with Speed Scientific School) dedicated its new research building on June 12, 1947.

### Herman F. Mark Accepts Belgian Chair

Herman F. Mark, Director of the Institute of Polymer Research and Professor of Organic Chemistry, Polytechnic Institute of Brooklyn, has been invited to accept the Chair Franccki at the University of Liége, Belgium, for the academic year 1947–1948. The guest professorship involves a six-month lecture tour of several Belgian universities.

### *Spectrochimica Acta* Re-Established

The journal *Spectrochimica Acta* has been re-established as an international organ for spectroscopists and spectrochemists, to be published in the Vatican under the editorship of Dr. Alois Gatterer, assisted by a group of coworkers in other countries, as follows: Dr. R. Breckpot of Belgium, Dr. H. Kaiser of Germany, Dr. E. Van Someren of England, and Dr. Lester W. Strock of America. It is expected that the first number of the journal will be ready for press by August 1, and that from six to eight numbers a year will be issued thereafter. Papers in English from America should be submitted to Dr. Strock at 21 Madison Avenue, Saratoga Springs, New York. The official languages of *Spectrochimica Acta* are English, French, and German, and papers will also be accepted in Italian and Spanish.

### Second Instrumentation Exhibit

Over ninety manufacturers of instruments and devices for measurement, inspection, testing, and control have already signed up to exhibit their latest developments at the coming second annual Instrument Conference and Exhibit at the Stevens Hotel, Chicago, September 8–12, 1947, sponsored by the Instrument Society of America.

### Lehigh to Remodel Two Buildings

Lehigh University is remodelling its physics and chemistry buildings at an approximate cost of $105,000. Work is expected to be completed before the opening of the fall semester. The physics building will be equipped with new laboratories for high voltage x-ray equipment, electronics, electric waves, and optical and spectroscopic work.

### Awards

Otto Stuhlman, Jr., Professor of Physics, University of North Carolina, received the Poteat Award at the 64th annual meeting of the North Carolina Academy of Science, May 9–10, in recognition of his biophysical paper "A Dynamical Analysis of the Movements of the Lobes of the Venus' Flytrap."

Presidential Medals for Merit were presented on May 5 to the following scientists for outstanding contributions to the Navy's war effort: John T. Tate, Chairman of Research and Professor of Physics, University of Minnesota; Frederick V. Hunt, Chairman of the Department of Engineering Sciences, Harvard University; Gaylord P. Harnwell, Chairman of the Department of Physics, University of Pennsylvania; and William V. Houston, President of Rice Institute.

### Detection of Isotopes by Tracer Micrography

A method for the more effective tracing of radioactive isotopes in materials in which they have been intentionally introduced has been developed by L. Marton of the National Bureau of Standards with the cooperation of P. H. Abelson of the Department of Terrestrial Magnetism, Carnegie Institution of Washington. In this procedure, by means of a magnetic focusing arrangement, the radiation given off by a radio-isotope within a sample material is made to form an image of the emitting surface upon a photographic plate. The image may then be used in studying the distribution and concentration of the radioactive element present in the sample.

In many chemical, biological, biochemical, and other fields of research, there is growing application of the method of tracers, in which the isotope of a given element is used as an indicator to tag or label certain groups of atoms so that they may be distinguished from other atoms of the same kind. Identification of tracer elements is at present greatly facilitated through the use of radioactive isotopes, which, because of recent developments in atomic energy, are now available in large quantities and are relatively easily detected through their radiations.

In the well-known method of radio autography a radioisotope is introduced in a biological or other system, and the distribution of that particular element within the system is determined by bringing the sample in close contact with a photographic emulsion. This method lacks resolving power, because, even in case of perfect contact of the sample with the emulsion, the circle of confusion from every point of emission is so great that details less than a tenth of a millimeter are very difficult or impossible to distinguish.

In order to improve the resolution of this tracer method, it was decided to use electron optical image formation for determination of the distribution of a radioactive element within a given sample. This process, which may be called "tracer micrography," is based on the emission of high speed electrons (beta-rays) by many tracer elements and the use of magnetic lens elements for forming an image on a suitable recording surface.

In the absence of any means for correction of the chromatic aberration of electron optical lenses, the first micrographs were limited to those elements that emit electrons of uniform speed. After some attempts with columbium 93, yttrium 87, strontium 85, strontium 87, protactinium 233, and gallium 67, the latter was selected for the initial tests. Gallium chloride, prepared by chemical separation from zinc, was bombarded by heavy hydrogen nuclei in the cyclotron at the Carnegie Institution, and the solution was evaporated drop after drop on a ¼-inch tantalum disk. Radiation emitted from the surface of the disk, upon passing through a magnetic lens consisting of a small iron-clad coil with Armco iron pole pieces, was brought to a focus on a photographic film at a distance of about 3½ inches. An image of the tantalum disk was thus obtained showing radioactive areas. The conditions were selected so that a linear magnification of 2 was produced.

For calibration of the instrument, the photographic film was replaced by a Geiger counter, and the lens current necessary to produce a maximum number of counts in unit time was determined for radiations of varying velocities. This established the focusing current for a given type of radiation.

In preliminary experiments with samples of different concentration and thickness of the radioactive layer, exposure times ranged from 2 to 12 hours according to the age and concentration of the sample and the numerical aperture of the lens. It was found that micrographs with good definition were obtained consistently when the layer was sufficiently thin to avoid considerable self-absorption. The best resolving power attained so far has been about 30 microns.

The simplicity of this method, both in apparatus and technique, is one of its more important features. Vacuum requirements are very moderate, since the mean free path of the electrons is large in comparison with the apparatus dimensions, even at forepump pressure.

Scientists at the National Bureau of Standards expect to obtain further improvements in tracer micrography through after-acceleration of the beta-particles by means of a homogeneous electrostatic field. Such after-acceleration may well result in reduced exposure time and in better resolution due to a reduction in spherical aberration. A further reason for after-acceleration is that chromatic aberration, which is always present, even in sources emitting particles of uniform speed, can be markedly decreased if the accelerating potential is at least comparable in magnitude to the energy of the primary emission.

### Utah Symposium on Sound

In connection with the Utah Centennial Celebration a Symposium on Sound was held at the Salt Lake Tabernacle and the University of Utah on July 21 and 22. Invited papers were presented by eleven academic and industrial experts in the field of sound.

# New Books

## Scientific Progress in the Field of Rubber and Synthetic Elastomers

INITIATED BY THE LATE ELMER O. KRAEMER, EDITED BY H. MARK AND G. S. WHITBY. Pp. 453, 15½×23½ cm. Interscience Publishers, Inc., New York, 1946. Price $7.00.

This book which is volume II of *Advances in Colloid Science* is a sequel to volume I and describes recent advances in the physics of rubber and synthetic elastomers. The work and plans of the late Elmer O. Kraemer have been admirably carried out by the co-authors, H. Mark and G. S. Whitby.

This book consists of ten chapters on various phases of high polymer physics, each written by specialists; and they have all done an excellent job. In addition, a biography of the late Dr. Kraemer is included with a list of his many publications. Complete author and subject indexes are included. The book contains around 450 pages and over 800 references.

The first chapter or introduction gives some well-known facts concerning the origin, chemical nature, and some of the properties of the cured polymers of both natural rubber and the more common synthetic elastomers.

The second chapter, a real treatise on the subject of second-order transitions, is extremely well written and contains over 125 references. Tables on second-order transition temperatures and brittle points are given for over thirty different plastics, rubbers, and synthetic rubbers. The theory of second-order transitions is elaborated upon with particular reference to the theory of segment rotation. Experimental results, together with factors influencing second-order transitions, make this section of particular value to workers in the high polymer field.

Chapter 3 is an excellent résumé of the past and most recent information and theories on crystallization phenomena in synthetic and natural rubbers. This section contains a complete bibliography of 150 references.

The fourth chapter goes into a study of crystal and molecular structure of high polymers by means of x-ray diffraction methods. There is some duplication of information in this and the previous chapter; however, it is not objectional, as crystallization phenomena are followed in the first instance primarily by dilatometer and other methods, and in the second instance primarily by x-ray diffraction methods.

There are also valuable chapters on thermodynamics of rubber solutions and gels, viscosity of high polymers, kinetic theory of rubber elasticity, vulcanization, rubber photogels, and photo-vulcanizates. The volume fittingly concludes with a chapter on reinforcing agents in rubber.

Some of the newer organic plastics and resins as vulcanizing agents and as reinforcing agents for rubber and synthetic rubbers are not covered in this volume.

The authors are to be congratulated on the general make-up and quality of the chapters on the timely subjects which are covered in this book.

Duplication of information is surprisingly low in a volume covering such a diversity of inter-related subjects by such a large number of authors.

This book will be a welcome library addition to all those interested in the field of high polymer physics.

## Electron and Nuclear Counters—Theory and Use

By Serge A. Korff. Pp. 212, 22×14½ cm. D. Van Nostrand Company, Inc., New York, 1946.

In his book, *Electron and Nuclear Counters - Theory and Use*, Korff has gone a long way towards removing the aura of "magic" from detectors used in the field of nuclear physics. The student desiring to enter this field has had in the past practically no recourse but to learn peculiarities of nuclear detectors the hard way, namely, the trial and error method of making and using them. This same student now has available in this very readable book a fairly complete qualitative account of the operation and construction of ionization chambers, proportional counters, and Geiger counters.

The first chapter is devoted to the history and general operation of particle detectors. Korff points out that the main differences between the ionization chamber, proportional counter, and Geiger counter is the voltage region in which they are operated. The next three chapters give a more detailed account of the operation of these detectors. The last of these chapters, namely, the one covering the Geiger counter, is by far the most detailed and complete since this is the author's special field. Even though they have much theory and operation in common, Korff discusses separately the non-self-quenching counter and the self-quenching counter. Expecially interesting is the discussion of the quenching process caused by the presence of certain polyatomic gases in a Geiger counter. The presence of spurious counts or a continuous discharge in a Geiger counter is interpreted as being caused by the emission of photoelectrons and/or secondary electrons from the outer electrode because of photons or positive ions formed in the discharge striking this electrode. If certain polyatomic gases are present they are found to absorb the photons and neutralize the positive ions of the counter gas, the excitation energy of the polyatomic molecule then being dissipated harmlessly through the process of predissociation.

The last three chapters cover, respectively, the constructional aspects of nuclear counters, statistics of counting random events, and finally the auxiliary electronic circuits involved, such as quenching circuits, scaling circuits, coincidence circuits, and linear amplifiers.

The book contains several erroneous and conflicting statements and at least one incorrect circuit diagram. At one point the author speaks of reducing the alpha-particle background of an ionization chamber through the use of a positively charged grid which "would repel any alpha-particles approaching it and drive them back into the wall." The expression for the percentage of missed counts has been developed in Chapter 6 on the basis of very naive assumptions and is valid only for recovery times small compared to the average time between counts. The Neher-Pickering circuit as presented is obviously not capable of quenching. In several cases the circuits given in the book are not the most up-to-date ones used for that particular purpose.

This book, the reviewer feels, has provided the newcomer with a good way of getting acquainted with the field but does not fill the need for a critical and detailed review of the present status of our knowledge of counter mechanisms. A worker in this field will still have to refer to the literature for a complete and quantitative account.

*Case Institute of Technology*

## Colloids, Their Properties and Applications

By A. G. Ward. Pp. 133, Interscience Publishers, Inc., New York, 1946; Blackie and Son, Ltd., Glasgow.

A book on colloid chemistry of this limited size can obviously serve, as the author intended it should, only as an elementary account of recent progress in colloid science, and as an introduction of the subject to those who are unfamiliar with it. In general it accomplishes these aims in a satisfactory manner, and can be recommended highly.

The book has three major subdivisions: I. The Nature of the Colloidal State; II. The Colloidal Systems; III. Colloids in Industry and Living Matter. The treatment throughout is descriptive in nature. The author has tried to make the field of colloidal dimensions intelligible to the layman by giving all dimensions first in microns and then, in parenthesis, on a scale one hundred million fold enlarged. Thus a particle of tobacco mosaic virus is said to have a length of 0.5 μ (50 meters). This is rather disconcerting to one who opens the book at random, unaware of the convention adopted.

The author points out that the usual tendency to explain trends in scientific progress on the basis of social and economic needs of the community is not valid in the colloid field. The practice of colloid chemistry is one of man's oldest endeavors in such realms as textiles, pottery soils, paints, etc. Colloid science has lagged behind practice mainly because the tools which were needed to explore the colloidal domain are all fairly new. Hence he places special emphasis on these new tools.

It was a pleasure to read this book and see a broad field free from the complex technical and mathematical details which one needs for active work in colloid chemistry.

# New Booklets

The National Research Council of the National Academy of Sciences, Prevention of Deterioration Center, Room 204, 2101 Constitution Avenue, Washington, D. C., can now offer the *Prevention of Deterioration Abstracts* on a yearly subscription basis. These abstracts are set up under the following headings: electrical and electronic equipment; finished assemblies; fungicides; lacquers, paints, and varnishes; leather; lubricants; metals; microorganisms; optical instruments; packaging; paper; plastics; resins, rubbers, and waxes; storage, textiles; and wood. Items abstracted include journal articles, patents, specifications, unpublished reports prepared by various Army, Navy, and other governmental groups, and unpublished British, Australian, and Canadian reports.

There will be approximately 1500 pages of the abstracts per year. The individual abstracts are in loose leaf form, so that they may be arranged in manner desired by the individual receiving them. Throughout the calendar year, all the abstracts classified under any one heading will be numbered consecutively.

Comments made by the personnel of the Prevention of Deterioration Center are added to many of these abstracts. In these comments attempts are made to relate a specific report with other relevant ones, to evaluate reports, or to make suggestions concerning further needed research.

The price, which includes two binders and index guides, will be $37.50 per year. Two binders are required for one year's subscription. The fiscal year will be from July 1 to June 30. For the year 1946 back issues will be supplied, since these abstracts started in April 1946.

Dow Corning Corporation, Midland, Michigan, has published a new silicone data sheet entitled *Specifications for Rewinding Motors with Silicone Insulation.* 2 pages, free on request.

The Gaertner Scientific Corporation, 1201 Wrightwood Avenue, Chicago 14, Illinois, has announced publication of two bulletins: 157–74, *Divided Circle Spectrometers and Accessories,* 20 pages; 158–74, *Wavelength Spectrometers and Monochromators,* 12 pages. Available free on request.

The Tube Department of Radio Corporation of America, Harrison, New Jersey, has brought out a revised edition of the *Quick-Reference Chart on Miniature Tubes.* It is form MNT-30A. 4 pages.

North American Philips Company, Inc., 100 East 42d Street, New York 17, New York, has published a two-page chart (R-1066) entitled *Basic Characteristics of Useful Industrial Laboratory Instruments.* Data are presented in a convenient form to facilitate hanging on the wall for ready reference. Free on request.

Littelfuse, Inc., 4757 Ravenswood Avenue, Chicago 40, Illinois, has recently published its first completely new catalog since the beginning of the war. It is a manual of progress in the field of circuit protection, including a brief historical survey of fusing and the announcement of many new developments in the company's line of fuses, fuse mountings, and circuit indicators. The catalog's number is 9.

Dewey and Almy Chemical Company, Boston 40, Massachusetts, has issued a new catalog of *Darex* meteorological balloons, containing many new performance and data charts calibrated in both the English and metric systems. 30 pages. Free on request.

RCA Application Note for May 15, 1947, published by the Tube Department of Radio Corporation of America, Harrison, New Jersey, is entitled *Use of the 2E24 and 2E26 at 162 Megacycles.* 8 pages, available on request.

Interscience Publishers, Inc., 215 Fourth Avenue, New York 3, New York, has published a 50-page catalog of its recent releases in the fields of chemistry, physics, mathematics, engineering, and medicine.

Eastman Kodak Company, Rochester 4, New York, has issued a revised data book on *Infrared and Ultraviolet Photography.* Priced at 25 cents a copy, it is available through all Kodak dealers.

# Microwave Dielectric Measurements

T. W. Dakin and C. N. Works
*Westinghouse Research Laboratories, East Pittsburgh, Pennsylvania*

(Received March 7, 1947)

The method of measurement of the dielectric properties of solid dielectrics described by S. Roberts and A. von Hippel has been applied with 3-cm wave-length waves in a rectangular wave guide. In this method the dielectric sample is placed at a short circuited end of the transmission line, and the dielectric properties of the sample, calculated from the position of a minimum of the standing wave and the ratio of the minimum field strength to the maximum field strength of the standing wave. A simplified procedure for calculating the dielectric properties from the measurements is presented. Values are given of the dielectric properties of some common plastic and ceramic materials at 10-cm wave-length and 3-cm wave-length, which were measured with this method.

## INTRODUCTION

At microwave frequencies the dielectric properties of a material can be obtained accurately only by measuring the wave-length in the material or its reflecting power and the attenuation of the wave in the material. There are many experimental ways in which the problem can be attacked. A summary of the experimental work in this field up to 1927 is given by Romanoff.[1] His summary includes the pioneering work of Drude,[2] who proposed two methods, the first of which consisted of measuring the wave-length directly in the dielectric media surrounding a resonant section of a pair of lecher wires, and the second of which consisted of measuring the capacitance of a small capacitor containing the dielectric and closely attached to the resonant section of lecher wires. Drude's second method contains inherent errors, when applied at very short wave-lengths, because of the inaccuracy of considering a capacitor as a lumped capacitance at these wave-lengths. Drude's second method has, however, been used by many investigators[3] even up to recent years. Modifications and improvements of Drude's first method, including experiments where only a part of the resonant section of a transmission line is filled with dielectric, have been made by many investigators[4] since the summary of Romanoff. In more recent work, enclosed coaxial or hollow

transmission lines have been used.[5] Optical methods where the transmission through slabs of the dielectric and reflection from the dielectric surface are measured have also been used[6] with microwaves. Direct measurement by probes of standing waves set up within liquid dielectrics and in front of dielectric surfaces by reflection have also been used to obtain dielectric properties.[7] Resonant-cavity methods where all or part of the cavity is filled with dielectric are an extension of the resonant-transmission line idea and these have been used at microwave frequencies.[8]

## MEASUREMENT TECHNIQUE AND CALCULATIONS

The method using standing-wave measurements in the transmission line in front of the dielectric sample proposed by S. Roberts and A. von Hippel[9] has been developed for the measurement of solid dielectrics to a more practical state than any other method in recent years. This is the method which is used and discussed in this paper. This method consists of reflecting the wave at normal incidence from a slab of the dielectric which is placed against a perfectly reflecting surface. The process of reflection sets up standing waves in the space region in front of the sample as a result of the superposition of the incident and reflected waves (See Figs. 1a, 1b, 1c). The electric field direction is maintained at right angles to the direction of propagation of the wave (TE wave).

In actual practice the wave and the dielectric sample are restricted to an enclosed hollow or coaxial wave guide, although this is not in principle a necessary restriction. The same equations are valid in principle for a measurement using lecher wires or free space with a parallel beam of radiation, although it is more difficult in practice to do measurements under those conditions.

The separation of the first minimum from the face of the sample will depend on the wave-length of the wave in the sample and its thickness, since the first minimum will be an integer number of half-waves from the reflecting surface behind the sample (See Fig. 1b). In Figs. 1b and 1c the shortening of the wave-length in the sample is shown. Insertion of the dielectric shifts the minima of the standing wave toward the end. The separation of the first minimum of the standing wave from the surface of the sample is a measure of the dielectric constant.

If there is any attenuation in the dielectric, there will be a reduction in the standing-wave ratio $E_{\max}/E_{\min}$, since all the incident wave intensity would not be reflected. There is, of course, a finite standing-wave ratio with no dielectric present, because of the slight attenuation by the copper- or silver-walled transmission line. The measured value of $E_{\max}/E_{\min}$ is mathematically

related to the attenuation constant and the dielectric constant of the slab of dielectric by the relation (1) which was derived by S. Roberts and A. von Hippel.[9]

$$\frac{\dfrac{E_{\mathrm{min}}}{E_{\mathrm{max}}}-i\tan\dfrac{360x_0}{\lambda_g}}{1-i\dfrac{E_{\mathrm{min}}}{E_{\mathrm{max}}}\,\dfrac{\tan 360x_0}{\lambda_g}}\cdot\frac{\lambda_g}{2\pi d i}=\frac{\tanh\gamma_2 d}{\gamma_2 d}. \tag{1}$$

Where $x_0$ is the distance from the first electric field strength minimum of the standing wave to the face of the sample, $d$ is the thickness of the sample, and $\lambda_g$ is the wave-length along the wave guide outside the sample. $E_{\mathrm{min}}/E_{\mathrm{max}}$ is the ratio of the electric field strength at an adjacent maximum point. $\gamma_2$ is the propagation constant of the wave in the wave guide and within the sample.

The most general procedure is to solve the above complex transcendental equation for $\gamma_2 d$ after the measured values of $E_{\mathrm{min}}/E_{\mathrm{max}}$, $\lambda_g$, $d$, and $x_0$ are obtained. The solution of this equation can be obtained directly only by the use of charts of the complex function: $\tanh\gamma_2 d/\gamma_2 d$. Such charts have been prepared by Professor von Hippel and co-workers.[10] A convergent series solution has also been obtained by them for the case where $360x_0/\lambda_g$ is near to 90° or an odd multiple of 90°, and $E_{\mathrm{min}}/E_{\mathrm{max}}$ is small. But this direct method of solving the complex transcendental equation is very laborious.

A simpler solution, usually of sufficient accuracy, can be obtained when the value of the dissipation factor of the dielectric is less than 0.1 by separating Eq. (1) into its real and imaginary parts and equating them separately, remembering that $\gamma_2=\alpha_2+\beta_2 i$. Equation of the real parts gives:

$$\frac{-\lambda_g\tan\dfrac{360x_0}{\lambda_g}\left(1-\dfrac{E^2_{\mathrm{min}}}{E^2_{\mathrm{max}}}\right)}{2\pi d\left(1+\dfrac{E^2_{\mathrm{min}}}{E^2_{\mathrm{max}}}\tan^2\dfrac{360x_0}{\lambda_g}\right)}=\frac{\beta_2 d\tan\beta_2 d(1-\tanh^2\alpha_2 d)+\alpha_2 d(1+\tan\beta_2 d)\tanh\alpha_2 d}{(\alpha_2{}^2d^2+\beta_2{}^2d^2)(1+\tanh^2\alpha_2 d\tan^2\beta_2 d)}. \tag{2}$$

When $\alpha_2 d$ and $E_{\mathrm{min}}/E_{\mathrm{max}}$ are small, the above equation reduces to:

$$\frac{-\lambda_g\tan\dfrac{360x_0}{\lambda_g}}{2\pi d}=\frac{\tan\beta_2 d}{\beta_2 d}. \tag{3}$$

This is an equation involving no complex numbers which may be readily solved for $\beta_2 d$ by reference to a table of $(\tan\theta)/\theta$ for radian arguments. Such an abbreviated table exists in Jahnke Emde's ***Funktionentafeln***. A more complete table has been prepared at the Westinghouse Research Laboratory, and another by the Laboratory for Insulation Research at MIT.[11] The values on the left side of Eq. (3) are measured quantities, and after $\beta_2 d$ has been obtained the dielectric constant can be calculated from the following equation:

$$\epsilon'=\frac{1/\lambda_c{}^2+\dfrac{(\beta_2 d)^2}{(2\pi d)^2}}{1/\lambda_c{}^2+1/\lambda_g{}^2}, \tag{4}$$

where $\epsilon'$ is the dielectric constant, $\lambda_c$ is the cut off wave-length of the wave guide. If coaxial wave guide is used, $1/\lambda_c{}^2$ is zero. The above equation is accurate only for materials having dissipation factors less than 0.1. The solution of Eq. (3) for $\beta_2 d$ is multi-valued and will give several values of $\epsilon'$. If the correct one cannot be selected by previous knowledge of the material, a second measurement is necessary using a sample of different length, $d$.

An expression can now be obtained for the attenuation constant by equating the imaginary

[10] Report III by A. von Hippel, D. G. Jelatis, and W. B. Westphal, Laboratory for Insulation Research, MIT Contract OEMsr 191, N.D.R.C.

parts of Eq. (1).

$$\frac{-\lambda_g\dfrac{E_{\min}}{E_{\max}}\left(1+\tan^2\dfrac{360x_0}{\lambda_g}\right)}{2\pi d\left(1+\dfrac{E^2_{\min}}{E^2_{\max}}\tan^2\dfrac{360x_0}{\lambda_g}\right)} = \frac{\alpha_2 d\tan\beta_2 d-\alpha_2 d\tanh^2\alpha_2 d\tan\beta_2 d-\beta_2 d\tanh\alpha_2 d-\beta_2 d\tanh\alpha_2 d\tan^2\beta_2 d}{(1+\tanh^2\alpha_2 d\tan^2\beta_2 d)(\alpha_2^2d^2+\beta_2^2d^2)}. \quad (5)$$

When $\alpha_2$ and $E_{\min}/E_{\max}$ are small, Eq. (5) reduces to:

$$\alpha_2 d \cong \frac{\beta_2^2d^2\lambda_g}{2\pi d}\cdot\frac{E_{\min}}{E_{\max}}\cdot\frac{\left(1+\tan^2\dfrac{360x_0}{\lambda_g}\right)}{\beta_2 d(1+\tan^2\beta_2 d)-\tan\beta_2 d}. \quad (6)$$

Roberts and von Hippel[9] have shown that $E_{\min}/E_{\max}=\pi\Delta x/\lambda g$ where $\Delta x$ is the width of the minimum of the standing wave to the double power points. After making this substitution, and putting in an equivalent value for $\alpha_2$, Eq. (6) gives an analytical expression for the dissipation factor:

$$\tan\delta_2=\frac{\Delta x}{d}\left[\frac{(1/\lambda_c^2+1/\lambda_g^2)-1/\lambda_c^2\epsilon'}{(1/\lambda_c^2+1/\lambda_g^2)}\right] \times\frac{\beta_2 d\left(1+\tan^2\dfrac{360x_0}{\lambda_g}\right)}{\beta_2 d(1+\tan^2\beta_2 d)-\tan\beta_2 d}. \quad (7)$$

In the above equation the term within the brackets reduces to unity for coaxial wave guide, since $1/\lambda_c^2$ is zero in that case. In carrying out calculations it is first necessary to obtain $\beta_2 d$ and $\tan\beta_2 d$ from Eq. (3) before the dissipation factor is calculated using Eq. (7).

Fig. 2.

Since there is always some dissipation in the walls of the wave guide, a measurement of $E_{\min}/E_{\max}$ includes those losses together with the dielectric losses. These wave guide losses must be subtracted. The proper procedure is first to correct the measured value of $E_{\min}/E_{\max}$ for the loss due to the wave guide in front of the sample, between the sample face and the measured minimum. Then the total dissipation factor of the wave guide and sample are calculated from Eq. (7), and the dissipation factor of the wave guide subtracted from the result. The dissipation factor of the wave guide can be obtained from Eq. (7) after measuring the value of $\Delta x$ with the wave guide empty. In this case $\epsilon'$ would be unity, $d$ would be the distance from the measured minimum to the shorted end of the wave guide, and both $\tan(360x_0/\lambda_g)$ and $\tan\beta_2 d$ would be very large. Then Eq. (7) gives for the dissipation factor of the wave guide:

$$\tan\delta_w=\frac{\Delta x}{d}\,\frac{1}{1+\lambda_g^2/\lambda_c^2}. \quad (8)$$

Since the approximations involved in going from Eqs. (2) to (3) and from (5) to (6) are not readily obvious except in the limiting cases of very large $\tan(360x_0/\lambda_g)$ and $\tan\beta_2 d$ or of $\tan(360x_0/\lambda_g)$ and $\tan\beta_2 d$ less than unity, a numerical check of the validity of the approximations was made by substituting in typical measured values of $\Delta x$, $d$ and $(360x_0/\lambda_g)$. It was verified by numerical calculation that Eq. (3) is accurate to about ±1 percent in the dielectric constant for dissipation factors less than 0.1. This numerical check was made for a wide range of values of $(360x_0/\lambda_0)$, varying from 0° to 120° and also a wide range of values of $\Delta x$ and $d$ by comparing values of $\epsilon'$ and $\tan\delta$ obtained from Eqs. (3), (4), and (7) with those obtained from a direct graphical solution of Eq. (1) for $\gamma_2$. The accuracy of the approximation increases with decreasing $\tan\delta$. Similar accuracy is also obtained in the calculation of $\tan\delta$

## EXPERIMENTAL

The complete electrical system is shown in schematic form in the block diagram, Fig. 2. Figures 3 and 4 show the standing-wave detector and sample holding section of the instrument. The cross section of the guide and the sample is 0.900" by 0.400". Typical samples vary in length from about ⅛" for high loss and high dielectric constant materials to about 1½" for low loss and low dielectric constant materials.

The position of the probe must be known with great precision, so a Gaertner comparator, No. 1658, 0–100 mm, which reads accurately to 0.001 mm, was used to carry the probe. The probe must have sufficient length to give sufficient signal at the minimum of the wave pattern; its presence should not disturb the field; it must be shielded so that it does not produce disturbing radiation.

The steel brackets shown as $E$ and $F$ in Fig. 3 enabled a careful adjustment of the comparator so that the probe would move parallel (within ±0.0001") with the bottom of the wave guide. The wave guide was milled from two pieces of brass with the inside silver plated. The dimensions of the guide were held to a tolerance of ±0.0001" with parallel top and bottom. The 13-cm slot which accommodates the probe was made narrow (0.070") and deep (0.175") to reduce the radiation from it. This choice of slot dimensions makes it possible to place one's fingers on the slot without changing the response of the detector.

Details of the probe assembly are shown in Fig. 4. The probe which extends into the guide is a silver-plated steel wire of 0.012" diameter, and its extent of penetration into the guide is adjustable. The probe is tuned with an adjustable choke so that maximum energy will be transferred from the probe to the detector.

The wave guide instrument has been used both tuned and untuned. When operating untuned, a tapered non-reflecting attenuator is placed between the end where the power is introduced and the end where measurements are made. This requires the introduction of more energy for the same detector current than in the case where the guide is tuned with a shorting plunger at the end opposite where the measurement is made.

Two different reflex klystron tubes (WE 721A and Sperry 2K25) operating in the vicinity of 10,000 megacycles have been used with the wave-guide instrument.

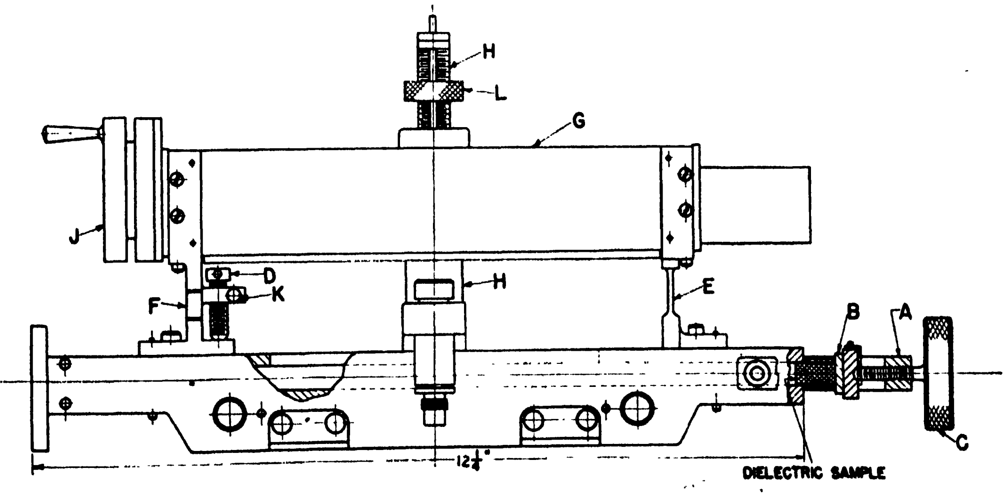

FIG. 3. The wave-guide instrument for dielectric measurements at 3 cm.

The power supplies for these tubes are of the conventional electronic voltage-regulated type.[12] The reflector voltage is pulse modulated by a square wave generator operating at an audiofrequency to amplitude modulate the microwave intensity. But where an automatic frequency control system was used to stabilize further the frequency of the oscillator tube for increased accuracy in the measurement of low loss materials, the microwave intensity was usually not modulated and a d.c. detector was used.

The crystal d.c. current from the 1N21 crystal detector shown in Fig. 4 was assumed to be proportional to the square of the radiofrequency electric field in the wave guide for low currents at which it is used. Galvanometers have been used as crystal current meters when the microwaves are unmodulated. The galvanometer should have a sensitivity of at least 0.002 micro ampere per mm to give a deflection that is readable with sufficient accuracy for measurements at the minimum voltage region.

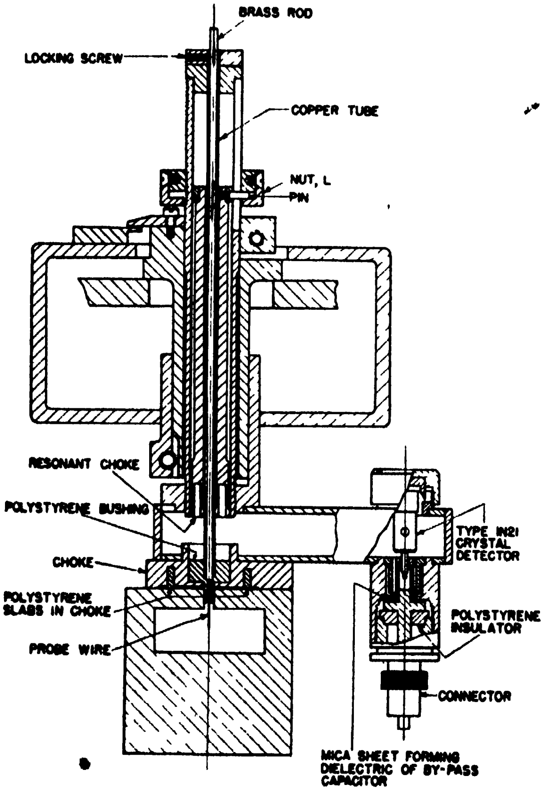

FIG. 4. Cross section through probe assembly and wave guide.

The rapid response of an a.c. amplifier makes it preferred over a galvanometer as a crystal-current indicator. When the microwave power is pulse modulated at an audiofrequency, a sensitive tuned audiofrequency amplifier is used with a panel output meter. The amplifier must be linear so that the output meter reading is always proportional to crystal current. Use of a reasonably high audiofrequency-tuned amplifier also has the advantage of largely eliminating spurious noise developed in the crystal.

## SOURCES OF ERRORS IN THE MEASUREMENTS

### (1) Errors Due to Change in the Frequency of the Oscillator

Changes in frequency may result during the measurement as a result of too close coupling between the oscillator tube and the measuring wave guide, or because of inadequate regulation of the electrode voltages on the tube. This, of course, results in changes in position of the voltage minima in the wave guide.

### (2) Errors Due to Excessive Projection of the Probe into the Wave Guide

If the probe projects too far into the wave guide, it causes an error in both the position of the minimum and the value of $\Delta x$. If the detecting system and the standing wave detector are adjusted for maximum sensitivity, the required projection of the probe to obtain a satisfactory deflection of the indicating instrument should be such that no error is introduced. When very high loss samples are in the wave guide, it is well to check against this source of error by increasing or decreasing the projection of the probe into the wave guide by about 1/64 inch and again measuring the location of the minimum and the value of $\Delta x$. No change should be observed.

### (3) Errors Due to Frequency Modulation

It has been found that appreciable frequency modulation of the source causes the value of $\Delta x$ to be increased. This effect is analyzed by M. G. Haugen and W. B. Westphal.[13]

* $\tan\delta < 0.1$ and neglecting conductor losses.
** Divide $\lambda$ by $(\epsilon')^{\frac{1}{2}}$ where guide is filled with dielectric.
*** Not comparable to characteristic impedance of coax ($\mu = 1$ for most dielectrics).
$\lambda_a$ = free space wave-length.

However, if the wave form of the square wave signal used to modulate the oscillator is properly adjusted so that it reaches maximum value in a very short time and has a flat top or, in other words, approaches an ideal square wave closely, the frequency modulation introduced in this way will be so small that the error in the value of $\Delta x$ will be less than the precision with which this quantity may be measured, because of mechanical limitations in the design of the standing wave detector.

### (4) Errors Due to Faulty Tuning

Changes in the apparent value of the width of the minima have been noted when the wave guide is tuned slightly off resonance. This does not occur when operating with a non-reflecting attenuator and an untuned section of the guide.

### (5) Higher Transmission Modes in the Dielectric

It is possible to have higher modes than the lowest TE mode within the dielectric at the end of the wave guide, even though the wave guide is beyond cut off for those modes in that part of the guide filled with air. The existence of other modes within the dielectric will cause a spurious reflection at the surface of the dielectric and lead to erroneous results in the dielectric constant and dissipation factor.

From the relations in Column 2 of Table I, it can be seen that when a dielectric is present, the wave-length should be longer if only the lowest TE mode is desired. Probably resonant lengths of dielectric samples, i.e., ones which are a multiple of $\frac{1}{4}$ or $\frac{1}{2}$ wave-length (in the sample) for the higher mode, should be avoided, for these lengths are more likely to give the higher modes. The values of $\lambda$ given by the expressions in Column 2 of Table I give the cut off wave-lengths for the next higher modes. From these the wave-length in the guide in the dielectric sample can be calculated for the higher mode of transmission. The effect of higher modes on the accuracy of measurements has not been thoroughly investigated. Care should be taken especially with high dielectric constant materials where the possibility of higher modes is increased. Even with the coax instrument, the possibility of higher modes is prevalent.

period of several years. These results have been reported to interested persons when they requested the information, but have not been contained in any previous report in a tabulation. These data are now collected together with this paper.

The measurements were all made according to the method outlined in this paper, and the dielectric properties calculated according to the scheme outlined in this paper. The results of these measurements are tabulated in Table II along with useful attenuation and reflection constants of these materials for those frequencies.

The values for 10-cm wave-length were obtained on the MIT designed coaxial wave guide instrument (Reference 10) with the same technique in measurement as with the hollow rectangular wave guide.

In some cases, the materials are quite variable in composition, and deviations from the values reported in Table II might be found. In some cases, the dissipation factor and dielectric constant are quite sensitive to moisture. In these cases, the conditions of humidity or dryness of the materials when the samples were measured are given.

## SUMMARY

A method of measurement of the dielectric properties of solids at microwave frequencies has been discussed. A rectangular wave-guide apparatus for performing measurements in the vicinity of 10,000 megacycles has been described in detail. A simplified method of calculating the results of the wave-guide measurements is presented. Included in the paper are values of the dielectric properties of some common plastics and ceramics measured at 10-cm wave-length and 3-cm wave-length.

The authors wish to acknowledge guidance they obtained through the prior and simultaneous work in this field carried out at the laboratory for insulation research at the Massachusetts Institute of Technology under the direction of Professor A. von Hippel. Appreciation is also expressed to members of the Electronics Department of the Westinghouse Research Laboratory, who introduced us to some of the microwave apparatus which we have applied.

# Electron Beam Deflection

## Part II. Applications of the Small-Angle Deflection Theory

R. G. E. Hutter*

(Received February 26, 1947)

The theory developed in Part I is applied to a number of typical deflection fields such as the fields produced by parallel plates, parallel cylinders, semi-infinite co-planar sheets, and bent-plates. Graphs for the magnitude of deflection are given. An electrolytic tank potential-plotting device is described which was used for the determination of the potential distribution of some of the deflection fields.

The theory shows that the deflection is a function of the initial conditions of the electron beam before entering the field and that it is a slightly non-linear function of the field strength. It follows that the fluorescent spot and the pattern produced on the screen of cathode-ray tubes will show distortions. These distortions were calculated for several deflection fields and electron beam shapes; the results are shown graphically.

The problem of the reduction of these distortion effects is discussed.

### A. THE DEFLECTION BY TYPICAL ELECTRIC DEFLECTION FIELDS

ELECTROSTATIC deflection systems are ordinarily designed by experienced personnel. Since no design formulae or charts of reasonable accuracy exist to aid the inexperienced person, he must therefore use the deflection formula for the parallel-plate deflection field without edge effects[1] as a guide. He may then correct the resultant error by adjustment of the deflection potential. This means that deflection amplifiers having a wide gain adjustment must be provided. It is the purpose of this paper to present design charts for a number of typical electric deflection systems.

The paper "Electron Beam Deflection," Part I,[2] contained a mathematical expression for the deflection in terms of the accelerating potential $\phi$ and the axial field-strength distribution $E(z)$ (Part I, Eq. (31)). It is (assuming $x_0=y_0=x_0'=y_0'=0$):

$$d=Y(z_i)=Y_i=-(1/2\phi)\int_{z0}^{z_i}d\zeta\int_{z0}^{\zeta}E(u)du. \quad (1)$$

where $z_0$ is a point on the axis on the entrance side of the deflection field and $z_i$ is the coordinate of the screen position; $z_0$ and $z_i$ are ordinarily in regions where the field-strength of the deflection field is nearly equal to zero. (The deflection electrodes are assumed to be of infinite extent in the $x$ direction.)

If Eq. (1) is used to determine the deflection, the axial field-strength distribution $E(z)$ must be known. Some electrode configurations exist for which $E(z)$ may be determined mathematically. In most cases, this distribution must be obtained by an experimental method, e.g., one which makes use of an electrolytic tank. Electrode systems of the first type are parallel plates with and without fringing fields, parallel cylinders or wires, and semi-infinite co-planar sheets. A field of the second type is that produced by the commonly employed bent-plate electrode system.

Before going into the discussion of these fields it should be mentioned that an alternative method might be used to determine the deflection $d$ by such fields. This method is based on a formula derived by H. G. Rudenberg[3] which expresses the deflection $d$ in terms of the capacitance per unit width of the deflection system. The derivation of this formula may be based on Eq. (30) of Part I for $Y(z)$ which led to Eq. (1). The slope of the electron path is given by (assuming $y_0'=0$)

$$Y'(z)=-(1/2\phi)\int_{z0}^{z}E(u)du=\tan\theta. \quad (2)$$

---

* Sylvania Electric Products, Inc., 34-10 Linden Place, Flushing, New York.

[1] I. G. Maloff and D. W. Epstein, *Electron Optics in Television* (McGraw-Hill Book Company, Inc., New York, 1938), p. 198.

[2] R. G. E. Hutter, J. App. Phys. 18, 740 (1947).

[3] H. G. Rudenberg, J. App. Phys. 16, 279 (1945).

If the field is essentially different from zero only between the axial coordinates $z_1$ and $z_2$, the angle at $z_2$ for small deflection angles will be given by

$$\theta_2 = -(1/2\phi)\int_{z_1}^{z_2} E(u)du. \tag{3}$$

Rudenberg has shown by an application of Gauss' theorem that Eq. (3) is equivalent to

$$\theta_2 = (1/2\phi)\rho\ \epsilon_0,$$

where $\rho$ is that portion of the charge density on the deflection electrodes which is active in producing the deflection, and $\epsilon_0$ is the dielectric constant of free space. The charge density $\rho$, the capacitance $c$ per unit width of the deflecting electrodes, and the deflection potential $\Delta\phi$, are related by

$$\rho = c\cdot\Delta\phi.$$

Hence,

$$\theta_2 = c\Delta\phi/2\phi\epsilon_0. \tag{4}$$

The deflection at the screen becomes

$$d = (z_s - z_2)\cdot\theta_2 = (z_s - z_2)\cdot(c\Delta\phi/2\phi\epsilon_0). \tag{5}$$

For some electrode configurations it is possible to determine the capacitance per unit width mathematically; in most cases this quantity would have to be measured.

It is apparent that both expressions for the deflection $d$ (Eq. (1) and Eq. (5)) will yield the same result if $z_s$ is greater than $z_2$. The formula given by Eq. (5), however, cannot be used to determine the deflection at the coordinate of the exit side of the electrode configuration because of the contribution of the fringing field on that side of the electrodes to the value of the capacitance $c$. The magnitude of the deflection at that point is important in deciding the question of whether or not an electron beam hits the electrodes. It may be determined by means of Eq. (1).

FIG. 1. The parallel-plate deflection field.

## 1. Mathematically Obtained Field Distributions

### a. *Parallel Plates without Fringing Effects*

The field that can most easily be treated mathematically is an idealized one which, however, cannot be produced in practice if the electrodes are of finite length. It is that between two parallel plates which are at the potentials $\phi+\frac{1}{2}\Delta\phi$ and $\phi-\frac{1}{2}\Delta\phi$. The geometry of this field is shown in Fig. 1. The idealization is expressed by making the following assumption regarding the field-strength distribution:

$$E(z) = \left\{\begin{array}{lll} 0 & \text{For} & z<z_1, \\ -\Delta\phi/h & \text{For} & z_1 \leqq z \leqq z_2, \\ 0 & \text{For} & z>z_2. \end{array}\right\} \tag{6}$$

If $E(z)$ of Eq. (6) is substituted in Eq. (1), one obtains the familiar formula

$$d = (\Delta\phi/2\phi)(1/h)L(D+\tfrac{1}{2}L), \tag{7}$$

where $z_2 - z_1 = L$, $z_s - z_2 = D$, $h$ is the distance between the electrodes, $\phi$ is the accelerating potential (potential of the last anode) and $\Delta\phi$ is the potential difference between the electrodes.

Because of the idealization of the field-strength distribution, large errors occur if Eq. (7) is applied to actual parallel-plate deflection systems.

### b. *Parallel Plates with Fringing Effects*

An application of the Schwartz transformation of the theory of functions of a complex variable yields an expression for the equipotential distribution at the edge of semi-infinite parallel plates.[4] It is, therefore, possible to obtain a mathematical expression for the axial field-strength distribution of such an edge field. In order to obtain the axial field-strength distribution of parallel plates of finite length two expressions for a single edge may be used. If the axial coordinates of the entrance and exit edge of the parallel plates are given by $z_1$ and $z_2$, respectively (Fig. 1), the axial field strength may be written as:

$$E(z) = -(\Delta\phi/h)(1/1+r), \tag{8}$$

where $r$ is given in terms of the axial coordinate

---

[4] R. Rothe, F. Ollendorff and K. Pohlhausen, *Theory of Functions* (Technology Press, Massachusetts Institute of Technology, Cambridge, 1942), p. 138.

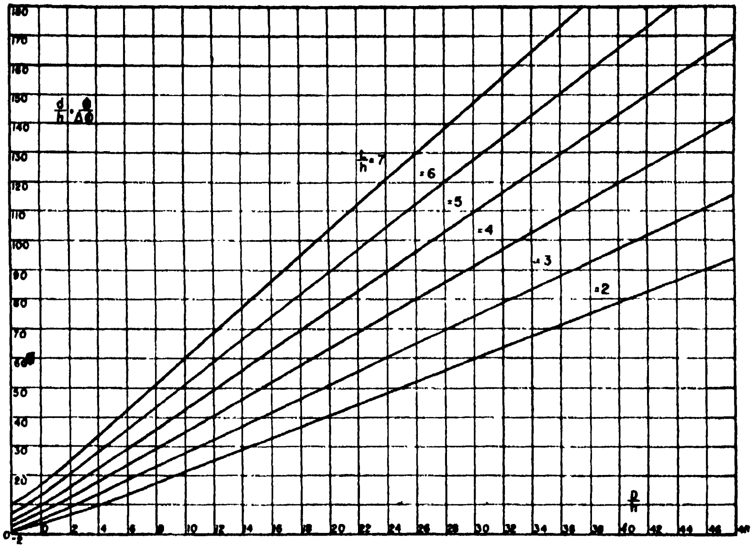

FIG. 2. The deflection by parallel plates (I form).

by:

$$\left.\begin{aligned} z&=z_1+h/2\pi[1+r+\ln r] \\ &\qquad\text{For}\quad -\infty<z\leqq z_1+z_2/2, \\ z&=z_2-(h/2\pi)[1+r+\ln r] \\ &\qquad\text{For}\quad z_1+z_2/2\leqq z<+\infty. \end{aligned}\right\} \quad (9)$$

Measurements have shown that Eqs. (8) and (9) describe the axial field-strength distribution well for plates for which the field strength $E(z)$ is very nearly $-\Delta\phi/h$ at $z=\frac{1}{2}(z_1+z_2)$. This was found to be the case for parallel plates with ratios of $L/h$ larger than two.

The integration indicated by Eq. (1) must be performed in two steps corresponding to the two branches of the axial field-strength distribution. The resultant mathematical expression for the deflection is unwieldy, hence the deflection is better presented in the form of a graph. Any quantity except $h$ can easily be determined from Fig. 2 if the other quantities are known. It is possible to replot the graph and obtain a new one (Fig. 3) which permits the determination of $h$ with ease if the other quantities are known.

### c. *Parallel Cylinders or Wires*

The method of conformal mapping yields in this case a mathematical expression for the axial field distribution.[5] The geometry is shown in Fig. 4. With the notation explained in this figure, the axial field-strength distribution becomes

$$E(z)=\frac{2\Delta\phi}{cq/2}\cdot\frac{1}{\ln\dfrac{1+q}{1-q}}\cdot\frac{1}{1+\left(\dfrac{z}{cq/2}\right)^2}. \quad (10)$$

Substituting Eq. (10) in Eq. (1), the deflection $d$ is given by

$$d=\frac{\Delta\phi}{\phi}\cdot\frac{cq}{2}\cdot\frac{1}{\ln\dfrac{1+q}{1-q}}\left[\frac{z_i}{\dfrac{cq}{2}}\arctan\frac{\dfrac{z_i}{cq/2}-\dfrac{z_0}{cq/2}}{1+\dfrac{z_iz_0}{(cq/2)^2}}+\frac{1}{2}\ln\frac{1+\left(\dfrac{z_0}{cq/2}\right)^2}{1+\left(\dfrac{z_i}{cq/2}\right)^2}\right], \quad (11)$$

which is shown graphically in Fig. 5. $[z_0/(cq/2)]$ was assumed to be equal to $-30$. At this point $E\cong(1/900)E(0)$.

This deflection field was discussed by G. Rudenberg.[3]

### d. *Semi-Infinite Co-planar Sheets*

Another field for which the axial field-strength distribution may be determined accurately by the method of conformal mapping is that produced

[5] K. Kupfmüller, *Einführung in die Theoretische Elektrotechnik* (Julius Springer Verlag, Berlin, 1932), p. 71.

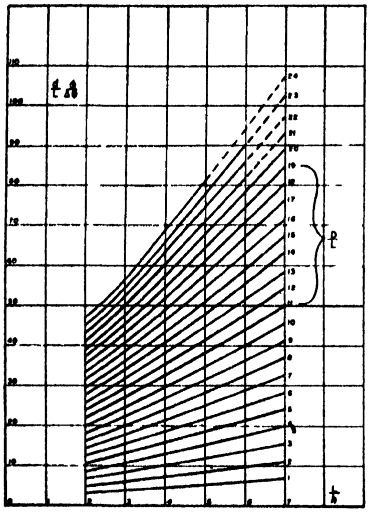

FIG. 3. The deflection by parallel plates (2 form).

by two semi-infinite co-planar sheets.[6] The geometry is shown in Fig. 6. With the use of the notation indicated in this figure, the axial field-strength distribution becomes

$$E(z)=(1/\pi)\Delta\phi(1/a)1\bigg/\left[1+\left(\frac{z}{a}\right)^2\right]^{\frac{1}{2}}. \qquad (12)$$

The deflection is then given by

$$d=\frac{a\,\Delta\phi}{2\,\pi\phi}\left\{\frac{z_i}{a}\ln\frac{z_i/a+[1+(z_i/a)^2]^{\frac{1}{2}}}{z_0/a+[1+(z_0/a)^2]^{\frac{1}{2}}}-\left(\frac{z_i}{a}-\frac{z_0}{a}\right)-\left(\frac{1}{z_i/a+[1+(z_i/a)^2]^{\frac{1}{2}}}-\frac{1}{z_0/a+[1+(z_0/a)^2]^{\frac{1}{2}}}\right)\right\}. \qquad (13)$$

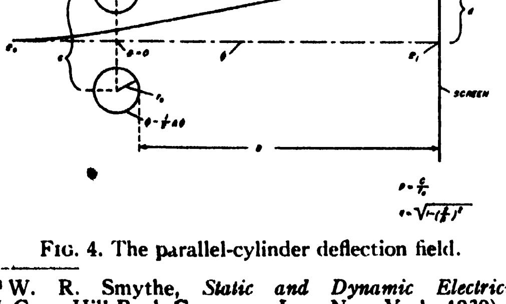

FIG. 4. The parallel-cylinder deflection field.

This expression is shown graphically in Fig. 7. $z_0/a$ was assumed to be equal to $-900$. At this point $E\cong(1/900)E(0)$.

## 2. An Experimental Method to Determine the Field Distribution

In general, it is not possible to determine the axial field distribution mathematically. It may, however, be determined experimentally with sufficient accuracy by means of an electrolytic tank. This instrument is useful in many electron-optical investigations and is available in many electronic laboratories in one form or another.

The theory underlying the use of the tank has been presented many times in the literature[7, 8] and will, therefore, not be repeated here. The following paragraphs will give a brief description of the instrument, developed in the Research Laboratories of Sylvania Electric Products, Inc., and its application to a number of problems of deflection systems.

### a. *The Electrolytic Tank Potential-Plotting Apparatus.*

Figure 8 is a photograph of the entire set-up which consists of two electrolytic tanks ($T_1$, $T_2$), a plotting board ($B$), an instrument rack (I.R.), a plotting mechanism, and an arrangement for positioning the electrodes to be investigated.

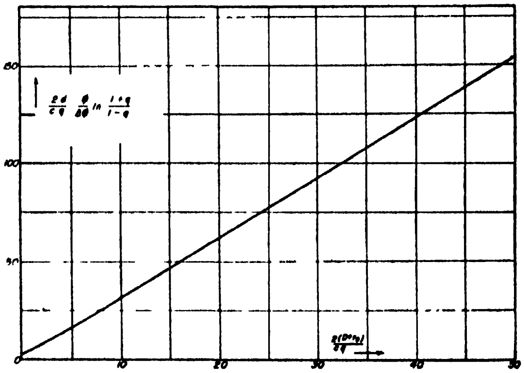

FIG. 5. The deflection by parallel cylinders $\left(z_0/(cq/2)=-30,\ E\left(\frac{z_0}{cq/2}\right)\cong\frac{1}{900}E(0)\right)$.

[8] V. K. Zworykin, G. A. Morton, E. G. Ramberg, J. Hillier, and A. W. Vance, *Electron Optics and the Electron Microscope* (John Wiley and Sons, Inc., New York, 1946), p. 389.

These tanks are constructed of lava slabs; the inside dimensions of tank $T_1$ are 30″×30″×60″, and 5″×30″×30″ for tank $T_2$. Ordinary tap water is used as the electrolyte in tank $T_2$, while deionized water is used in tank $T_1$. The plotting mechanism consists of two rails (R.R.) extending the full length of both tanks. A carriage $C_1$ is provided which travels on the rails R.R., and is provided with another pair of rails r.r., at right angles to R.R., upon which is mounted a second carriage $C_2$. The second carriage carries the probe ($P$) and a long beam member ($b$) which holds the stylus ($S$). A close-up view of the tank $T_2$ and the components $C_2$, $b$, and $P$ is shown in the photographs, Fig. 9. The probe is a 5-mil platinum wire which is sealed into one end of a glass tube which is enclosed in a metal tube for shielding purposes. The probe may be brought to any point on the water surfaces of either of the two tanks by turning two hand wheels which operate—through gears—the motion of both carriages. Stylus and probe are rigidly connected and trace out identical curves. Figure 9 also shows a larger sized view of the electrode holders. The electrodes under investigation (in Fig. 8—two bent plates) are supported by adjustable arms (L.L.) which slide on two flat rails ($R_1$, $R_2$). The heads (H.H.) of the support mechanism can be tilted in two directions and the electrodes can be adjusted in the vertical direction. The instrument rack (I.R.) above the tanks holds three units: the potential source ($O$), a single vacuum-tube voltmeter (VTVM), and a unit comprising 5 vacuum-tube voltmeters (5 VTVM's). The potential source is a 500 cycle/sec. resistance-capacitance oscillator which provides a signal of about 50 volts r.m.s. across 500 ohms without distortion of the wave shape. The circuits of all six vacuum-tube voltmeters are alike, the circuit diagram being shown in Fig. 10. The meter reads zero if the signal from the probe is equal to the potential across the calibrated potentiometer.

A block diagram of the complete wiring circuit is shown in Fig. 11. The writing pen is operated electromagnetically from a push button near the hand wheels on the carriage $C_1$.

### b. *Procedure and Measurements*

The large tank, $T_1$, may be used for the study of focusing fields or for the determination of axial field-strength distribution of deflection fields which are not of infinite length in any direction. The shallow tank, $T_2$ is convenient for the investigation of two-dimensional electric fields. The problem of determining the axial field-strength distribution, $E$, for a given electrode system may be solved by measuring two equipotential lines near the axis. The field strength, $E(z)$, is computed as the ratio of the potential difference between the lines to the distance between them at every point $z$. A comparison between mathematical and experimental results is shown in Fig. 12 for the case of two parallel cylinders; the agreement is quite satisfactory. The same tank can also be used for the inverse problem of determining electrode shapes producing a prescribed field-strength distribution $E(z)$. By means of Eq. (20), Part I,[2] two equipotential lines near the axis are computed. The convergence of the series is generally good for small values of $y$. Then the five probes—connected to the unit consisting of five VTVM's—are placed in the tank along the computed equipotential line, and the electrode shapes varied

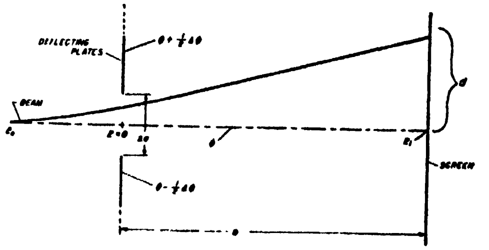

FIG. 6. The semi-infinite co-planar-sheet deflection field.

FIG. 8. Potential-plotting tank (Sylvania Electric Products, Inc.).

until all five meters read the potential value of the line simultaneously.

In order to increase the versatility of the tank set-up, an arrangement $T$ tilts the tank $T_2$, thus producing a wedge-shaped volume of electrolyte. In this manner the tank may be used to investigate so-called "Pierce-guns."[9] The five VTVM's are employed to measure the potential distribution along the edge of the electron beam, which is, in this case, represented by an insulator shaped in the form of the desired beam.

### 3. Bent-Plate Deflection Systems

The axial field-strength distributions of a number of bent-plate deflection systems were measured in the manner described in Section 2-b. The geometry of the electrodes and the notation are shown in Fig. 13. The parameters $L_1/h$, $L_2/L_1$, and $\theta$ were chosen to cover a range sufficient to compute the deflection for other values than those for which the graphs are given by interpolation. The integrations according to Eq. (1) were performed by means of a planimeter and the results are plotted in Figs. 14 and 15.

## B. DEFOCUSING AND DISTORTION EFFECTS OF TYPICAL ELECTRIC AND MAGNETIC DEFLECTION FIELDS

Crossed deflection fields, as used in cathode-ray and television tubes, produce undesirable effects of two kinds. One is the beam deformation causing a change in size and shape of the luminous spot on the fluorescent screen of the tube. The other is the distortion of the "pattern." The "pattern" may be the rectangular scanning pattern of the television tube or a Lissajou figure on the screen of a cathode-ray tube in an oscilloscope. Many factors may contribute, and usually do, to the pattern distortion. Only one of these will be investigated here, namely that due to the electric or magnetic field distribution. Discussion of other factors, such as wave-shape of driving circuits, frequency response of the amplifiers, coupling between circuits, or coils of the magnetic deflection yoke, etc., will be omitted.

Idealizations concerning the electron beam and the focusing system mentioned in Part I[2] will be used here.

This method of investigation permits one to distinguish defects caused by the deflection fields from those caused by other components of the device employing such fields. It then becomes possible to attribute a certain observed defect to the proper component.

There are a number of elementary explanations for the mechanism of both types of defects. All of them are qualitative in nature with one exception—that of electron-ray tracing. The electron trajectory through a given potential or field-strength plot is determined by means of numerical or graphical methods of integration. However, unless this method is used with extreme care, the results are not very reliable. In the language of this work, the deflection of an electron at the screen must be determined accurately to distances which are small compared with the quantities here called $\Delta x_i$ and $\Delta y_i$, which in turn are

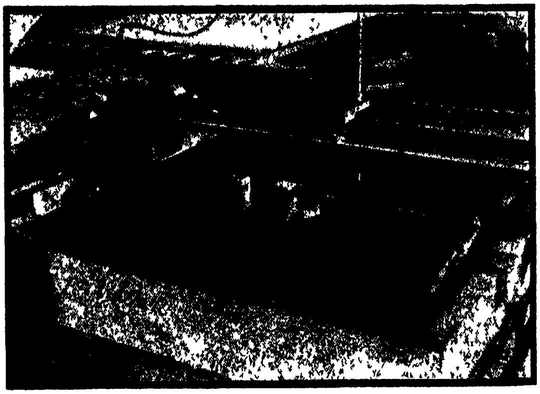

FIG. 9. Partial view of potential-plotting tank.

---

[9] J. R. Pierce, J. App. Phys. 2, 548 (1940).

small compared with the first-order deflection $Y(z_i)$. In order to achieve this accuracy it is necessary to proceed in very small steps in the determination of the trajectory, increasing the amount of numerical work considerably and requiring a very accurate equipotential line or field-strength plot. Furthermore, it is difficult to apply this method to initially deflected electrons and to magnetic deflection fields. In the search for better deflection fields only qualitative hints, at best, were obtained.

The theoretical procedure outlined in Part I, Section 2[2], avoids the difficulties mentioned above. It will now be applied to a number of special deflection fields.

### 1. Special Electric Deflection Fields

The electric deflection fields discussed in this section are those produced by parallel plates (including the fringing fields), parallel cylinders, and bent plates. A comparison of the defocusing and distortion effects of these fields is of interest. In order to make such a comparison it will be necessary that some basis be chosen upon which to compare the defects which are the functions of the accelerating potential $\phi$, the deflection potential $\Delta\phi$, the electrode-to-screen distance, the deflection $d$, and the geometry of the deflection electrodes which determines the axial field-strength distribution $E(z)$. It is possible to formulate various bases of comparison. One way, for instance, requires that the potentials $\phi$ and $\Delta\phi$, the deflection $d$, the distance from the exit side of the electrodes to the screen, and the minimum separation between the electrodes should be the same for otherwise different fields which are being compared. This basis was chosen for the examples discussed below. A better basis might be the following which also requires that $\phi$, $\Delta\phi$, and $d$ should be the same, but which replaces the before-mentioned condition concerning the electrode-to-screen distance and electrode separation by another one. The field-strength distribution will ordinarily be such that $E(z) < E_{\max}/n$ for all axial coordinates $z$ smaller than a value $z_2$ and larger than a value $z_1$, where $n$ may be arbitrarily chosen, so that one could say that the essential part of $E(z)$ lies between the coordinates $z_1$ and $z_2$ (e.g. $n$ a value between 10 and 100). Fields may then be compared for which $\phi$, $\Delta\phi$, $d$, $z_2 - z_1 = L$, and $z_i - z_2$ are the same. Again, keeping $\phi$, $\Delta\phi$, and $d$ equal, fields produced by electrodes occupying a given volume may be compared. The choice of a basis is, therefore, arbitrary and should be made to suit one's particular requirements.

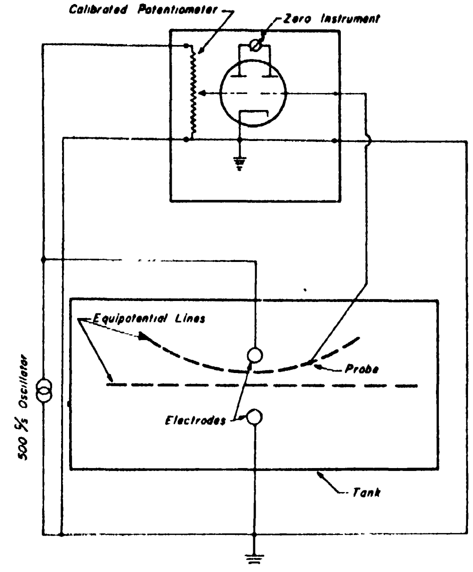

FIG. 11. Block diagram of electrical circuit.

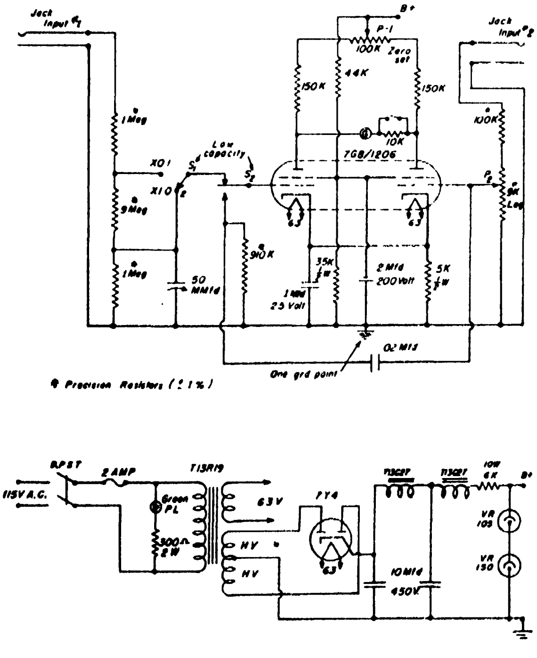

FIG. 10. Circuit diagram of the vacuum-tube voltmeter.

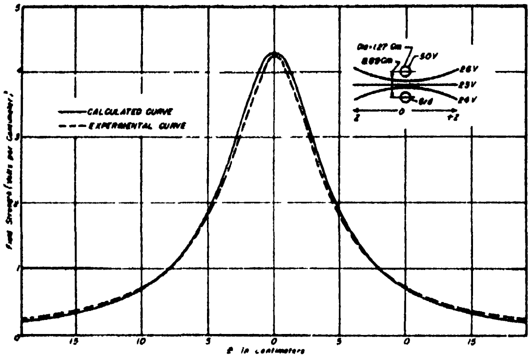

Fig. 12. Comparison between a measured and a computed axial field-strength distribution (parallel-cylinder deflection field).

Figure 16 shows the electrode geometry of three two-dimensional electric deflection fields whose defocusing and distortion effects were computed. This figure shows that the minimum distance between deflecting electrodes was kept nearly the same in all three cases.

Figure 17 shows the spot distortion for the case of a cylindrical beam whose diameter was assumed to be 0.08 inch. The figures show the focusing effect of the deflection field, demonstrating the statement[2] made that electron prisms are always joined to weak cylinder lenses.

Figure 18 shows pattern and spot distortions of a conical beam produced by parallel-plate and parallel-cylinder deflection fields. The deflections were assumed to be those produced by electrodes of dimensions shown in Fig. 16, the horizontal deflection fields preceding the vertical ones. The horizontal deflection potential could be reduced to $\Delta\phi = 140$ volts for a 2.5-inch deflection due to the larger electrode-to-screen distance. The electrode-to-electrode spacings of the horizontal and vertical fields in the axial direction were one inch for the parallel plates and 0.266 inch for the parallel cylinders. The diameter of the conical beam before entering the fields was 0.08 inch, and the apex of the cone was at the center of the fluorescent screen when undeflected. It should be mentioned that the calculations of spot and pattern distortion take into account the defocusing which is caused by a flat screen.

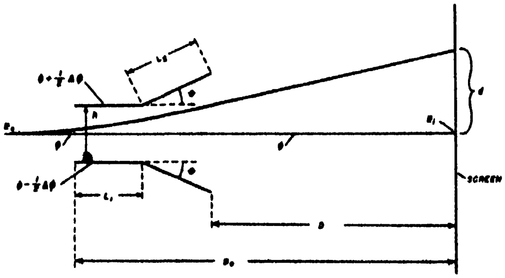

Fig. 13. The bent-plate deflection field.

In the cases investigated so far, it was assumed that perfect alignment of the focusing and deflection systems existed. The distortion figures were therefore mirror-symmetrical with respect to the $x_i$ and $y_i$ axes. In actual tubes, distortions of the spot are observed which do not show this type of symmetry. It was thought that some kind of misalignment of gun and deflection system might be the cause of this. Calculations were made assuming the circumference of the electron beam at $z_0$ to satisfy the equation

$$(x_0-r_b)^2+(y_0-r_b)^2=r_b^2,$$

with $r_b$ again equal to 0.04 inch. The beam was point-focused at the center of the screen. The resulting pattern and spot distortions are shown in Fig. 19 for the case of the parallel-plate field. The distorted spots are shown as little polygons, the corners of which are the points on the circumference of the beam for which the $\Delta x_i$ and $\Delta y_i$ were determined. Actually, the corners will appear rounded off.

### a. *The Parallel-Cylinder Deflection Field*

Most electrically deflected cathode-ray and television tubes use either parallel or bent plates as deflection electrodes. A discussion of such fields with regard to the change of their defocusing effects with the electrode geometry would require many tables. Instead, a textbook-type of example of a deflection field will be discussed here in greater detail. It is that of the parallel cylinders or wires, which was suggested for use where electron transit time and capacitive-shunting effects begin to influence the operation of a cathode-ray tube.[3] It is possible to describe the defocusing effects of parallel-cylinder deflection fields with one set of reduced distortion coefficients for all radii and distances between the wires. These coefficients are given in Table I for various reduced screen distances $[z_i/(cq/2)]$. For

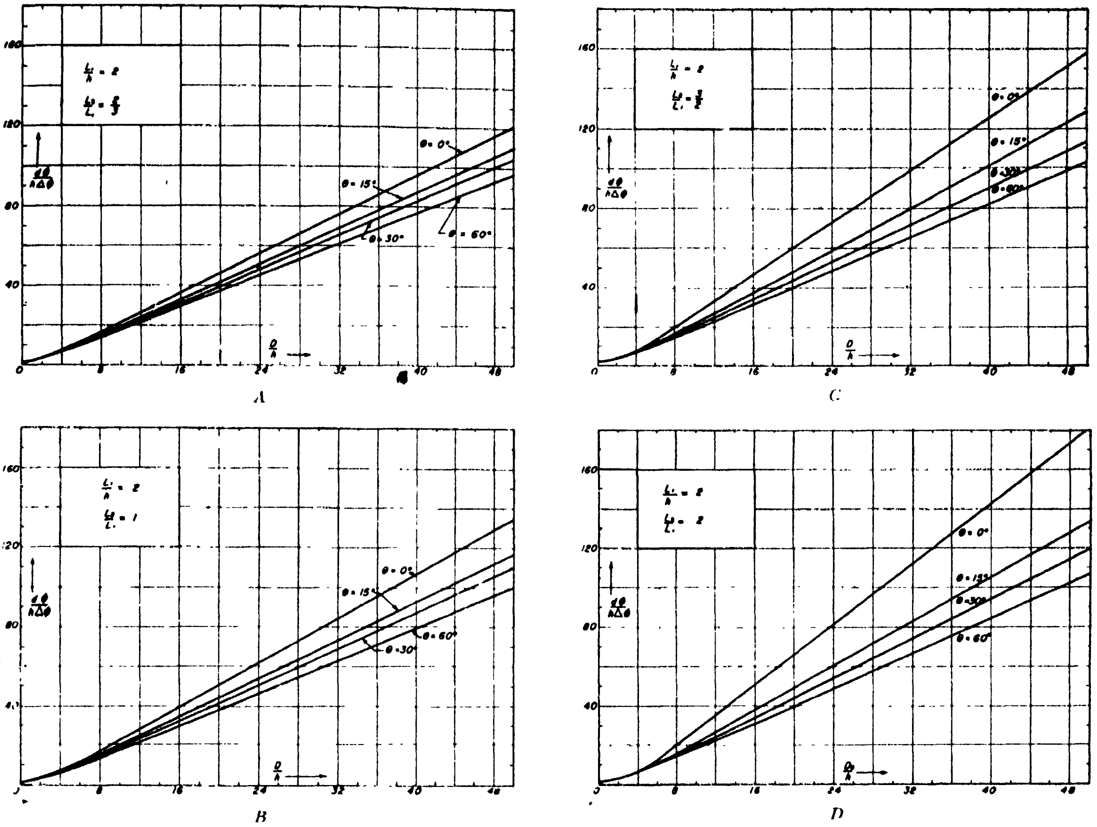

FIG. 14. The deflection by bent plates $A$, $B$, $C$, $D$.

large values of $[z_i/(cq/2)]$ some coefficients are straight lines on linear graph paper, others on logarithmic paper which simplifies the problem of extrapolation.

The notation is the same as was used in Part I.[2] Here $c$ is the center-to-center distance between the cylinders which have the radius $r_0$, and $z_i$ is the distance from the center-to-center plane to the fluorescent screen; $z_0$ is the axial coordinate of a point where the field strength is relatively small compared with that of the maximum at $z=0$. The quantity $(z_0/(cq/2)]$ was chosen as $-30$, i.e.,

$$E_{z0}=(1/901)E_{\max}.$$

The use of the Table to determine a coefficient is simple. As an illustration, one may take

$$\beta_{0000}=\{-31.48\epsilon^3+334.34\epsilon^5-1773.69\epsilon^7\}\cdot c\cdot q,$$

for

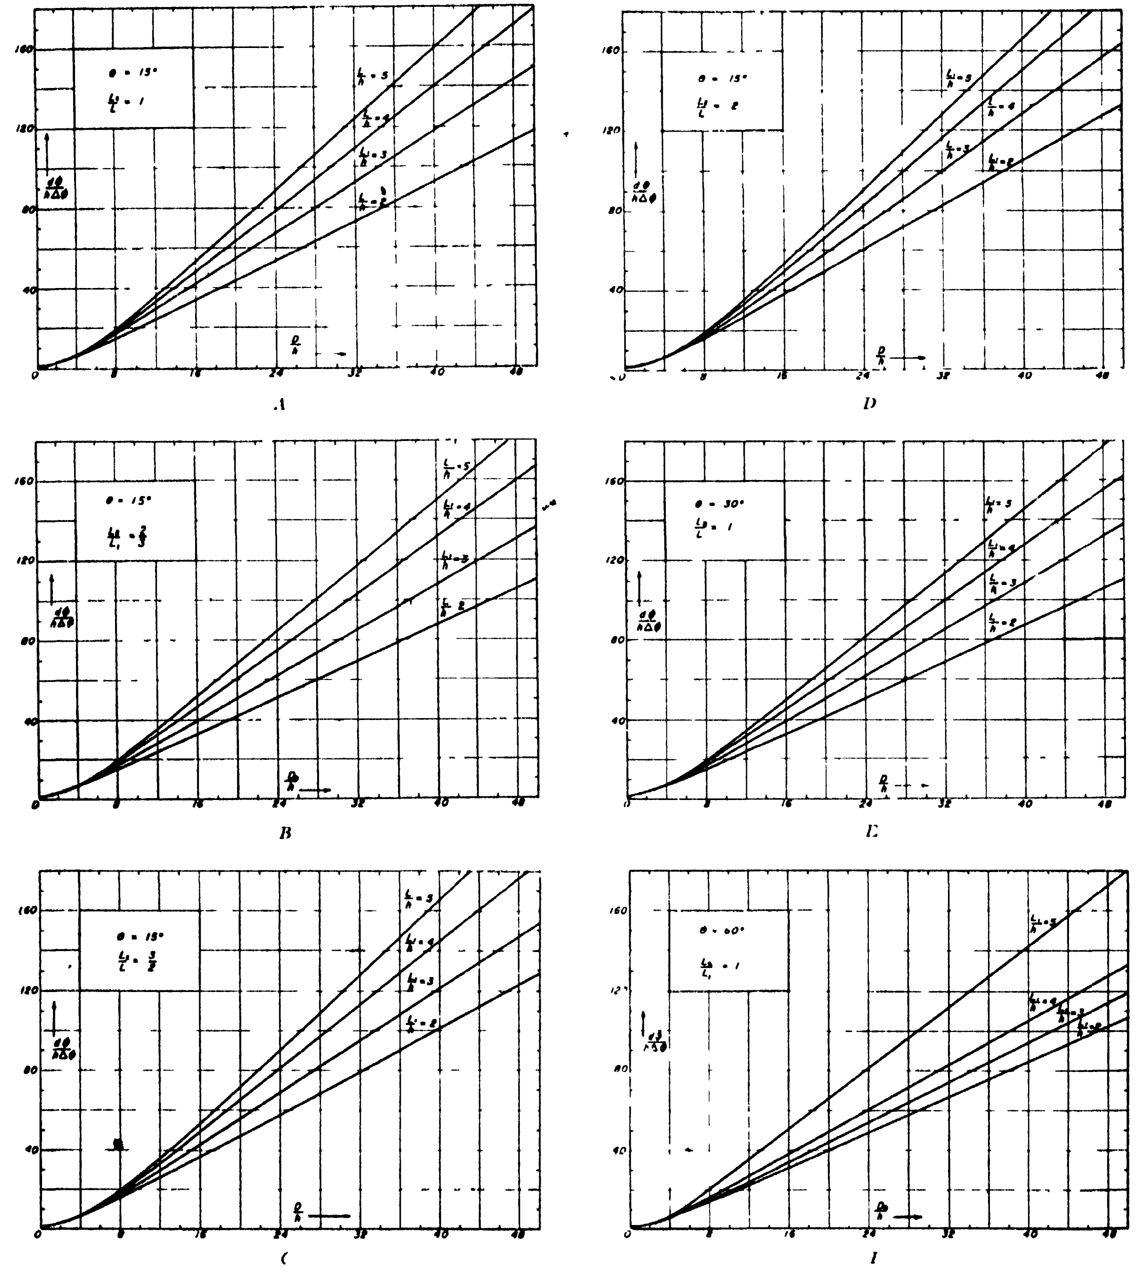
$$2(z_i/cq)=30.$$

The deflection field for the parallel cylinders had the following dimensions: $c=.178''+2\cdot r_0$, $r_0=.598''$, $\Delta\phi=173\,V$, $\phi=2000\,V$, $z_i=10.198''$, and $Y_i=2.5''$. If the minimum distance between the surfaces of the cylinders is kept fixed (0.178″) and the radius is varied in steps from $r_0=.0565''$ to $r_0=23.3''$, the half-width of the field-strength curve ($cq=c[1-(2r_0/c)^2]^{\frac{1}{2}}$) varies between 0.268″ and 4.08″. In order to keep the deflection constant at $Y_i=2.5''$, the deflection potential $\Delta\phi$ will be decreased with increasing value of $r_0$. Keeping the beam dimension the same as in the example shown in Fig. 16, it is found that the aberration coefficients $\alpha_{0010}$, $\beta_{0000}$, $\beta_{0100}$, $\beta_{0001}$, $\beta_{0002}$ decrease rapidly with increasing $r_0$, while $\beta_{0020}$ remains constant over the range of values for $r_0$ given above.

Instead of keeping the distance between the cylinders constant and varying the deflection sensitivity, the latter may be kept fixed and the distance between the cylinders varied, hence

$\Delta\phi$, $\phi$, $z_t$, $V_t$ are kept constant. The larger distance then corresponds to the larger radius. A computation of the distortion coefficients shows that the defocusing effects become less with increasing radius. Similar considerations can be applied to other electrode systems, i.e., if all dimensions except the distances $z_t$ and $V_t$ are multiplied by an arbitrary factor, an improvement of the defocusing effects is obtained. (See paragraph 2.)

It becomes apparent that it is difficult to compare the defocusing effects of different types of electrode systems. It is necessary to introduce assumptions concerning the actual physical size



A D

B E

C F

Fig. 15. The deflection by bent plates *A*, *B*, *C*, *D*, *E*, *F*.

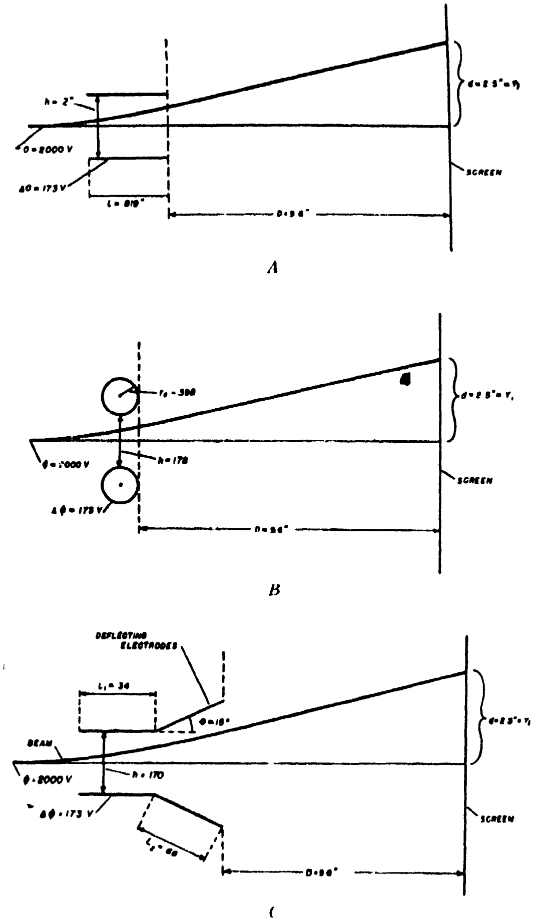


FIG. 16. The geometry of three two-dimensional electric deflection fields.

of the electrodes which are being compared; such assumptions are hard to formulate for electrodes of different shapes.

### b. *A Magnetic Deflection Field*

Pattern and spot distortion were also computed for a special magnetic deflection field. The axial field distributions of the two crossed fields were assumed to be of the form

$$H_x{}^v = -\frac{H_m}{1+(z/b)^2+(y/a)^2},$$

$$H_y{}^h = \frac{H_m}{1+(z/b)^2+(x/a)^2}.$$

The superscripts $v$ and $h$ indicate the vertical and horizontal fields, respectively. The assumption about $H_x{}^v$ means that the field-strength distribution of the $x$ component is a bell-shaped function with a half-width of $2b$ along the $z$ axis and a half-width of $2a$ along the $y$ axis. The half-width in any other direction $y=cz$ in the $(y, z)$ plane will be $[2ab(1+c^2)^{1/2}]/[(a^2+c^2b^2)^{1/2}]$. This half-width is measured in terms of the coordinate $w=(z^2+y^2)^{1/2}=z(1+c^2)^{1/2}$ along the line $y=cz$. A similar interpretation holds for the horizontal deflection field for $H_y{}^h$ in the $(x, z)$ plane. Pole pieces or coil arrangements producing exactly such a distribution were not determined. The magnetic field everywhere else in space is uniquely determined. The functions $V_0$, $V_2$, $H_0$, $H_2$ of the series expressions for the components of $\vec{H}$ (see Part I[2] Eq. (55)) may be determined by expanding $H_x{}^v$ and $H_y{}^h$ in the manner shown for $H_x{}^v$:

$$H_x{}^v = -H_m\left\{\frac{1}{1+(z/b)^2} - \frac{1}{a^2}\frac{1}{[1+(z/b)^2]^2}y^2 - + \cdots\right\}.$$

Hence

$$V_0 = H_m/1+(z/b)^2,$$

$$V_2 = -1/a^2[H_m]/[1+(z/b)^2]^2,$$

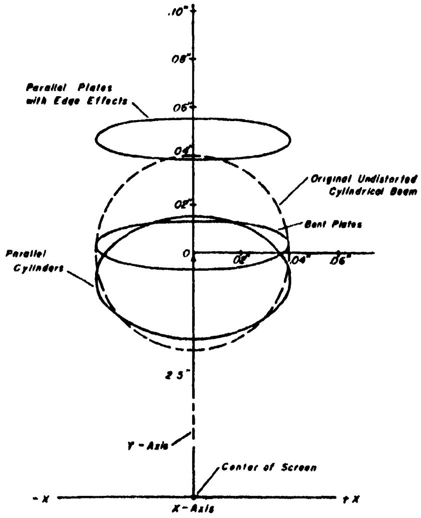

FIG. 17. The spot distortions by three two-dimensional electric deflection fields. (The electrode geometry of these fields is shown in Fig. 1.)

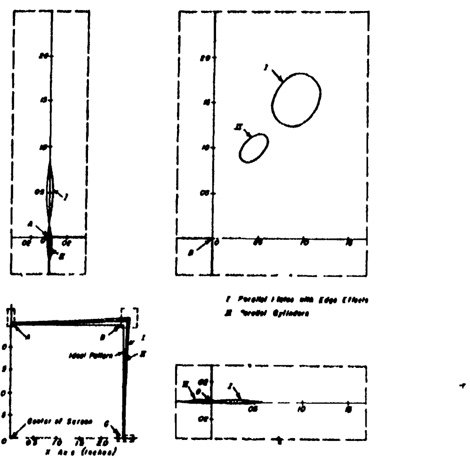

FIG. 18. Pattern and spot distortions by two special crossed electric deflection fields (The electrode geometry and the shape and dimensions of the electron beam are described in the text.)

and similarly for $H_0$, $H_2$

$$H_0 = H_m/1+(z/b)^2,$$

$$H_2 = -1/a^2[H_m]/[1+(z/b)^2]^2.$$

The distortions are shown in Fig. 20 for the following set of parameters: $\phi = 2000$ v, $H_m = 35.4$ gauss, $b = 0.34''$, $z_s = 10.198''$, $z_s/b = 30$, and two values of $a$, namely, $a_1 = 1.36''$, $a_2 = 0.68''$. The maximum deflections on the screen were $d_v = 2.5''$, $d_h = 2.5''$. The electron beam was assumed to be of cylindrical shape with $r_b = 0.04$ inch.

It can be seen from these graphs that the spot distortion increases if the half-width of the field-strength distribution curve, which is in the direction of deflection, is decreased. For very small half-widths, $2a$, the defocusing quantities $\Delta x$, $\Delta y$ become so large that the aberration theory can no longer be applied. A condition similar to that for electrostatic fields Eq. (27) Part I[2] could be formulated for magnetic fields. It is this condition which is violated by allowing $2a$ to become too small.

The graph also shows an elongation of the spot in the direction of the deflection at the corner points of the pattern. This is surprising when compared with the action of one single magnetic field for which an over-focusing is observed in the direction of deflection. A single vertical deflection field over-focuses because the upper edge of the beam passes through weaker portions of the field than does the lower part of the beam. An explanation of the under-focusing of two crossed fields is found when it is discovered that the field-strength function along the line of deflection, $y = x$, $z = 0$, is saddle-shaped, hence causing the outer portions of the beam to pass through stronger fields than the inner parts.

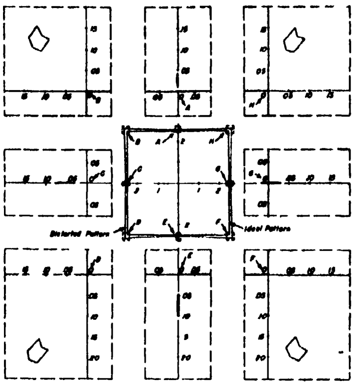

FIG. 19. Pattern and spot distortions by a special parallel-plate field (Electron gun and deflection system were assumed to be misaligned. The electron beam was assumed to point-focus at the center of the screen.)

## 2. *The Problem of Reducing the Defocusing Effects*

At this time only an outline of a method can be given which might lead to deflection fields with less defocusing and distortion.

Each of the coefficients $\alpha_{abcd}$ and $\beta_{abcd}$ determines a characteristic distortion. It was found that $\alpha_{0010}$, $\beta_{0000}$, $\beta_{0020}$ are the important coefficients which determine pattern distortion, while $\beta_{0100}$, $\beta_{0001}$, $\beta_{0002}$ are of primary importance in describing the spot distortion produced by electric deflection fields. It is, therefore, unnecessary to graph every distortion since the magnitude of the coefficients gives the information.

These coefficients may be computed for a number of different fields. A comparison will show which of these is the best so far as they concern defocusing effects. One can then proceed to modify the axial distribution of this field in order to obtain another, having smaller distortion coefficients. The form of the coefficients reveals the "direction" of modification.

The field-strength function obtained in such manner determines the proper configuration of the deflection electrodes or magnets. In case of electric deflection fields, this problem may be solved relatively easily; it is a difficult one in the case of magnetic fields.

In routine design work the method just outlined will not be of much help and is carried out more properly by the development and research groups. A paper written by H. Moss[10] states a theorem which "is of fundamental importance in the design of all-electrostatic cathode ray tubes, since it indicates a general method by which the beam width, and therefore the spot density, can be increased, without an increase in deflection defocusing. Large deflectors and a large neck diameter to accommodate them are used." This theorem reads:

TABLE I. Distortion coefficients of the parallel-cylinder deflection field.

$$\left[\epsilon=\frac{\Delta\phi}{\phi}\,\frac{1}{\ln(1+q/1-q)}\right].$$

| Coefficient | $[z_i/(cq/2)]=5$ | $[z_i/(cq/2)]=10$ | $[z_i/(cq/2)]=20$ | $[z_i/(cq/2)]=30$ | Factor |

"If the beam width and scale of the whole deflectors (including their spacing) are multiplied by $k$, then the increase of spot size on deflection through a constant angle is unchanged, provided the distance between the screen and the center of deflection is also unchanged."

The proof of this theorem was based on theories of scale, energy, dimensional homogeneity, and experiment. A more rigorous proof showing at the same time some limitations of the scaling process can be based on the theory developed here.

Consider a point-focused (conical) electron beam. The defocusing effects will be given to a first approximation by

$$\Delta y_i=\beta_{0000}+\beta_{0001}y_{iu}'.$$

If *all* dimensions are now increased by a factor $k$ (keeping all potentials constant), the deflection $d$ will very nearly increase by this factor $k$ as long as the electrode-to-screen distance is sufficiently large. The coefficients $\beta_{0000}$ and $\beta_{0001}$ will also increase by the same factor and, since $y_{iu}'$ remains unchanged, $\Delta y_i$ will increase to $k\cdot\Delta y_i$. If the screen is now brought back to its original

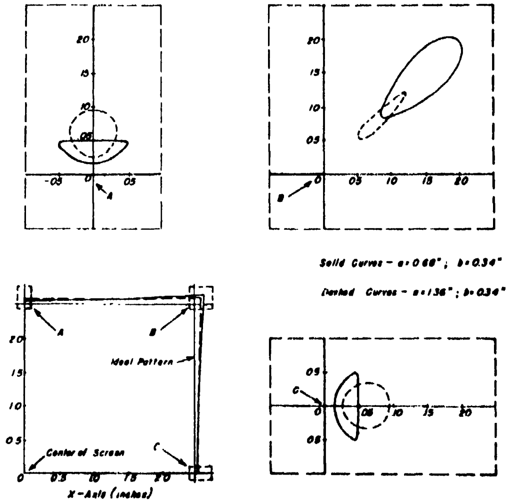

FIG. 20. Pattern and spot distortions by a special pair of crossed magnetic fields. (The fields are given by: $H_x^v=-\frac{H_m}{1+(z/b)^2+(y/b)^2}$, $H_y^h=\frac{H_m}{1+(z/b)^2+(x/a)^2}$)

---

[10] H. Moss, J. Tel. Soc. 4, 206 (1946).

position and the electron beam is refocused to a point at the center of the screen, the deflection will again be equal to $d$. The angle $y_{iu}'$, however, will be $k$ times its original value (for small angles). An inspection of the coefficients $\beta_{0000}$ and $\beta_{0001}$ shows that $\beta_{0000}$ is a linear function of the electrode-to-screen distance, while $\beta_{0001}$ is a quadratic function of this distance (for large electrode-to-screen distances). Decreasing the electrode-to-screen distance restores, therefore, $\beta_{0000}$ to its original value. Since $\beta_{0001}$ increased to $k$ times its original value, and since $\beta_{0001}$ is a quadratic function of the electrode-to-screen distance, $\beta_{0001}\cdot y_{iu}'$ will reduce to its original value when this distance is decreased to its original value. Hence $\Delta y_i$ has the original value.

## ACKNOWLEDGMENT

I would like to thank Mr. L. H. McKee for his assistance in the experimental work, and Miss Gloria Glaston and Mrs. Shirley Harrison for their help with the computations. I also would like to thank Dr. R. M. Bowie, Manager of Research of the Sylvania Electric Products Research Laboratory, for helpful discussions and constant encouragement in our work.

# A 70-Mev Synchrotron

F. R. Elder, A. M. Gurewitsch, R. V. Langmuir, and H. C. Pollock
*Research Laboratory, General Electric Company, Schenectady, New York*

(Received April 22, 1947)

A synchrotron for the production of 70-Mev x-rays has been built and tested. The general mode of operation, and various features of its design and construction, are discussed. Some preliminary information on the characteristics of the electron and x-ray beams is included. This work has been supported by the Office of Naval Research.

## I. INTRODUCTION

Soon after the synchrotron principle was proposed by Veksler[1, 2] and McMillan[3] for the acceleration of electrons to high energies, the construction of a 70-million-volt machine, using betatron injection,[4] was begun. The completed synchrotron (Fig. 1) has been in operation at the 70-Mev level for several months. The results obtained with it confirm and extend the experimental results of Goward and Barnes[5] with an 8-Mev machine. The synchrotron provides a satisfactory means of producing high energy electrons and x-rays. By varying the important parameters of the present machine, information is being acquired to facilitate the design and construction of larger units.

The general theories of both the betatron and the synchrotron have been described in earlier publications.[6–10] This particular machine may be regarded as a betatron during the initial portion of each cycle of the magnet. The electrons, after their injection, are accelerated by the changing magnetic flux carried by iron laminations within their orbit. Later, these central flux bars of the magnet begin to saturate and the acceleration is supplied instead by the electric field at the gap of a radiofrequency resonator.

The magnet is driven at 60 cycles from an induction regulator. The magnetizing coils are resonated with a 3000-kva capacitor bank. As the magnetic field begins to increase, electrons are injected into the vacuum tube from a betatron-type gun pulsed with a voltage of the order of 40 kv. The gun filament is pulsed negative for 2 to 3 microseconds in each cycle, the timing of

the pulse being adjustable from $t=0$, when $B_0=0$, to $t=20$ microseconds. This timing is accurately controlled by a multivibrator circuit which is initially triggered from a permalloy peaking strip mounted across the magnet gap. Since the central flux bars do not possess uniform permeability during the betatron acceleration, the betatron orbit is slowly shrinking as $t$ increases. It matches the theoretical synchrotron orbit, which is slowly expanding, at about 200 microseconds. At this time, when the electron energy is about 2 Mev, and the electron velocity 97 percent that of light, another multivibrator circuit turns on a radiofrequency oscillator which excites a 163-megacycle cavity, forming a part of the vacuum envelope. The electrons become bunched in orbital distribution by the electric field at the gap of the resonator, and on successive revolutions they are held in synchronism with the r-f field with a stability which is characteristic of the synchrotron. Following the turn-off of the cavity resonator, the electron energy will remain essentially fixed. If the magnetic guide field has not reached its peak, the electron beam contracts to strike a tungsten-wire target placed within the tube inside the synchrotron orbit. If the field has passed its peak when the resonator is turned off, the beam expands to hit the back of the injection gun and accordingly the x-ray beam comes from the gun.

When the magnet is fully excited, the peak value of $B$, at the orbit radius of 29.3 cm, is 8100 gauss, which permits a peak electron energy of 70 Mev. At present the x-ray yield in the center of the beam at 1 meter from the tungsten target is 50 roentgens per minute as measured by a Victoreen thimble in a $\frac{1}{8}''$ thick lead shield. This output undoubtedly will improve as the many variables of the equipment are adjusted to their optimum settings.

## II. THE MAGNET

The 70-Mev synchrotron magnet (Fig. 2) resembles in general design and construction the betatron magnets which have been built in this laboratory.[11, 12] The total weight of the magnet and coils is approximately 8 tons.

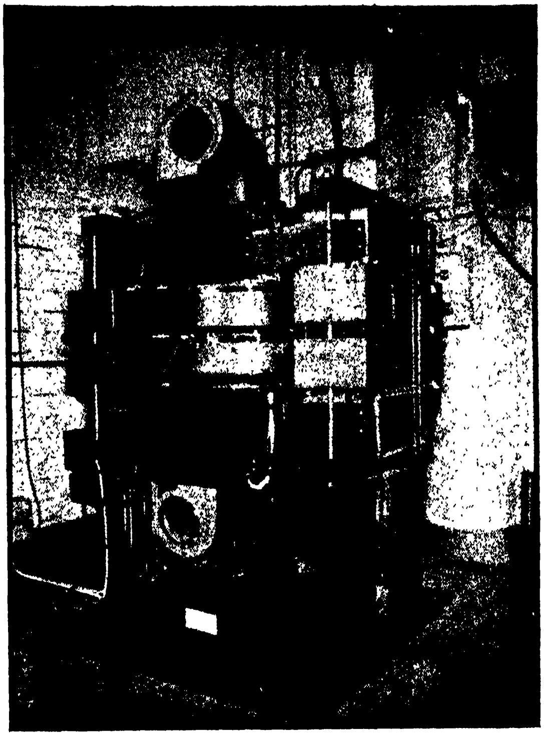

FIG. 1. Photograph of 70-Mev synchrotron.

The shape of the pole face was determined by using a half-scale model made of solid steel. The magnetic field intensity in the plane midway between pole faces varies inversely as the $\frac{3}{4}$ power of the radius. The width of the pole face near the orbit is 4″, and the gap at the 23″ diameter orbit is $2\frac{3}{4}''$.

The pole pieces were assembled from approximately 4° sectors made of enamelled punchings of dynamo-grade silicon steel 0.014″ thick. Each sector was impregnated with permafil and baked while held in a special clamp. The individual punchings, which were properly profiled, varied from 1″ to 12″ wide in steps of 1″. To avoid excessive eddy currents in the pole pieces, a total of 3 sheets of 0.005″ paper was equally spaced between bunches of laminations during the stacking of each sector. A 2″ wide copper sheet, which extended about $\frac{1}{4}''$ beyond the inner end of the iron stack, was placed in the middle of each sector. To assemble accurately pole pieces of 27″ O.D., the sectors were placed on a ground steel plate of this diameter and clamped together with a Textolite ring. The ring, fabricated from

6 semicircular pieces, was fastened together with brass pins after assembly in the rectangular groove at the outer edge of the sectors. The joints in the ring were staggered by 120°.

In the central 3″ diameter hole of the pole piece was inserted a spiral cooling coil of copper together with a $\frac{3}{4}''$ brass pipe inside the coil. The space between the brass pipe and sectors was filled with soft solder to provide heat transfer from the copper fins in the sectors to the spiral coil. The brass pipe, long enough to extend through a 2″×2″ hole through the yokes, then served as a support for the central part of the pole piece.

For the yokes and legs of the magnet, enamelled transformer-grade silicon steel .014″ thick was used. For the purpose of cooling, pairs of .030″ copper sheets were distributed at appropriate intervals during the stacking of the yokes and legs. Water flowing through copper tubes, soldered in a V groove formed by bending the outside edges of the copper sheets, serves to remove the heat produced in the iron. The cooling fins also provide a means of attaching the pole pieces to the yokes. This was accomplished by punching T-shaped notches in the sheets into which beryllium-copper hangers were inserted during stacking. By spacing the fins suitably, and by varying the distance of the notches from the center line of each yoke, the hangers were arranged to lie at equal intervals on the circumference of a circle. The circular pole pieces were then attached securely to the yokes with thirty-two brass bolts through each of the Textolite clamping rings, previously assembled in a rectangular groove in the pole piece.

The flux bars of 0.004″ enamelled strip steel consist of twenty-four bundles of strips, $5\frac{15}{16}''$ long. Each bundle contains approximately 120 strips of average width 2″ and is supported in a Textolite holder. Two spacing disks, of about 0.128″ thickness, position the holder between the pole pieces. A stream of air introduced through one of the brass pipes cools the flux bars.

### III. THE COILS

The magnetizing coils, placed around the pole pieces, carry current to produce both flux through the orbit and guiding field at the orbit. Approximately 35,000-ampere turns r.m.s. are needed for 70-Mev operation. The apparent power is furnished at 22,900-volts r.m.s. from a capacitor bank through a high voltage cable to the coils. The two coils are connected in series (Fig. 3) and each contains 130 turns of cable. The cable which consists of 12 strands of 0.050″×0.150″ Formex-covered copper wire is taped together in a bundle while being wound. Glass cloth spacers, treated with permafil, serve to provide insulation between coil layers and to form ducts for forced air cooling. After the coils were wound, they were impregnated in vacuum with permafil and then baked to produce a rigid structure. The coils are supported and held in place inside Herkolite cylinders by insulating blocks bolted to the cylinders. The cylinders, which are fastened to the yoke structure by four brackets, carry through the coils the air flow from two ½-hp blowers.

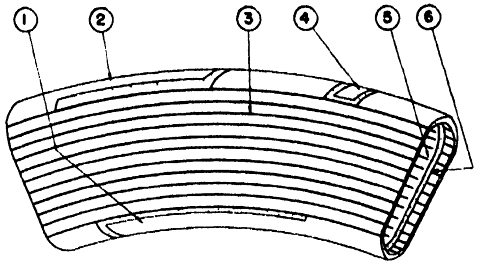

FIG. 4. Pictorial view of cavity.

1. Tuning strip
2. Coupling strip
3. Slots in silver to reduce eddy currents
4. Insulated patch for voltage monitor
5. Connection between adjacent strips
6. Accelerating gap

The exciting coils are connected across an induction regulator which supplies 74.5 amperes at 372 volts for 70-Mev operation of the synchrotron. Each coil has two turns of No. 2 insulated code wire wrapped around the pole piece between the Textolite clamping ring and the yoke, as is shown in Fig. 2.

The saturating coils, two of which are mounted on each leg of the magnet, are required for starting the machine. The inductance of the magnet varies during each cycle as the flux bars saturate. When the machine is not running, its inductance and the capacitor bank are in tune at approximately 40 cycles. Accordingly, in starting, the exciting coils draw an excessive current from the 60-cycle line. Therefore, the saturating coils are supplied with 60 amperes of d.c. which, by partially saturating the magnetic structure, tunes the circuit to 60 cycles for low power operation. As the excitation is increased, the d.c. is reduced by an automatic phase-sensitive control circuit which keeps the magnet-driving current and voltage nearly in phase. Finally, when the magnet is fully excited, no d.c. remains in the saturating coils. Each of the four coils has 46 turns, wound in a single layer on an insulating frame. The individual coils are connected in series so that the a.c. voltages which are induced in them balance out and do not appear across the d.c. supply.

## IV. THE CAPACITOR BANK

The 3000-kva capacitor bank, which supplies the apparent power for the magnetizing coils, consists of 121 units arranged with 8 banks in series. Seven banks have 15 units in parallel, and one bank 16 units in parallel. Each Pyranol-filled unit is rated at about 7 micro farads, 3 kv r.m.s., and 24 kva. The 8 insulated metal racks holding the capacitors are contained within a sheet-steel housing through which air is circulated by a low pressure blower. The power loss in the capacitor cabinet is ⅓ of 1 percent of the voltamperes, or approximately 10 kw.

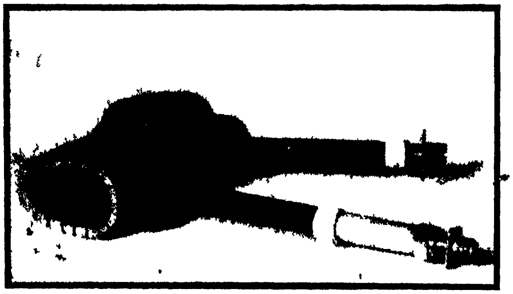

FIG. 5A. Photograph of r-f resonator

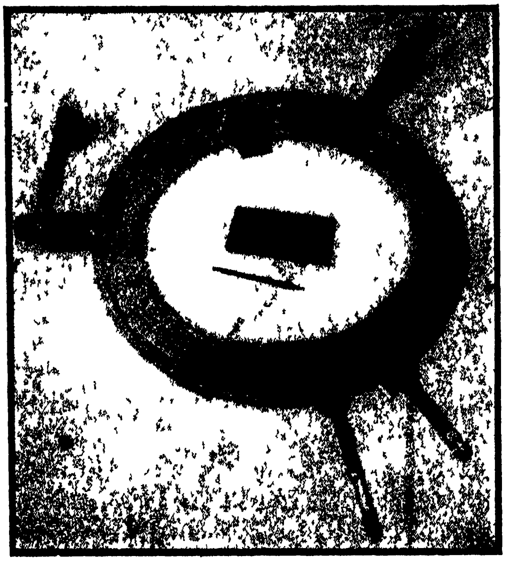

FIG. 5B. Photograph of resonator installed in vacuum tube

## V. VACUUM TUBE AND R-F CAVITY

The vacuum tube was molded by the Corning Glass Works of 774 Pyrex glass, ¼" thick. It is of toroidal shape with an outside diameter of 27", an inside diameter of 19", and with a nearly elliptical cross section; the major axis is 4" and the minor axis is 2¼". Two side arms are provided 120° apart for gun and target, the pumping lead being on the target arm. From the tube, a 57° sector was removed by making radial cuts with an emery wheel. This sector was replaced by one of similar shape, but of 707-DG glass, the loss tangent of which at 163 megacycles is 0.0012, a value low enough to make this glass suitable for the radiofrequency resonator. The 707-DG glass sector, cast in the same mold as the original tube, had its ends ground so that it fitted tightly in the place of the sector which was cut out. The resonator (Fig. 4) was prepared in the following way. The low loss glass was coated appropriately with DuPont silver paint which was baked onto the glass at 500°C. In an electrolytic plating bath, the thickness of the silver coating was increased to 0.001". A tungsten wheel, mounted on a rotating arm and connected to a current transformer, was then used as a tool for removing silver from the glass so as to subdivide the silver coating into narrow strips. This reduces the eddy currents produced in the coating by the a.c magnetic field.

The complete cavity (Fig. 5) may be regarded as a ¼-wave concentric resonator which has been fore-shortened physically by the introduction of glass between inner and outer conductors. Voltage is developed across a ⅛" wide gap inside the sector close to one end. The r-f excitation from the oscillator is fed from a coaxial 50-ohm line. Coupling is achieved by having the central conductor of the cable make proper contact with a strip of the outer silver coating of the cavity. The coupling can be varied to secure a good match by moving the point at which the center conductor of the cable makes contact with the silver strip. This strip is only connected to the remainder of the silver coating at the extreme end of the cavity, away from the gap. It is not necessary to bring any metal leads through the glass. For measuring the voltage across the gap, a calibrated probe and crystal is supported outside the glass near the gap. All the electrical connections are made by silver strips supported on Textolite blocks which are taped to the resonator by permafil-treated glass cloth.

Before the silvered cavity was inserted into the main tube, the inner surface of the tube was chemically coated in a uniform manner to obtain a resistance of 200 to 1000 ohms per square cm. When the cavity is permanently positioned, 0.002″ gaskets are used at the joints. Molded sleeves of butyl rubber hold cavity, gun, and target in position. These sleeves when painted with Glyptal insure vacuum-tight joints. A glass oil diffusion pump of 20 liters per second capacity, backed up by a suitable fore-pump, keeps the tube pressure below $10^{-5}$ mm of mercury. This pressure, measured with an ionization gauge, is satisfactory for regular operation.

The cavity requires 250 watts to produce 1000 volts peak across the gap. As the duty cycle is normally 25 percent, considerably less average power is used. Operation of the cavity shows that the voltage can be developed across the gap without excessive heating of the dielectric or the rubber sleeves. The $Q$ of the cavity has been measured as 375. It is possible to change the resonant frequency 10 percent by moving the position of a piece of foil attached to the tuning strip outside of the cavity. In practice, this tuning is done only to adjust a new cavity to the desired frequency. The power is supplied to the cavity by an 832-A oscillator driving an 829-B grid-modulated power amplifier.

## VI. ORBIT LOCATION

The location of the betatron orbit is of interest only during the time that the magnetic field is low. The orbit is located by methods which are similar to those already published.[12] The voltage induced in a small coil placed at the desired orbit position is balanced against a fraction of the voltage from a single turn of wire of 23″ diameter on the pole face. A null-voltage indication on an oscilloscope enables the orbit position to be calculated. This null indication is observed on a sweep which is triggered when the magnetic field passes through zero. By varying the fraction of the single-turn voltage which is used, the null indication can be obtained at various times following $B=0$. Thus the location of the orbit as a function of time can be found. Adjustment of the betatron orbit is readily carried out by changing the paper shims between the yokes and legs of the magnet. Since the gap of approximately 0.25″ between the central flux bars and pole pieces varies more rapidly, relatively, than the main gap of 2.75″, the flux within the orbit can be altered by a large amount without appreciably affecting the flux density at the orbit. In this way, the betatron condition can be fulfilled in order to match the desired orbit diameter.

The orbit shrinks considerably as the flux bars begin to saturate. The contraction in orbit radius is about 1½″ in 350 microseconds, with most of the contraction occurring near the end of this period. This contraction does not prevent a satisfactory transition to the synchrotron condition. Indeed, the exact location of the betatron orbit in the center of the glass vacuum tube does not appear important. The orbit has been shifted over a wide region inside the tube with little change on the x-ray output. The synchrotron orbit is defined by the energy of the electrons and the frequency of the r-f oscillator.

## VII. POWER CIRCUIT

A diagram of the main power circuit of the machine is shown in Fig. 3A. Power is supplied from a 220 volt 60-cycle a.c. line through a motor-controlled induction regulator to the exciting coils of the magnet. The $Q$ of the resonant circuit is approximately 113. Variations in line frequency could have a relatively large effect on operation, but trouble from this source has rarely been observed with this installation. If the capacitor bank is cold, and hence the capacity high, the machine will be in resonance at a slightly higher power level because of the nonlinear inductance of the magnet. After ten minutes of running, the temperature of the capacitor bank has reached equilibrium. The power required to energize the machine fully is 26.5 kw.

The machine has also been run with d.c. bias on the magnetizing coils as is shown in Fig. 3B. The large increase in electron energy which is obtainable by biasing a betatron[13] of given

---

Fig. 6. Oscillogram showing operation of the machine; the trace is cut off every 100 microseconds. (1) marks the time of electron injection. At (2) the r-f voltage is turned on and at (3) it is turned off. (4) marks a signal from a photo-multiplier tube placed in the x-ray beam. For this trace the energy was about 20 Mev.

weight cannot be realized with a synchrotron. However with a biased synchrotron, for a given energy output, the voltage across the magnetizing coils may be reduced by nearly 50 percent and the effective value of the current by about 15 percent. Because of the lowered a.c. component of flux, the iron losses decrease to about $\frac{1}{3}$, which reduces the cooling requirement of the magnet. The a.c. power input is also lowered. Theoretically, the capacitor bank is reduced to about 30 percent of that required for full a.c. operation. The full saving in capacitor kva cannot be realized since it is necessary to compensate the inductance of the reactor required to introduce the d.c. bias current into the magnetizing coils. The net saving in practice may thus amount to about 50 percent. With the present machine, the cost of the reactor was comparable to that of the added capacitor kva required for full a.c. operation. For a higher energy machine, some saving in cost might be obtained by using bias.

With d.c. bias, it was somewhat more difficult to start up and get the machine on the line. The operation was also rather unstable. A large part of the instability was due to the regulation characteristics of the input circuit coupled with the non-linearity of the reactance of the magnet. Normally, the input lines have a small inductive reactance. When the magnetizing circuit is near resonance at the line frequency, the operation will be stable provided the power factor of the circuit is slightly lagging. A small change in the d.c. bias current can cause the power factor to swing from lagging to leading or *vice versa.* If the power factor becomes leading, then the voltage at the machine terminals rises because of the inductive reactance of the input lines. A rise of voltage on the exciting coils causes a higher effective inductance of the magnet, and hence a tendency for the power factor to become still more leading, since the capacitor bank has a fixed value. Obviously, under such conditions, the operation will be unstable. One way in which this difficulty can be overcome is by means of a series capacitor in the input circuit. This was tried and found to be reasonably effective. We are confident that stability can be obtained when it is desirable to use a biased magnet.

With full a.c. operation, there is stability. An increase of voltage at the input terminals decreases the effective inductance of the magnet, there by making the power factor more lagging, which tends to lower the input voltage.

### VIII. OPERATION

The operation of the machine is quite simple. The sequence of events in each cycle is illustrated by Fig. 6. The final energy of the electrons is easily changed by a single knob controlling the time that the r-f cavity stays on. Figure 7 shows that the time at which the r-f is turned on is not very critical. The time at which the electrons are injected into the tube is critical as is shown by Fig. 8. Under good conditions, when the line frequency is stable, the injection timing multivibrator is adjusted perhaps once or twice a minute. It is easy to keep the intensity of the x-rays constant to within about 10 percent for long periods of time.

The transiton from betatron operation to synchrotron operation seems to be rather efficient.

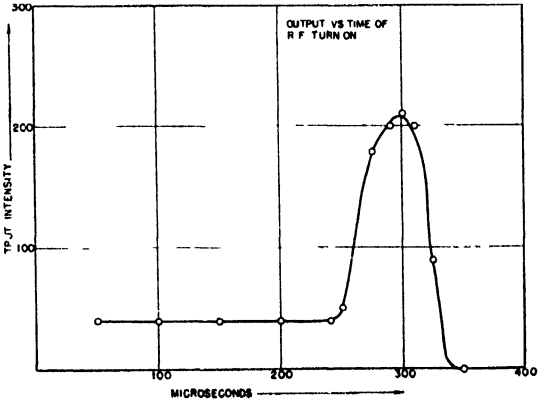

Fig. 7. Output *vs.* time r-f is turned on.

This is shown by operating the machine at a low intensity and observing the output by means of a Geiger counter. The pulses from the counter are displayed on an oscilloscope with a 60-cycle sweep. If the r-f oscillator is not turned on, a count is registered almost every cycle a few hundred microseconds after injection, at the sweep position where 3.5-Mev x-rays are expected. This is of course the betatron beam collapsing to the target as the central flux bars saturate. If the r-f is turned on, no betatron counts are observed, but higher energy quanta produce counts following r-f turn off. This indicates that a large fraction of the electrons which previously had collapsed to the target are bunched in the synchrotron orbit and are accelerated to high energy.

The rate of rise of the r-f envelope was varied from 2 to 20 microseconds and does not seem to affect the efficiency of the transition. Increasing the peak r-f voltage on the accelerating gap beyond twice the minimum voltage needed per turn does not increase the output appreciably (see Fig. 9). It is felt that further increase in x-ray output will result from improvement in betatron injection techniques rather than from changes in the synchrotron mode of operation.

Two types of electron gun have been used. One is a standard gun which has been used with betatrons for several years in this laboratory. It is quite similar to a gun described by D. W. Kerst.[14] A rather different gun, designed by J. P. Blewett, and initially studied on a rubber model, has been in use for a short time. The required orbit contraction is less than that in the earlier guns. Initial comparative experiments indicate that this improved gun gives a larger output than the standard gun.

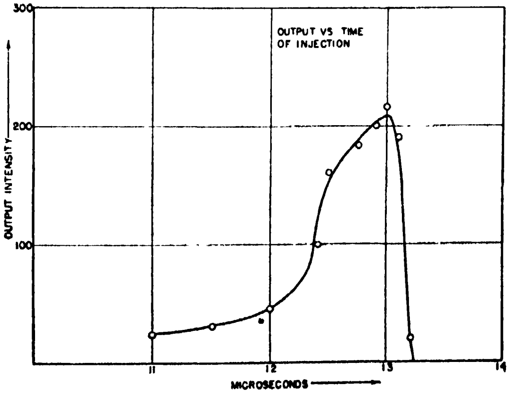

FIG. 8. Output *vs.* time electrons are injected by gun.

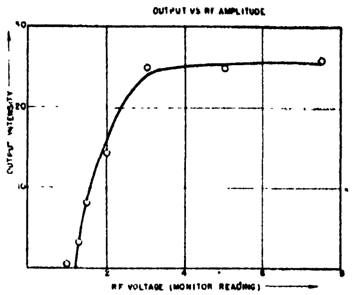

FIG. 9. Output *vs.* r-f accelerating volts. Monitor readings are directly proportional to peak voltage at the accelerating gap.

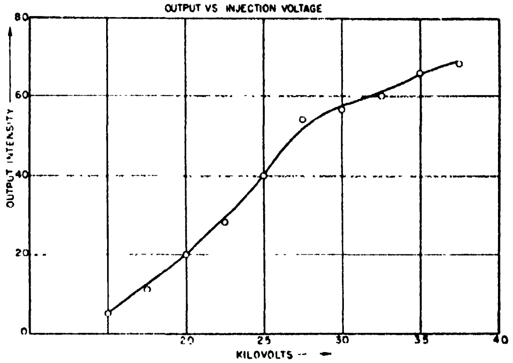

FIG. 10. Output *vs.* gun injection voltage.

The electron gun is always mounted on a side arm of the tube through a metal bellows which allows the gun position to be easily varied. Maximum x-ray output always seems to occur when the gun is located at a position in the tube just outside that where the magnetic field falls off inversely with the radius. It can be shown that in this region the electron beam has no radial stability, and accordingly the electrons can rapidly spiral in towards the center of the tube. A typical plot of x-ray output *vs.* injection voltage is shown in Fig. 10.

The x-ray output can be considerably increased by slight changes in the azimuthal distribution of the magnetic field. This is accomplished by placing flat sector-shaped coils along the top and bottom pole pieces of the magnet. These coils are connected to variable resistors. When the machine is operating, the output can usually

FIG. 11. Oscillogram of x-rays from internal target. The length of the sweep is 1000 microseconds. The trace begins at the time the r-f was turned off, when the electron orbit starts to contract. The irregular signal is from the output of a photo-multiplier tube placed in the emergent x-ray beam.

be increased several-fold by varying the current flowing through these coils.

When the x-ray intensity is low, the output of the machine is observed by a Geiger counter. With higher output, it is convenient to monitor with a 931 photo-multiplier tube contained in a light-tight box, and set a few feet from the target in the center of the beam, which is approximately 3° wide. The 931 is followed by a single stage of amplification and a cathode follower whose output is observed on an oscilloscope. The circuit has good frequency response which permits details of the x-ray beam structure to be observed on a fast sweep of the oscilloscope. An ionization chamber and d.c. amplifier are used to measure the average output of the machine.

The structure of the x-ray beam as a function of time is rather complicated. The distribution of x-rays from a contracted electron beam, as determined by a photo-multiplier tube is shown in Fig. 11. Upon moving the target by means of a metal bellows, it was found that a contracted electron beam gives a single x-ray pulse if the target is placed at a radius where $n>0[n=-d(\log B)/d(\log r)]$. If the target is at a smaller radius than that at which $n=0$, the x-ray beam becomes very complicated, probably because the electron beam has no vertical stability in regions where $n<0$.

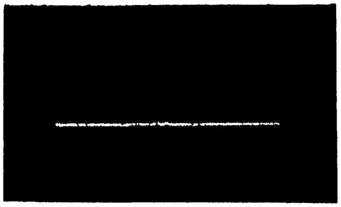

FIG. 12. Oscillogram of x-rays generated by electrons expanding to the gun as the magnetic field decreases. The 1000-microsecond trace is keyed at the time of r-f turn off. Two sharp pulses are registered by the photo-multiplier tube, about 50 microseconds apart.

An expanded electron beam, striking the gun as a target, gives a single pulse unless the gun is placed at a radius larger than that at which $n=1$. In this case, the x-rays emerge in two well separated sharp pulses as shown in Fig. 12. This splitting of the expanded beam is not understood at present, but is being investigated further.

In these experiments, the ejection of the electron beam to a target is accomplished by turning off the r-f resonator and letting the beam expand or contract as the magnetic field changes. If an x-ray pulse of shorter duration is needed for experimental work, some faster method of electron ejection should be used.[15]

## ACKNOWLEDGMENTS

The authors wish to acknowledge the many helpful suggestions made by Dr. E. E. Charlton, Dr. W. F. Westendorp, and Dr. J. P. Blewett. Mr. P. C. Noble, Mr. J. F. Tracy, Mr. R. L. Watters, and Mr. G. M. Kirkpatrick designed and tested many of the r-f components. Mr. F. Haber, Mr. G. N. Knowlton, and Mr. S. Sebis participated in much of the construction. This project has been supported throughout by the Office of Naval Research under Contract No. N5ori-178, task I.

# Cathode-Ray Presentation of Three-Dimensional Data*

OTTO H. SCHMITT
*Airborne Instruments Laboratory, Inc.,*** *Mineola, New York*

(Received March 24, 1947)

The cathode-ray oscilloscope is usually regarded as a means for displaying data in one or two variables as a function of time. By means of simple transformations which are easily performed electrically, it is possible to present three variable electrical data in the form of isometric or other conventional projections or as true perspective drawings. It is further possible to change the observer's viewpoint in the presentation coordinate system at will by turning range, elevation, and azimuth controls.

A more elaborate but similar set of transformations permits presentation of separate pictures to the two eyes. These pictures are optically superimposed but differ in such a way as to yield stereoscopically correct perspective pictures. These pictures are fully acceptable to the eye as patterns in space.

WHEN we are interested in examining an object of moderate size, we instinctively try to position it so that we look directly at it with both eyes from a distance ranging from a few inches to a few feet, depending upon the size of the object. We next turn the object or move about it so as to get several different views of it. Then, if we find certain details of the object particularly interesting, we move up and examine these details from a very short distance, sometimes even using a lens system to assist our eyes in focusing.

By the time we have completed such an examination we know pretty thoroughly what the object is like three-dimensionally, even though we have, in reality, seen only a series of pairs of the two-dimensional images formed on the retinas of our eyes.

The "realness" and "solidity" of an object in our field of view depends on a complex of subjective and objective factors, all of which our minds quickly and accurately put together into a mental image of the three-dimensional object. This mental picture is never a simple accumulation of the various retinal images: it is a real three-dimensional picture, nicely painted onto a framework provided by clues contained in the image pairs.

In this mental picture, missing details are neatly filled in, compromises are automatically made between various inconsistencies actually present in the data as seen, and errors resulting from optical and mechanical imperfections in the eye mechanisms are smoothed over.

Our visual apparatus is remarkably adaptable; if furnished with a few clues—even if some of them are contradictory—it will piece together a plausible, single clear picture, though this picture may not be the right one. When a wrong cue is taken and the data gets just too confusing, the eyes will try to find another picture that also fits the available data. The search for an intelligible picture will be repeated again and again before the eyes finally give up and register a blur.

This picture synthesis is the basis of many familiar optical illusions, especially those in which surfaces suddenly reverse or shift position. It is this process also that allows a skilled draftsman to convey a clear three-dimensional picture by a drawing on a flat sheet, using one of the systems of projection or perspective. In addition to having no real depth, these drawings may violently distort certain angles or lengths; yet so long as a few strong clues are given and the observer is trained to reject conflicting data, a clear picture can be formed.

In any scheme that proposes to present a three-dimensional picture to the eye in terms of one or a pair of flat pictures, we must attempt to suppress, or eliminate by education, the tendency for the eye to cling to features of the picture which reveal that it is "really" two-dimensional and we must emphasize those elements which

---

* Paper presented at the national convention of the Institute of Radio Engineers, March 3, 1947.

** Now at University of Minnesota, Department of Physics.

give the actually false impression of depth. Perception of depth by accommodation is subordinate to depth perception by binocular convergence, and depth perception by binocular convergence is subordinate to that by perspective. Consequently, a presentation that provides only perspective is convincing, whereas one that provides both perspective and stereoscopic view is very "real" indeed.

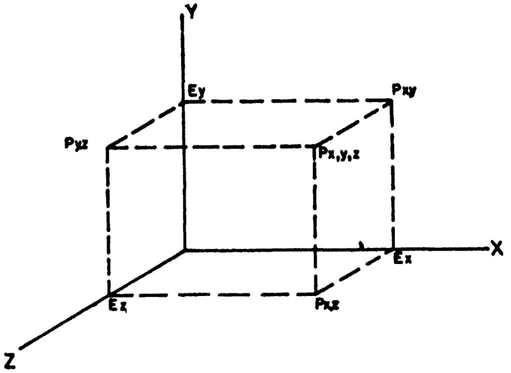

FIG. 1. Right-handed Cartesian coordinate system.

A cathode-ray tube provided with suitable deflecting and modulating voltages is capable of painting *any* two-dimensional picture within reasonable limits of brilliance, color, and grain size. It thus becomes obvious that a single cathode-ray tube can convey any three-dimensional-appearing picture that a perspective drawing can. In addition, two cathode-ray pictures, properly interrelated, can yield a real three-dimensional view if eye accommodation and comparison with surroundings are properly suppressed so that the eyes will be forced to rely on convergence and object shape for depth perception.

It is the purpose of this report to point out how easily the underlying principles of projective and perspective drawing and of stereoscopic photography can be applied to cathode-ray presentation so as to convert raw electrical data directly into vividly recognizable three-dimensional pictures.

Let us consider first the cases where both eyes look at the same picture. These are the projections and the perspective pictures familiar to every engineer and draftsman. In all these methods of presentation, a degree of three-dimensionality is given to the picture by having it resemble, in greater or less degree, the actual picture formed in the eye when viewing the object from some particular viewpoint, imaginary or real, the viewpoint in each case being chosen to bring out certain features of the picture.

In perspective drawing, some advantageous viewpoint is chosen and a serious attempt is made to develop, as accurately as is possible with simple rules of procedure, a picture like that which one eye would see if placed at that point. Projections, on the other hand, attempt to present as many as possible of the lines and angles of the picture in directly measurable form. Consequently, perspective drawings are easily recognized as three-dimensional even by the uninitiated, whereas projections tend to be distorted and often tax the eyes' ability to synthesize them into clear mental pictures, though great ingenuity has been shown in devising special projections that tend to neutralize the intrinsic distortions by counter-distortions.

To investigate the feasibility of presenting three-dimensional data on the cathode-ray tube let us start with the most general assumption: that we have at each instant three coordinate electrical data representing a point in our three-dimensional picture space, and that we also have a voltage specifying the spot brightness desired at that point, thus representing in a limited sense an additional parametric variable. We thus leave unrestricted the paths of the cathode-ray spot and are therefore able to deal with stationary or moving patterns made up of lines, spots, or surfaces; we need not consider separately whether the final picture is formed by scanning or by directed motion of the cathode-ray beam. (Remember, however, that direct, complete, three-dimensional scanning is ordinarily impractical because of the immense number of picture elements involved.)

Though coordinates other than Cartesian might obviously be used, we shall restrict ourselves to these for simplicity (Fig. 1). Let us call the three component voltages with which we are supplied $E_x$, $E_y$, and $E_z$, and let us think of $X$ as directed to the right, $Y$ as up, and $Z$ as toward us—the three axes comprising a right-handed Cartesian system. The three component voltages taken together represent a point $P$ in the three-dimensional $X$, $Y$, $Z$ space.

Plotting $E_x$ against $E_y$, $E_x$ against $E_z$, or $E_y$ against $E_z$ by means of a cathode-ray tube, we find that we get nothing new: we have one or another conventional cathode-ray presentation of part of the data. But looked at from the draftsman's standpoint, we have made standard multi-planar orthographic projection drawings: respectively, an elevation, a plan, and a profile projection of $P$ on these three projection planes. Following this lead we undertake to produce the draftsman's more difficult but more illustrative presentations on the cathode-ray tube.

Each of the orthographic projections is based on projection of the "object" data on a single projection plane by rays perpendicular to that plane. It can easily be shown that there is a perfectly general and always linear transformation from the three-dimensional voltage components $E_x$, $E_y$, and $E_z$ to the two-dimensional projection components on any specified projection plane. This transformation can be performed in the following manner.

Establish a new coordinate system $X'$, $Y'$, $Z'$ (Fig. 2) in such a fashion that one of its coordinate planes, say the $X'Y'$ plane, coincides with the desired projection plane. Call the cosines of the angles which the new $X'$ axis makes with the old $X$, $Y$, and $Z$ axes, respectively, $l_1$, $m_1$, $n_1$, and the cosines of the angles made by the new $Y'$ and $Z'$ axes with the old axes, correspondingly, $l_2$, $m_2$, $n_2$ and $l_3$, $m_3$, $n_3$. The general transformation for rotation of axes now yields the three component voltages $E_{x'}$, $E_{y'}$, $E_{z'}$, resolved along the new prime axes:

$$\begin{aligned}E_{x'}&=l_1E_x+m_1E_y+n_1E_z,\\ E_{y'}&=l_2E_x+m_2E_y+n_2E_z,\\ E_{z'}&=l_3E_x+m_3E_y+n_3E_z.\end{aligned}$$

Because each of these represents the total resultant voltage along one of the new prime axes, any pair represents the projection on one of the coordinate planes.

Electrically the meaning of this is simple. If we take, with a potentiometer, a fraction $l_1$ of our incoming $E_x$ voltage, add a fraction $m_1$ of $E_y$ and $n_1$ of $E_z$, apply this to our cathode-ray tube as $X$ deflection voltage, and use the corresponding fractions $l_2$, $m_2$, and $n_2$ of the original voltages for $Y$ deflection voltage, our tube will automatically plot the projection of the data on a new arbitrarily rotated $X'Y'$ plane. Since all the direction cosines are constant for any specified projection and since sine-cosine potentiometers, which are now readily available, yield the cosine directly when only the angle is set on the dial, this transformation is really a very simple one. It is often further simplified in particular resolutions by the fact that some of the angles are 0° or 90° and hence have cosines of 1 or 0—in which event no potentiometer is needed, all or none of a particular component voltage being used.

A specific example will serve to illustrate the simplicity of this projection transformation. Isometric projection occurs when the object axes are all inclined at equal angles of 35° 16′ to the projection plane. If the $Y$ projection is chosen to fall along the new $Y'$ axis, the transformation is:

$$\begin{aligned}E_{x'}&=\frac{\sqrt{2}}{2}(E_x-E_z)\\ &=0.707(E_x-E_z),\\ E_{y'}&=\sqrt{\frac{2}{3}}\left(E_y-\frac{E_x}{2}-\frac{E_z}{2}\right)\\ &=0.816\left(E_y-\frac{E_x}{2}-\frac{E_z}{2}\right).\end{aligned}$$

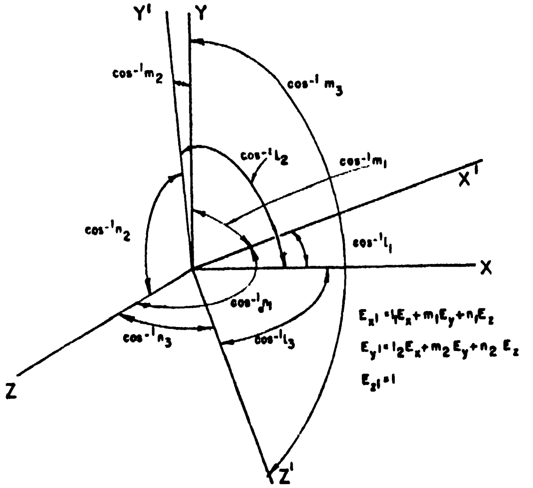

FIG. 2. General transformation for rotation of coordinates.

A little study will give values for the three coefficients for the $X'$ and for the $Y'$ that will yield any of the dimetric or trimetric projections.

Some of the most effective drawings are done in various "oblique projections." These are not really projections in the simple sense but they make use of the eyes' compromising ability to permit use of very simple drawing rules while still retaining good metric properties.

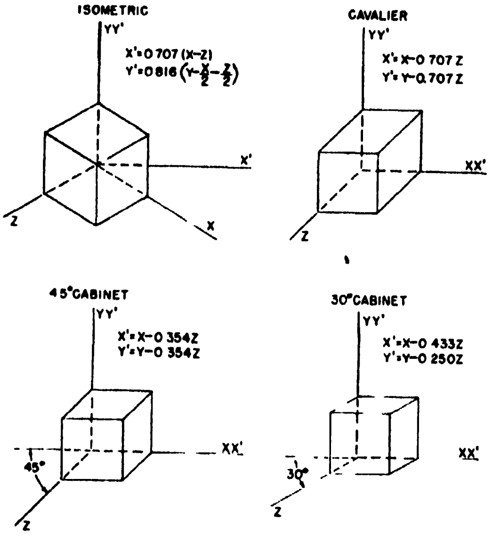

FIG. 3. Cube in isometric and various oblique projections with electrical transformation for each type of projection.

Figure 3 illustrates several projections, with a sketch of a cube in each, and gives the corresponding electrical transformations. Working independently, Carl Berkley of the DuMont Laboratories has devised and investigated certain of these projections in detail, both theoretically and experimentally, and has obtained excellent results. They were reported at the national convention of the Institute of Radio Engineers on March 5, 1947, and I shall therefore not elaborate on them here.

In military problems, in radar problems, indeed in most cases other than purely geometrical ones, we are likely to know angles other than those from which the direction cosines are derived. The most common case will be that of Fig. 4, in which voltage data are presented in rectangular $X$, $Y$, $Z$ coordinates. We wish (1) to take up our viewpoint at some little distance from the phenomenon, in a direction defined by an azimuth angle $\phi$ and an elevation angle $\theta$; (2) to see the data presented as a projection on a normal plane passing through a chosen origin; and (3), to keep our projection plane so oriented that the picture is still level, i.e., so that the new $X$ axis in the projection plane still lies in the old $XZ$ plane.

As it turns out, the transformation of electrical data to this new and completely general projection is very simple. Using two two-gang potentiometers, we can provide two knobs, one directly calibrated in azimuth and another marked in elevation, which will allow us to set the viewpoint anywhere around a complete sphere.

The transformation is simple if done as two separate coordinate rotations in proper order, as follows (Fig. 5). Starting as usual with data given as $E_x$, $E_y$, $E_z$, transform this for a rotation in azimuth $\phi$ about the $Y$ axis to give the $E$ data in terms of new coordinates $X'$, $Y'$, $Z'$:

$$E_{x'} = l_1E_x + m_1E_y + n_1E_z,$$
$$E_{y'} = l_2E_x + m_2E_y + n_2E_z,$$
$$E_{z'} = l_3E_x + m_3E_y + n_3E_z,$$

where $l_1$, $m_1$, $n_1$ are the direction cosines of the new $X'$ axis with respect to the old axes and $l_2$, $m_2$, $n_2$ and $l_3$, $m_3$, $n_3$ are the direction cosines of the new $Y'$ and $Z'$ axes. This yields:

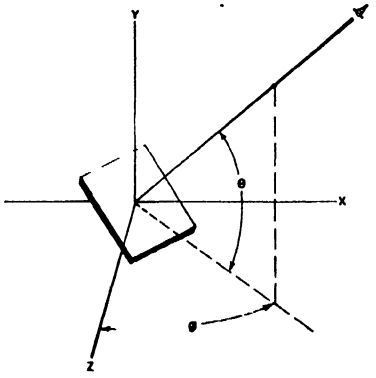

FIG. 4. Projection plane for viewpoint at azimuth $\phi$ and elevation $\theta$.

$$E_{x'} = E_x \cos\phi - E_z \sin\phi,$$
$$E_{y'} = E_y,$$
$$E_{z'} = E_x \sin\phi + E_z \cos\phi.$$

Now rotate this new coordinate system to a double-prime position (Fig. 6), where the $Z''$ axis, which is the desired line of view, is swung to an elevation angle $\theta$ by a rotation about $X'$.

$$E_{x''} = E_{x'}$$
$$E_{y''} = E_{y'} \cos\theta + E_{z'} \sin\theta$$
$$E_{z''} = -E_{y'} \sin\theta + E_{z'} \cos\theta.$$

To obtain these data, we need from the azimuth control system:

$E_x \sin\phi$ and $E_x \cos\phi$
(sine-cosine potentiometer No. 1),

$E_y$ (already available),

$E_z \sin\phi$ and $E_z \cos\phi$
(sine-cosine potentiometer No. 2).

For the second transformation, to put in elevation we need:

$E_{x'}$ (already available),
$E_{y'} \sin\theta$ and $E_{y'} \cos\theta$
(sine-cosine potentiometer No. 3),
$E_{z'} \sin\theta$ and $E_{z'} \cos\theta$
(sine-cosine potentiometer No. 4).

Since we desire to show the projection on the $X''Y''$ plane, we put the $E_{x''}$ and $E_{y''}$ voltages on the oscilloscope deflection plates and therefore do not need the $E_{z''}$ voltage. (Notice, however, that no extra potentiometers are required to obtain $E_{z''}$ because sine and cosine can come from a single unit. We shall have reason to return to $E_{z''}$ later, in connection with perspective and stereoscopic presentations.)

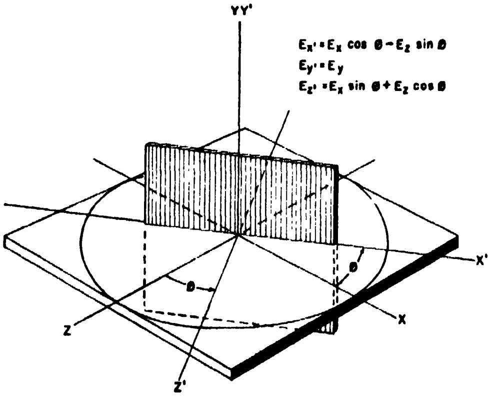

FIG. 5. Transformation by two separate coordinate rotations (rotation for azimuth angle $\phi$).

All the transformations thus far considered result in ideal or in stylized projections that are useful where distances along certain axes must be linearly measurable. Their extensive use in drafting as compared with perspective drawings results largely from their metric properties and from the difficulty of making good perspective drawings, especially from arbitrarily defined viewpoints. In the electric case, the use of view-rotating potentiometers permits any viewpoint to be chosen. For a complete presentation, therefore, it remains only to solve the problem of displaying perspective convergence on the cathode-ray tube.

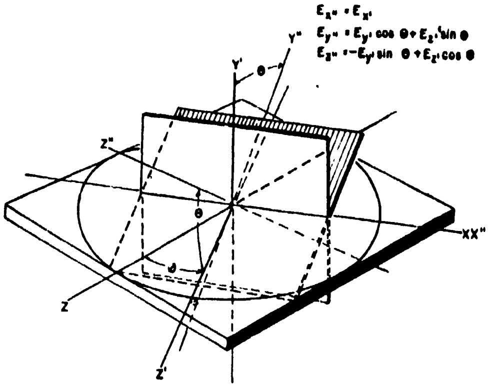

FIG. 6. Transformation by two separate coordinate rotations (rotation for elevation angle $\theta$).

Return to the original case—where $E_x$, $E_y$, and $E_z$ potentials are supplied directly or, what is equivalent, where the necessary rotations have already been accomplished—and consider how the picture would appear in perspective, looking along the $Z$ axis toward the origin (see Fig. 7). All points along the $Z$ axis project as a point at the origin $O$ on the $XY$ projection plane. Viewed from a distance $d$, the projection for a point $x = a$, $y = b$, $z = c$ would fall a distance $A = ad/(d-c)$ from the axis in the $X$ direction and $B = bd/(d-c)$ in the $Y$ direction. (This follows at once from inspection of similar triangles.) Since $a$ and $b$ are represented by the deflection voltages $E_x$ and $E_y$, respectively, and $d$ is a constant distance set on a dial, the multiplication indicated in the numerator can be accomplished by two simple linear potentiometers ganged to the "distance-of-view" control shaft. These potentiometers multiply the incoming $E_x$ and $E_y$ voltages, respectively, by the $d$ set on the dial. $c$ is a constantly varying quantity proportional to $E_z$. The reciprocal $1/(d-c)$ is obtained by using a non-linear amplifier. The $d$ in the denominator presents no difficulty because it is merely a d.c. bias proportional to the distance setting and is obtained from a third linear potentiometer on that shaft. Several components can be used in common for both $A$ and $B$ since both use identical circuits and contain the same multiplying factor $d/(d-c)$. This system has not been completed, and its performance characteristics cannot yet be stated.

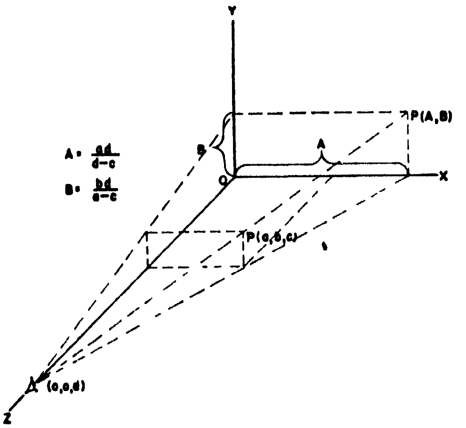

FIG. 7. Perspective projection presentation.

Adjustment of the distance-of-view control changes $d$—that is, it moves the observer's perspective viewpoint nearer or farther from the apparent object; since there is no focus problem here, it is equivalent to an ideal telephoto lens of adjustable magnification and corrected perspective.

Let us now consider what control over presentation we have, utilizing this perspective control combined with the azimuth and elevation controls previously described in connection with the orthogonal projection presentation. Let us take up a viewpoint a long way off and look over the data from all sides, as one does in inspecting an object visually. This we do by setting our perspective control for a long-distance viewpoint—just long enough, however, to permit us to see the whole picture at once. We now rotate the object—even though it may be actual radar data representing cubic miles of volume—by turning the two angular-selection controls. This permits us to select the one best viewpoint over the entire sphere of possible viewpoints. We now move ourselves nearer at will, going in among the data if this seems advantageous.

A word of caution should be injected at this point. It is feasible to utilize all the freedom just mentioned, but two factors must be remembered. On advancing the viewpoint into the field of data, data behind the observer may appear before him as a "negative." The occurrence of this phenomenon depends upon the design of the reciprocal amplifier and may in special cases require use of a special blanking circuit. However, this blanking circuit turns out to be quite simple.

The second factor concerns the apparent transparency of objects. It is obvious that no data can be presented which are not furnished electrically and, conversely, that all the data provided will be presented unless specifically blanked out. All "pictures" made by this process will then be "glass-block" pictures in which all surfaces of the object can be seen "through." This is generally desirable, especially when graphical or other line data are being presented. It may lead to optical illusions in certain cases, however, where the perspective picture shown is equivalent to another perspective picture of some other data configuration. Recall that in these pictures the eye is being asked to perceive depth solely by convergence of picture lines and cannot rely even on binocular convergence for a clue to real depth.

To investigate whether this one powerful aid to three-dimensional perception can be made to aid us in our attempt to present three-dimensional data realistically, let us see what further resolution of data would be needed to provide two suitably different sets of perspective data to be viewed by the two eyes separately to give the exact equivalent of stereoscopic, or perhaps even of enhanced stereoscopic, relief.

Ideal stereoscopic viewing presumes that both eyes look directly at the object from slightly separated points. In the language of our two

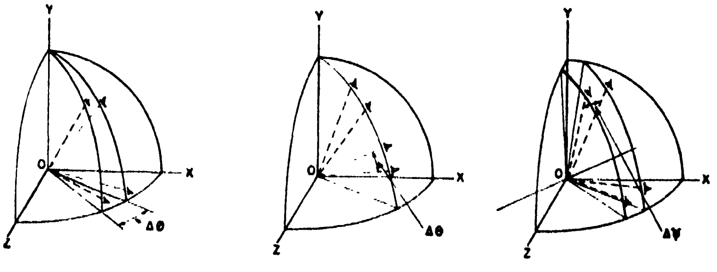

Fig. 8. Stereoscopic eyepoint separation by variation of $\phi$, $\theta$, and $\psi$.

angular-resolution potentiometers, this means that the tubes presenting data to the two eyes must be supplied with similar data for two slightly different viewpoints, and that this difference will depend upon the distance of the viewpoint from the data and upon the degree of stereoscopic enhancement desired.

As our coordinate transformation has been carried out, it is very simple to provide different viewpoints if those viewpoints differ by some simple and preferably constant amount in either $\phi$ or $\theta$. An extra set of contacts on the potentiometers that establish these angles or, at worst, a duplicate set of potentiometers lagging at a properly set angle will give the additional viewpoint.

Unfortunately, though the equivalent eye separation provided by a small change $\Delta\phi$ in azimuth (Fig. 8) corresponds to a desirable *horizontal* separation of eyepoints, it varies in amount with the cosine of the elevation angle $\theta$, since all the "longitude lines" converge.

Eyepoints produced by deviation of the elevation angle $\theta$ by a small amount $\Delta\theta$ are not subject to this error because lines of latitude are uniformly spaced. However, since they correspond to viewpoints above one another, the observer must view the picture as though lying on his side.

This problem can be ideally solved by a third re-resolution of the picture—this time by rotation about the $Y'''$ axis—to give eyepoints that are usable for any azimuth or elevation without readjustment. This is not a complicated transformation; it requires only two additional potentiometers and is therefore justified in special cases.

$$\begin{aligned}E_{x'''} &= E_{x''}\cos\psi - E_{z''}\sin\psi,\\ E_{y'''} &= E_{y''},\\ E_{z'''} &= E_{x''}\sin\psi + E_{z''}\cos\psi.\end{aligned}$$

These equations can also be expressed as follows:

$$\begin{aligned}E_{x'''} = {} & \cos\psi(E_x\cos\phi - E_z\sin\phi)\\ & -\sin\psi[-E_y\sin\theta + \cos\theta(E_x\sin\phi + E_z\cos\phi)],\end{aligned}$$

$$E_{y'''} = E_y\cos\theta + \sin\theta(E_x\sin\phi + E_z\cos\phi),$$

$$\begin{aligned}E_{z'''} = {} & \sin\psi(E_x\cos\phi - E_z\sin\phi)\\ & +\cos\psi[-E_y\sin\theta + \cos\theta(E_x\sin\phi + E_z\cos\phi)].\end{aligned}$$

If one does not need such complete generality but still wishes the advantages of stereoscopic vision, a good approximation can be had with very simple apparatus. Even the sine-cosine resolving potentiometers become unnecessary.

Consider the case where both eyes look at a nearby object $P$ on the axis of vision as projected

Fig. 9. Variation of binocular convergence angle with object distance.

on a plane perpendicular to the axis (Fig. 9). The convergence angle $\alpha$ for this point is determined solely by the proximity of the object to the eyes. The projection that represents this convergence must move to the right for the left eye and to the left for the right eye. The amount of deviation of each projection for an object to appear at a distance $d-c$ is given by

$$\Delta=\frac{Sd}{2(d-c)},$$

where $\Delta$ represents a deflecting voltage for application to the two cathode-ray tubes as $X$ bias of opposite polarities.

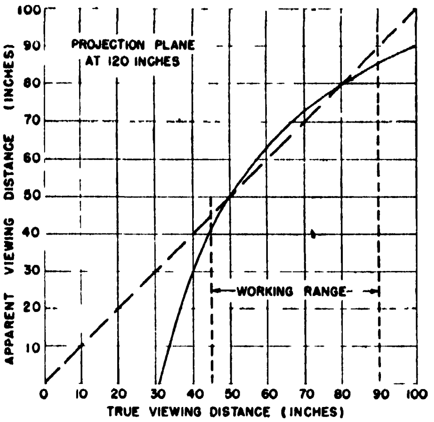

FIG. 10. Working range of simplified stereoscopic system.

$S$ is a d.c. voltage representing interocular distance and can be regarded as constant; $d$, as it multiplies $S$, can be represented exactly by a linear potentiometer on the distance-of-view shaft, working as a voltage divider on $S$. The factor of 2 is, of course, a mere scale factor.

Since $c$ is an instantaneous variable, it represents a reciprocal operation and requires a tube circuit; $d$, as it appears inside the parentheses with $c$ in the denominator, is applied as a d.c. bias to $c$. This quantity $(d-c)$ is already available from the perspective circuits, leaving only a reciprocal of a voltage to be taken. As before, this is accomplished by means of a non-linear tube circuit.

As a surprisingly good practical approximation in the case where the object field is not too deep or too close to the observer, a fraction of $(d-c)$, taken with reversed polarity and with a bias added, can be substituted for the reciprocal $1/(d-c)$. This apparently poor approximation works well because an error in the $\Delta$-voltage merely makes the object point appear stereoscopically a little nearer or farther than intended according to the perspective; this is an error that the eye can easily bear, as evidenced by its ability to understand perspective pictures on a flat sheet, where there is no correction at all. Figure 10 compares the apparent distance with the actual distance, using this simple stereoscopic system for a projection screen ten feet away and an object at various distances along the axis.

For objects off the axis the simplified stereoscopic method introduces small additional errors that increase as the object gets farther from the axis of view; however, these errors become important only for uncomfortably large angles of view.

If desired, the stereoscopic correction may be applied to simple projection data without the perspective correction. In this case the illusion of depth remains good, but objects seem to collapse as they approach and to expand as they recede in a very surprising manner.

In all these three-dimensional presentations the illusion is greatly enhanced if a few reference lines are sketched in to give the eye a comparison mesh with which to orient itself. There are many ways in which this can be done; one of the simplest is that of picture switching within the persistence period of the eye. It is relatively easy to commutate either mechanically or elec-

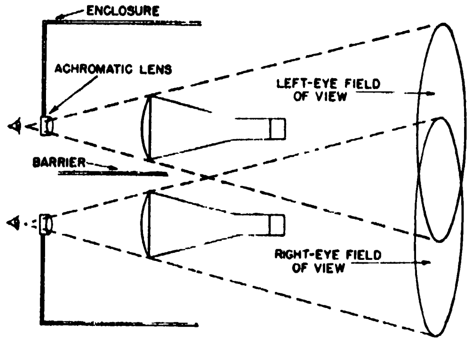

FIG. 11. Simple method for viewing stereoscopic images.

tronically between a sweep-circuit system and the picture data, and thus to draw in lines in any chosen direction and with any chosen spacing.

Though it is perfectly possible to superimpose such lines on the data, this may be difficult electronically in comparison with switching.

Again, it may be desired to measure the position of some intersection or other point in the picture space. This can be accomplished by a cursor system, using a calibrated set of controls to run a point or a line in a chosen orientation back and forth in the picture space.

The appearance on the market of multi-gun cathode-ray tubes offers an ideal solution to this problem of sketching in contour or grid lines, since it eliminates the need for any switching: with a two-gun tube, one gun paints in the data picture, and the other draws in the grid lines. Should one care to use the four-gun tube, the circuit is greatly simplified. Three of the guns can draw in three orthogonal coordinate-system grid lines in any of the conventional systems—Cartesian, polar, cylindrical—or even of the non-orthogonal systems.

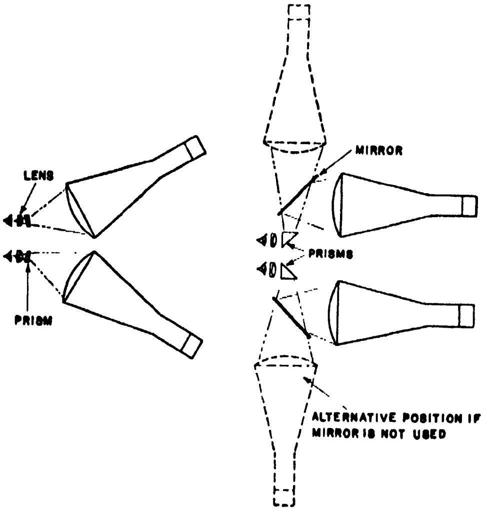

FIG. 12. Methods for viewing large cathode-ray tubes for stereoscopic presentation.

No special precautions need to be taken in viewing any of the monocular projections or the perspective pictures, whether they are viewed with one or with both eyes, since the eyes of a person used to reading such drawings are already completely conditioned to being deceived in these particular ways.

When viewing pictures that are mentally known to represent large objects, a little illusion is added by fitting the observer with positive lenses of sufficient strength to place the viewed image just short of infinity. Seeing the face of the cathode-ray tube and its mount does not weaken the illusion appreciably as it becomes part of the "drawing board."

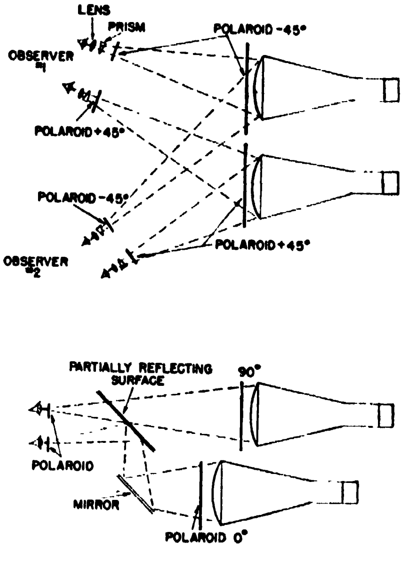

FIG. 13. (a) Use of Polaroid glasses to permit several observers to view stereoscopic presentation simultaneously; (b) Stereoscopic presentation for use in aircraft.

In contrast, data for stereoscopic viewing should be carefully presented to preserve the strong depth illusion of which this method is capable. The strength of stereoscopic reality found in the pictures varies markedly from observer to observer; airplane pilots, for example, are especially adept at perceiving it. That perception can be developed by learning is evident from the fact that a new observer seeing the stereoscopic CRO images for the first time may, if he is one of those least able to perceive the pictures, see almost no three-dimensional form to the images; however, after one hour of study, he will be able to see almost all the features. A very perceptive person will see all there is to see at first glance and will very likely be pointing out faults in the perspective rendition within five minutes.

Several satisfactory methods of viewing the stereoscopic images have been worked out. The simplest of these uses two small CRO tubes of diameter less than the interocular distance (Fig. 11). These tubes are viewed through simple achromatic lenses placed close to the eyes. The lenses make the tube face appear both at a distance and enlarged. An enclosure blocks out surrounding objects, and a partition prevents each eye from seeing the other's picture. This makeshift arrangement gives good results but permits seeing only such detail as can be presented on a three-inch tube. It also has the disadvantage that the eyes must be placed close to the viewing lenses.

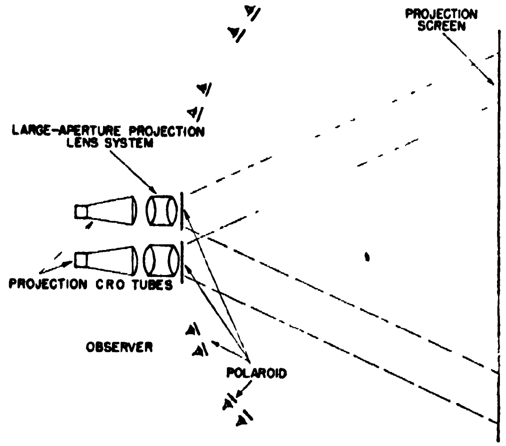

Fig. 14. Polarized projection for stereoscopic display.

If larger cathode-ray tubes are to be used, some optical arrangement must be made whereby each eye sees the center of one of the tubes directly ahead while the tubes are actually separated more than the interocular distance. Two of the easier ways of accomplishing this separation with prisms or mirrors are shown in Fig. 12.

By wearing Polaroid glasses it becomes possible to view the cathode-ray tubes over a reasonably wide angular range; consequently, several observers can see the presentation simultaneously (Fig. 13). If only the scopes are to be viewed, the observers can be fitted with prisms and enlarging lenses as well as Polaroids so that they can comfortably look at two tubes side by side and see them as superimposed because of the combined effect of the prism divergence and the Polaroid sorting out of the data. If this is undesirable, as in the case of data for an airplane pilot, the pictures can be shown superimposed with the aid of partially reflective surfaces. The Polaroid glasses are still worn but they do not interfere with ordinary vision.

Because of the selective reflection and transmission of plane polarized light by transparent sheets, proper choice of polarization plane will result in surprisingly little loss of light.

As a final and more elegant method, we may use polarized projection as a display means. Modern CRO projection techniques can provide a display several feet on an edge—a bright display that can be viewed by dozens of observers, each wearing ordinary 45° polarized Polaroid glasses (Fig. 14). By using highly directive projection screens, relatively little light is lost, and both images are displayed simultaneously on the same screen by simple polarization projection.

It is not my intention to enumerate here the many applications of three-dimensional cathode-ray presentation that can be made. I shall, however, list a few, chosen from widely separated fields, to illustrate its versatility.

The most general type of application is undoubtedly that in which three related quantities all vary simultaneously and where it is desired to visualize the whole complicated process. This visualization becomes especially important where the three interrelated quantities vary jointly as a function of still another parameter.

A case of this kind familiar to all of us is the common vacuum-tube characteristic. In its simplest three-variable form we have the co-variation of grid voltage, plate voltage, and plate current as one or more of them change in some chosen manner. Going to the more complicated case, we can present plate-current, plate-voltage, and grid-voltage data for a pentode or tetrode while we slowly change another parameter, say suppressor or screen voltage.

From the field of internal combustion or steam engineering we can take the case of the thermodynamic cycle. Here we can plot pressure, volume, and temperature together.

Acoustic engineers will, I am sure, find it instructive to plot the reactive and resistive components of loudspeaker impedance against frequency, thus giving in one easily photographed picture a good instantaneous summary of the device's over-all performance.

From the field of biophysics I would cite the advantages of plotting the entire set of heart potentials from the standard three cardiograph leads as a single space figure whose shape would characterize the patient's heart action. Similar thinking leads to a corresponding electro-encephalographic application.

For studying a.c. phenomena, both low frequency and high, the device is unusually useful. Non-linear components can be made to trace their current-voltage or reactance-resistance characteristics as a function of frequency, temperature, or other variable at will. Simultaneous plots of both complex impedance components as a function of frequency are a familiar need in the field of matching networks and filter design.

A three-dimensional cosmic-ray telescope could be built whose principal cost would be the set of Geiger counters.

The close relationship between the development of the theory of the three-dimensional oscilloscope and the theory of drafting leads one to wonder whether it might not profitably be put to work in the drafting room.

For presentation of radar- and sonar-type data, provision must obviously be made for supplying information in proper sequence, since it is impractical to scan all three-dimensional space. Thus, if we are scanning in elevation and azimuth by radar, we must be prepared, at the instant when the $x$ and $y$ coordinates correspond to the elevation and azimuth of a target, to supply the range to the $z$ circuit. Practicable pulse repetition frequencies do not permit scanning the $z$ axis in addition to the $x$ and $y$ axes. In the radar case, the advantages of the telescopic feature and the rotatable viewing position become obvious: for example, we could choose an optimum viewpoint to see whether planes were near a collision course.

Though it is true that three-dimensional television data can be transmitted by this system, real advantages would accrue only if the original data contained range information directly. Otherwise regular double-channel stereoscopic television has the advantage of simplicity.

From the antenna designer's viewpoint, one can see the elegance of the system as applied to presentation of a whole three-dimensional antenna radiation pattern visible in space, to be examined from any direction at will.

As a last example, I should like to propose the use of the system for exploration of electrostatic or magnetic fields. In this case a probe would be moved about in the field, and a "vector" on the oscilloscope screen would point out the direction and magnitude of the field at successive positions.

# A Least-Square Application to Relaxation Methods

O. L. Bowie
*Watertown Arsenal, Watertown, Massachusetts*

(Received April 24, 1947)

A least-square application to relaxation techniques is presented wherein the mean-square error is minimized in considering any corrections to a given set of values for the unknown function. A systematic procedure is, therefore, devised for weighting errors at various points of the lattice. The process has general applicability to various forms of equations and definitions of corresponding difference equations. As illustrations, Laplace's and the biharmonic equations are considered.

THE method of "relaxation" has recently come into prominence as a mathematical tool for overcoming the analytical difficulties encountered in the solution of partial differential equations from highly irregular shapes. Essentially, the differential equation is replaced* by a difference equation which may be solved either algebraically or by various iterative procedures. The iterative methods of solving the difference equation are known as relaxation techniques. It can be shown that if the mesh of the lattice used to cover the given region is made sufficiently fine, the solution of the difference equation approaches the solution of the original problem, and the difference quotients converge to the corresponding derivatives of the solution.

## I. A LEAST-SQUARES PROCEDURE

Consider the class of partial differential equations whose solutions have the additive property. That is, if $u_0$ and $u_1$ are solutions, then $(c_0u_0+c_1u_1)$ is also a solution where $c_0$ and $c_1$ are arbitrary constants. The same property will also hold for the solutions of the corresponding difference equations.

Let the given region be covered by a lattice. Then for defined points on the lattice, the differential equation can be replaced by a difference equation of the form

$$L(u_i)=0, \qquad (1)$$

where $u_i$ are the values of the function at the points of the lattice and $L(u_i)$ is a relationship valid for each $u_i$, which, in general, involves linear combinations of the $u_i$. If $L(u_i)=0$, for all $u_i$ of the lattice, and if the set of $u_i$ satisfies the original boundary conditions set up in a modified difference equation form, then the set of $u_i$ is a solution of the difference equation. In general, for a trial set, $\bar{u}_i$, it will be found that

$$L(\bar{u}_i)=p_i\neq 0. \qquad (2)$$

The $p_i$ are called the residuals and are defined for each point of the lattice. The relaxation procedure consists in altering the values of $u_i$ until $p_i\equiv 0$ for all $p_i$. In actual practice, sufficient accuracy is obtained by reducing the $p_i$ so that they are all nearly zero.

It should be noted that from the nature of $L(\bar{u}_i)$ an adjustment in $\bar{u}_i$ at a point will affect the values of $p_i$ at several points. The usual relaxation schemes (such as the Liebmann process) rely on smaller changes to the adjacent $p$'s as compared with the correction of $p_i$. It can be seen that the rate of convergence of relaxation methods will be speeded up if the correction of a $u_j$ is based on surrounding $p_i$ as well as on $p_j$. The following method which can be used for this purpose will now be presented.

Let the measure** of error of a given set of $\bar{u}_i$ over the whole lattice be defined as

$$\textstyle\sum_i [L(\bar{u}_i)]^2, \qquad (3)$$

where the summation extends over all the points of the lattice. The approximate solution, $\bar{u}_i$, will be chosen to satisfy the given boundary conditions. Now consider a second set of values, $\langle u_i\rangle$, such that $\bar{u}_i+c\langle u_i\rangle$ obeys the boundary conditions for any constant $c$. The question is now raised as to what value of $c$ will make the

---

* See reference 3.

** See reference 5.

total error a minimum for $\bar{u}_i+c\langle u_i\rangle$. Substituting into (3), one obtains for the total error

$$\sum_i [L(\bar{u}_i)+cL(\langle u_i\rangle)]^2. \qquad (4)$$

Differentiation with respect to $c$ yields for a minimum

$$c=-\sum_i L(\bar{u}_i)L(\langle u_i\rangle)/\sum_i [L(\langle u_i\rangle)]^2. \qquad (5)$$

For the criterion on the best correction in the sense of (3) to add to a single $\bar{u}_j$, one would choose a set of $\langle u_i\rangle$ identically zero at all points except at the single point corresponding to $\bar{u}_j$. The correction would be given by (5) if $\langle u_j\rangle=1$. Similarly, the best uniform correction to add to a group of the values of the function can be determined by (5). In this latter case, the set $\langle u_i\rangle$ again must be chosen so that $c\langle u_i\rangle+\bar{u}_i$ satisfies the boundary conditions for any arbitrary $c$. In addition, by defining $\langle u_i\rangle$ as identically equal to one at all points at which corrections are to be made and, otherwise, as identically equal to zero, the uniform correction, $c$, can again be determined by (5).

The procedure indicated in (4) and (5) is restrictive in the sense that it provides for only a uniform correction to the given set of $\bar{u}_i$. This is evidently an unnecessary restriction, for one can choose several sets of $\langle u_i\rangle$ with several corresponding arbitrary constants and again derive conditions on the arbitrary constants by referring back to (3). This, however, would involve the solution of a set of simultaneous equations and the simplicity of the form of (5) would be lost.

## II. APPLICATION TO LAPLACE'S EQUATION

The Dirichlet problem is that of finding a solution of Laplace's equation

$$(\partial^2 u/\partial x^2)+(\partial^2 u/\partial y^2)=0 \text{ in } R, \qquad (6)$$

where $u$ has specified values on the boundary of $R$. After $R$ is covered with a square lattice, then in rectangular coordinates and in terms of neighboring points the difference equation corresponding to (6) becomes a set of relationships in the form

$$L(u_0)=u_1+u_2+u_3+u_4-4u_0=0, \qquad (7)$$

where the notation is indicated in Fig. 1. One manner in which the $\bar{u}_0$ are adjusted so that the forms (7) are satisfied is to add iteratively to the quantities $\bar{u}_0$ the correction $\frac{1}{4}L(\bar{u}_0)$. The corrected $\bar{u}_0$ will then satisfy (7), to be sure, but $L(\bar{u}_1)$, $L(\bar{u}_2)$, $L(\bar{u}_3)$, and $L(\bar{u}_4)$ will be increased by an amount $\frac{1}{4}L(\bar{u}_0)$.

To illustrate the principle outlined in the first section, the criterion for the best correction will now be derived in terms of (7). The function $\langle u_i\rangle$ will thus be defined as unity at a single point and identically zero elsewhere. By (7) it is seen that $L(\langle u_i\rangle)$ has the values $-4$ at the point corresponding to the functional value of unity, 1 at four neighboring points, and zero elsewhere. A glance at Eq. (5) will show that for a single correction to $\bar{u}_0$ the best in the sense of (3) will be

$$c=-\frac{1}{20}[L(\bar{u}_1)+L(\bar{u}_2)+L(\bar{u}_3)+L(\bar{u}_4)-4L(\bar{u}_0)]. \qquad (8)$$

Formulae similar to (8) can likewise be obtained for a single correction to several of the functional values.

For corrections of points adjacent to the boundary, it is necessary to define in some manner values for $L(\bar{u}_i)$ at boundary points in order to use (8). Such a definition is somewhat arbitrary as it imposes more conditions on the set of simultaneous difference equations than there are unknowns. At the same time a wise choice of the definition is important to insure rapid convergence of the iterative process. In most cases, it is sufficient to modify the form of

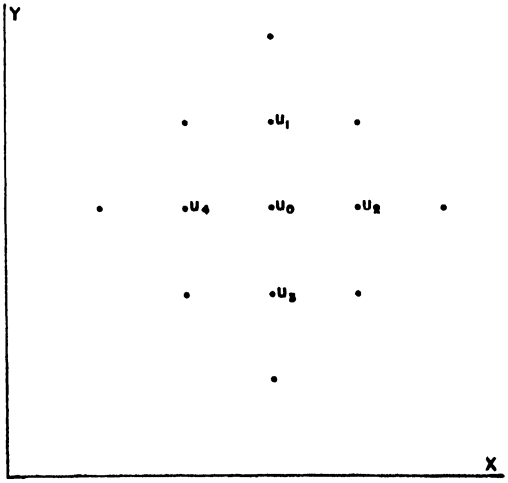

FIG. 1.

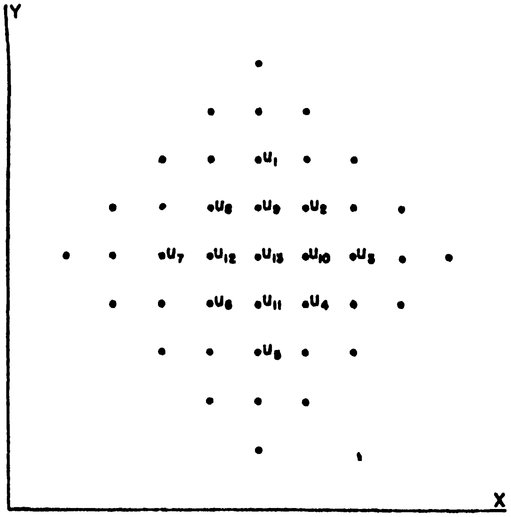

FIG. 2.

(7) by using forward differences when on the boundary. Then, during the process of iteration, a stage will be reached when the computer can vary the fictitious boundary $L(\bar{u}_i)$'s by visual inspection to speed the convergence.

It is interesting to note that a single correction based on (8) weights the values of $\bar{u}_i$ at the thirteen points shown in Fig. 1. Since the least-squares correction is based on adjacent residuals as well as the residual at the given point under consideration, it has a tendency to "smooth" the pattern of residuals. In general, this property has an advantage over usual "point by point" procedures. However, in some situations, the averaging effect slows down the rate of convergence. When the residuals are either predominantly positive or negative, the convergence is greatly speeded up by the larger corrections in the values of the function which one makes by using the usual "point by point" procedures. In practice, therefore, to obtain the full advantage of the least-square procedure, corrections should be made to the function at several points. It was found that a uniform correction, derived by the least-squares criterion, for small blocks of points proved very simple to handle and insured rapid convergence of the solution. For use of the least-squares method in the solution of the Dirichlet problem, therefore, it is recommended that the uniform correction to simple-shaped blocks of points be used in conjunction with the single-point correction.

## III. APPLICATION TO THE BIHARMONIC EQUATION

The biharmonic problem involves the solution of the equation

$$[\partial^4 u(x,y)/\partial x^4]+2[\partial^4 u(x,y)/\partial x^2\partial y^2]+[\partial^4 u(x,y)/\partial y^4]=0 \text{ in } R, \quad (9)$$

subject to specified values of $u$ and certain of its derivatives on the boundary of $R$. In terms of a square lattice of points, the difference equations involve thirteen points for each point of the lattice. With the notation of Fig. 2, the difference equations are in the form

$$L(u_{13})=(u_1+u_3+u_5+u_7)+2(u_2+u_4+u_6+u_8)-8(u_9+u_{10}+u_{11}+u_{12})+20u_{13}=0. \quad (10)$$

From Eq. (5) it is seen that for a single correction to $\bar{u}_{13}$ the best in the sense of (3) will be

$$c=-\frac{1}{676}\{[L(\bar{u}_1)+L(\bar{u}_3)+L(\bar{u}_5)+L(\bar{u}_7)]+2[L(\bar{u}_2)+L(\bar{u}_4)+L(\bar{u}_6)+L(\bar{u}_8)]-8[L(\bar{u}_9)+L(\bar{u}_{10})+L(\bar{u}_{11})+L(\bar{u}_{12})]+20L(\bar{u}_{13})\}. \quad (11)$$

Similarly, formulae for corrections to blocks of values of the function can be derived. Definitions must be set up for values of $L(u_i)$ where the lattice points are boundary points or points adjacent to the boundary. These may be set up by use of forward differences as in the previous section and adjusted as the computation progresses.

To obtain the full advantage of the least-squares procedure in the solution of the biharmonic equation, it is recommended that the uniform correction to simple-shaped blocks of points be used in conjunction with the single-point correction.

## IV. DISCUSSION

The principle outlined in Section I can be applied to relaxation procedures involved in the solution of general types of equations of physics. The forms $L(u_i)=0$, themselves, may be defined in many ways. The difference equation may be set up using higher ordered differences, or differences using diagonal neighbors. A non-homogeneous equation can be likewise treated by suitably defining $L(u_i)=0$. In general, the form of $L(u_i)$ should be chosen from the standpoint of the amount of weighting of errors possible with a minimum of calculation.

Although only a single-point correction has been explicitly derived in Sections II and III, the process for deriving similar formulae for corrections to blocks of points has been outlined. It would seem, in general, that such formulae for blocks of points should be derived only for the case of a uniform correction. More elaborate considerations would necessarily complicate the form of the correction formula.

Preliminary tests of this least-squares procedure have been found quite satisfactory when combining uniform corrections to blocks of points with single-point corrections. The advantage over usual "point by point" procedures increases as the process continues.

# An X-Ray Diffraction Study of the Silver-Magnesium Alloy System

HAROLD R. LETNER* AND S. S. SIDHU**

*Department of Physics, University of Pittsburgh, Pittsburgh, Pennsylvania*

(Received April 29, 1947)

Four homogeneous solid solutions were found in the silver-magnesium alloy system. The $\alpha$-primary solid solution of magnesium in silver has a f.c.c. structure. The $\beta$-solid solution has a b.c.c. structure. The $\gamma$-solid solution appears to have a complicated structure. While others have identified it as hexagonal, no definite structure could be assigned to it from our diffraction data. The $\delta$-solid solution has a h.c.p. structure of magnesium.

The lattic parameter $a_0$ in the $\alpha$-solid solution increases with increasing magnesium concentration but exhibits a marked negative deviation from Vegard's Law. The $a_0$ in the $\beta$-solid solution, however, increases linearly with increasing magnesium concentration.

Silver and magnesium atoms are distributed at random in the $\alpha$-phase but take up preferred positions in the $\beta$-phase. The ordering process takes place throughout the $\beta$-phase, but is most nearly complete in the region of 50 atomic percent Mg.

## INTRODUCTION

THE Ag-Mg alloy system presents an interesting crystal structure problem in that Ag is known to have a face-centered cubic (f.c.c.) structure, while Mg is hexagonal close-packed (h.c.p.). Ag, atomic number 47, is monovalent and has an atomic radius of 1.44 angstrom units (A); Mg, atomic number 12, is divalent and has an atomic radius of 1.60A.[1] The purpose of the present work was to study by x-ray diffraction methods the changes which take place in the structure of Ag as Mg atoms are added to its lattice.

The phase equilibrium diagram of the Ag-Mg system was first determined by Zemczuznyj.[2] Subsequent investigations were carried out by Saeftel and Sachs,[3,4] Payne and Haughton,[5]

## EXPERIMENTAL PROCEDURE

Fifteen alloys having compositions indicated in Fig. 1 were prepared in an automatically temperature-controlled electric furnace under a commercial flux obtained from the Dow Chemical Company. Upon completion of the melting process, the resulting ingots, weighing approximately 50 grams each, were allowed to cool in the furnace. The cooling rate in the solidifying range of the alloys was approximately 3C° per minute.

Samples of filings were removed from the centers of the ingots with specially cleaned iron files and placed in evacuated hard glass tubes. After annealing for five hours at 525°C to remove mechanical strains set up in the crystal lattice by the filing process, the samples were analyzed chemically for both Ag and Mg. Portions of the

same samples were used in making powder x-ray-diffraction photograms to insure that the compositions of the filings used for diffraction studies and those used for chemical analyses were identical.[11]

Powder x-ray diffraction photograms were made with filtered Cu $K_\alpha$ radiation using a camera of 57.3-mm diameter. Lattice parameters for the f.c.c. and b.c.c. structures were calculated from the relation:

$$a_0=\frac{n\lambda}{2\sin\theta}(h^2+k^2+l^2)^{\frac{1}{2}},\qquad(1)$$

where $a_0$ is the lattice parameter (i.e., the cube edge of the unit cell), $n$ is the order of the diffracted ray, $\lambda$ is the wave-length of the radiation used, $h\,k\,l$ are the Miller indices of the planes contributing to the diffracted ray, and $\theta$ is the angle between the incident x-ray beam and the diffracting planes. Lattice parameters for the h.c.p. structure were calculated from the corresponding expression:

$$a_0=\frac{n\lambda}{2\sin\theta}(4/3(h^2+hk+k^2)+(l/c)^2)^{\frac{1}{2}},\qquad(2)$$

where $a_0$ and $c_0$ are the lattice parameters, and $c=c_0/a_0$ is the axial ratio.

Values of $\theta$ were obtained directly from the photograms by measuring the spans between corresponding lies of the diffraction pattern.[12] From these values the lattice parameters were calculated by means of Eqs. (1) or (2) and plotted against $\cot\theta$. The resulting curves were extrapolated to $\cot\theta=0$ to obtain final values of the lattice parameters, since the percentage error approaches zero as $\theta$ approaches 90°.[13-15]

The relative intensities of the diffraction lines were estimated and tabulated simultaneously with the lattice parameter measurements. Photograms of alloys containing the α- and β-phases were scrutinized for superstructure lines. For the α-phase, this amounted to a search for lines corresponding to reflecting planes having Miller indices $h\,k\,l$ which are mixed odd and even integers and for the β-phase, lines corresponding to planes for which the sums of the Miller

indices $h+k+l$ are odd integers.[16–18] No satisfactory analysis could be made for superstructure in the γ- and δ-phases because of the large number of extremely weak lines obtained on the photograms.

## EXPERIMENTAL RESULTS

### A. Phases and Phase Boundaries

Four types of crystal structure were found to exist in the Ag-Mg alloys investigated. These were a f.c.c. structure corresponding to the α-phase, a b.c.c. structure corresponding to the β-phase, an undetermined structure corresponding to the γ-phase and a h.c.p. phase belonging to the δ-phase. (See Fig. 1.) Attempts to determine the structure of the γ-phase were not successful; photograms of alloys containing this phase showed a multiplicity of very faint and indistinct lines. Ageew and Kuznezow have identified the structure as hexagonal.[8] X-ray photograms of the diffraction patterns corresponding to the various structures found are shown in Figs. 2–4.

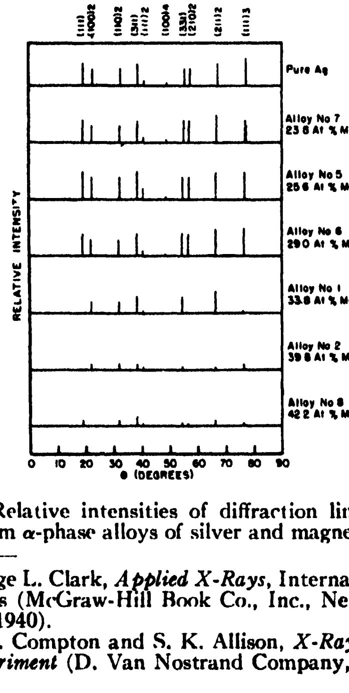

FIG. 7. Relative intensities of diffraction lines obtained from α-phase alloys of silver and magnesium.

Although no attempt was made to determine accurately phase boundaries, one point in this connection seems worthy of mention. Alloy No. 6 having a composition of 29.0 atomic percent Mg should, according to the phase equilibrium diagram in Fig. 1, contain both α- and β-phases. The photogram of this alloy, Fig. 2, shows only the f.c.c. lines of the α-phase. Similarly, alloy No. 8, also Fig. 2, having a composition of 42.2 atomic percent Mg, should contain only the β-phase according to Fig. 1. The photogram of this alloy shows unmistakably the f.c.c. and b.c.c. lines corresponding to both the α- and β-phases. Thus, while there is general agreement with the results of Zemczuznyj, the limited data available from the present work indicate that the

boundaries of the two-phase region between the $\alpha$- and $\beta$-phases are not straight lines of constant composition as shown in Fig. 1 but are slightly displaced toward the Mg-rich end of the diagram.

### B. Lattice Parameters

The lattice parameter $a_{0\alpha}$ varies with composition as shown in Fig. 5. The distribution of the alloy compositions studied does not permit the drawing of a complete curve for the entire phase; however, it is obvious that only a curve exhibiting a negative deviation from the linear relationship required by Vegard's law will fit the points obtained. This result is at variance with the work of Ageew and Kuznezow[8] who found that the lattice parameter increases linearly with increasing Mg content.

Within the precision of measurement, alloys of the $\beta$-phase show a linear variation of the lattice parameter $a_{0\beta}$ with change in composition. Rather wide discrepancies appear among alloys 1, 2, and 8 containing both the $\alpha$- and $\beta$-solid solutions, all of which should have the same value of $a_{0\beta}$. In Fig. 6 the value chosen for $a_{0\beta}$ in the two-phase region is the arithmetic mean of the values for the three alloys. The resulting phase-boundary discontinuity, indicated by the dashed line, lies well to the Mg-rich side of alloy No. 8 as previously mentioned.

The indistinctness of the diffraction lines on photograms containing the $\gamma$-phase rendered impractical any attempt to observe lattice parameter variations in alloys 13, 14, 16, and 17. The lattice parameters of pure Mg were found to be $a_0=3.202$A and $c_0=5.199$A, in agreement with accepted values.

### C. Superstructure

Photograms of alloys containing the $\alpha$-phase show no evidence of superstructure. Figure 7 shows the relative intensities of all the diffraction lines observed on the photograms of each of the $\alpha$-phase alloys. It will be noted that all of the lines correspond to reflections from planes which have either all odd or all even Miller indices; i.e., the (111), (100)2, (110)2, (311), (111)2, (100)4, (331), (210)2, (211)2, and (111)3 planes.

Photograms of the $\beta$-phase alloys, on the other hand, contain unmistakable evidence of superstructure lines. In Fig. 8 it will be noted that not only are lines corresponding to even values of the sum $h+k+l$ present, but relatively strong lines corresponding to odd values are also present. If the distribution of Ag and Mg atoms in the b.c.c. lattice were random, lines corresponding to the (100), (111), (210), (221), (311), (320), (322), and (410) planes would not appear on the photograms. Hence it is quite evident that the Ag and Mg atoms take up preferred positions in the $\beta$-solid solution to form an ordered structure. Comparison of superstructure lines corresponding to the various $\beta$-phase alloys reveals that they are strongest near the middle of the $\beta$-phase, indicating that the segregation of the Ag and Mg atoms into cube centers and cube corners is most nearly complete when equal numbers of each atom are available; i.e., in the region of 50 atomic percent Mg.

# Preliminary Analysis of Microwave Transmission Data Obtained on the San Diego Coast Under Conditions of a Surface Duct

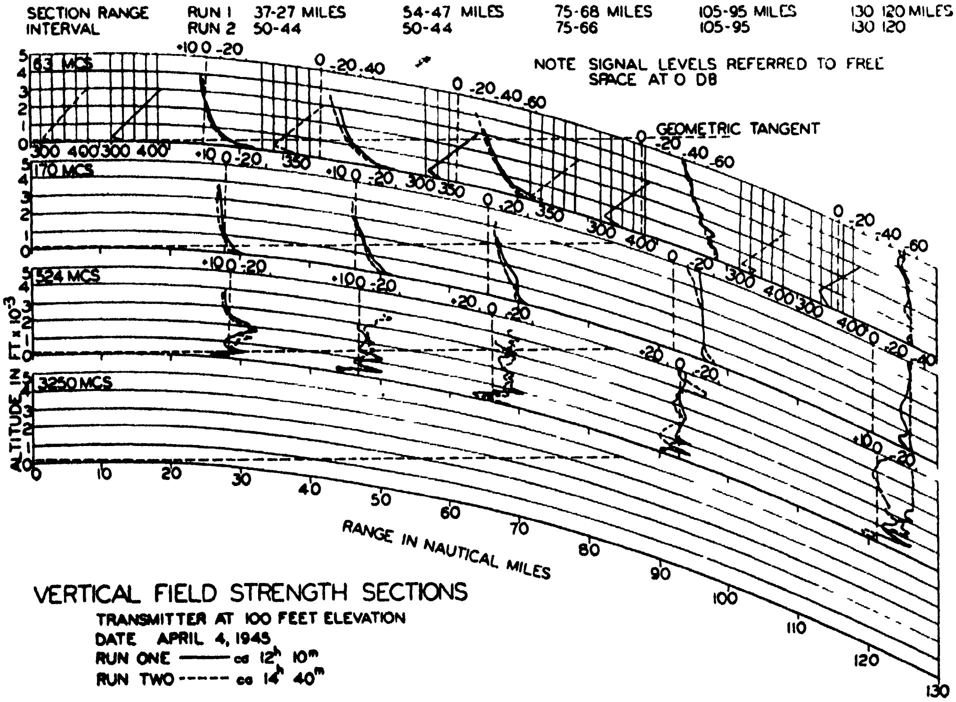
C. L. Pekeris* and M. E. Davis**

(Received May 6, 1947)

The transmission data for 63 Mc and 170 Mc obtained by the U.S.N.E.L. on the San Diego coast on April 4, 1945, when a strong duct was formed near the ground, were analyzed by wave theory. The average observed $M$-curve was fitted with a linear-exponential term, and the electromagnetic field beyond the horizon was computed by the theory of normal modes. Good agreement between theory and experiment was obtained for both frequencies at a range of 32 miles (see Figs. 7 and 8). In the ranges between 32 and about 70 miles the observed variation of intensity with height agrees with theory, but the theoretical horizontal decrement is less than the observed by about 0.1 d.b./n. mile for 63 Mc, and by about 0.2 d.b./n. mile for 170 Mc. Beyond about 80 miles the observed field tends to assume a uniform distribution with height and shows little horizontal attenuation. Such an effect had been observed by the U.S.N.R.L. expedition to Antigua for 9-cm waves under conditions of an oceanic surface duct. Its interpretation is still wanting.

## 1. INTRODUCTION

In this paper is given a preliminary analysis of transmission data for 63 Mc and 170 Mc obtained by the U.S.N.E.L. along the San Diego coast under atmospheric refraction conditions which produce a so-called surface duct. The set-



Note: Run 2 should read 37–27 instead of 50–44.

up of the experiment and the observed $M$-curves, as well as the measured cross sections of field intensity at various ranges from the transmitter are shown in Fig. 1. The average observed $M$-values based on 12 soundings are shown by curve $A$ in Fig. 2. Of the 12 soundings, the two taken at the maximum range of 115 miles deviate markedly from the others; another of the soundings taken about 2 hours before the experiment at a range of 10 miles also appears anomalous. This may be caused by both spacial and temporal variation of the $M$-curves. Leaving out these three soundings one obtains an average $M$-curve shown by curve $B$ of Fig. 2.

Taking the $M$-curve $B$ as characteristic of the average atmospheric refraction condition over the relevant portion of the transmission path, we attempt to represent it by a linear-exponential term. Various such representations are shown in Fig. 3, with curve $E$ appearing to give the best fit. This theoretical curve has a surface value for $(M-M_0)$ of 72.3, which is probably considerably in excess of the actual value. However, as has been pointed out by Professor Hartree, transmission is not seriously affected by the detailed distribution of $M$ near the surface because of the vanishing of the field intensity at the surface.

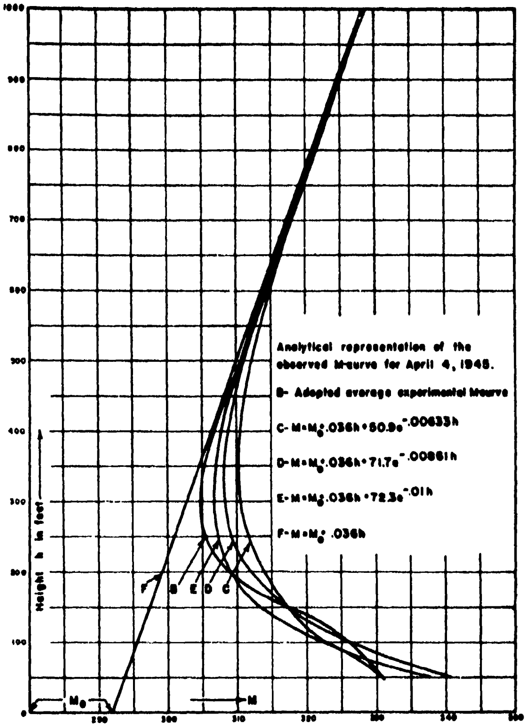

FIG. 3.

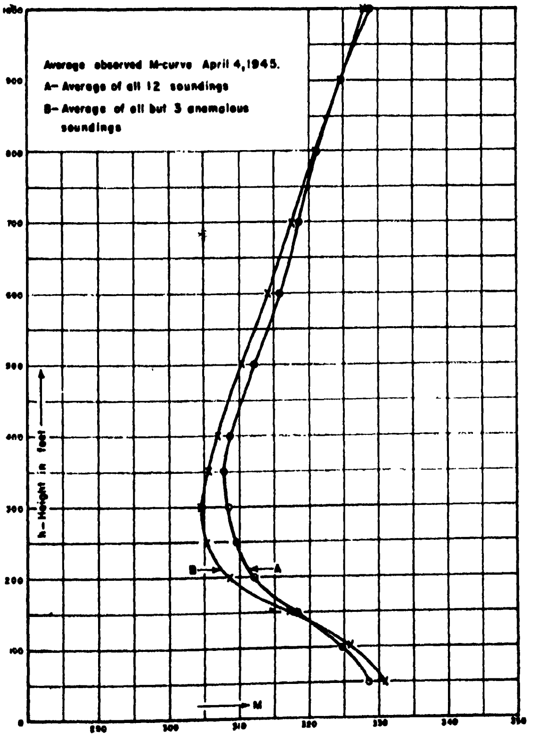

FIG. 2.

The surface duct under discussion, as represented by curve $E$

$$M = M_0 + 0.036h + 72.3e^{-0.01h}, \qquad (1)$$

with its surface $M$, excess of 72.3, and duct height of 300 feet is to be contrasted with curve $C'$ of the Antigua oceanic surface duct previously analyzed,[1]

$$M = M_0 + 0.036h + 12.06e^{-0.0714h}, \qquad (2)$$

where the surface $M$, excess, and duct height had values of only 12.06 and 45 feet, respectively. It is therefore of interest to test how wave theory can predict the electromagnetic field under such vastly different conditions. It turns out that when expressed in natural units, curve $E$ for 170 Mc (176 cm) is close to curve $C'$ for 9 cm, that is, the San Diego duct had about the same trapping power for 176 cm waves as the Antigua duct[2] had for 9 cm waves.

TABLE I. Data for 63 Mc, $\lambda=476$ cm, $H=442$ feet, $L=25.8$ n. miles. Curves $C$, $D$, and $E$ are shown in Fig. 3.

| Curve | $\alpha$ | $\lambda$ | $D_1$ | Theor. decrement d.b./n. mile | Obs. decrement d.b./n. mile | Obs. decrement range miles |
|---|---|---|---|---|---|---|
| $C$ | 3.21 | 2.80 | $-1.03+1.82i$ | 0.61 | 0.79 | 32 71 |
| $D$ | 4.52 | 3.80 | $-1.02+1.88i$ | 0.63 | 0.73 | 32–100 |
| $E$ | 4.56 | 4.42 | $-0.99+1.98i$ | 0.67 | 0.66 | 71–100 |

## 2. ANALYSIS OF THE FIELD BY THE THEORY OF NORMAL MODES

According to the theory of normal modes, the field $FS$ relative to free space, due to a dipole radiating in a horizontally stratified atmosphere is given by[1]

$$FS=20\log_{10}\left[2(\pi x)^{\frac{1}{2}}\left|\sum_{m=1}^{\infty}e^{-A_m x+iB_m x}U_m(z_1)U_m(z_2)\right|\right]\text{d.b.}\quad(3)$$

Here $x$ denotes horizontal distance from transmitter expressed in natural units $L$, $z_1$, and $z_2$ the heights of transmitter and receiver above ground expressed in natural units $H$, where

$$L=3.304\lambda^{\frac{1}{3}}\text{ n. miles},\quad H=7.243\lambda^{\frac{2}{3}}\text{ feet},\quad(4)$$

and $\lambda$ is the wave-length in centimeters. The height-gain functions $U_m(z)$ and the characteristic constants $A_m$ and $B_m$ can be computed by known methods[2] for the case of the linear-exponential $M$-curve given in Eq. (1). These depend on the values of the parameters $a$ and $c$ in the expression

$$M=M_0+0.036h+ae^{-ch}.\quad(5)$$

Again, it is convenient to use instead of $a$ and $c$ the natural parameters

$$\alpha=3.85a\lambda^{-\frac{1}{3}},\quad \lambda^{***}=Hc,\quad(6)$$

whereby the exponential term in (5) is transformed into $\alpha e^{-\lambda z}$.

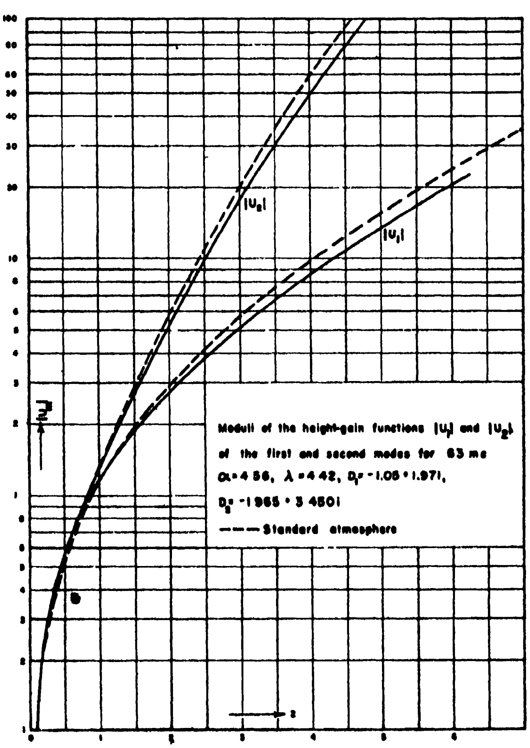

FIG. 4.

Tables I and II show the results of the analysis for the 63 Mc and 170 Mc, respectively. The characteristic values $D_1=B_1+iA_1$ of the first mode were obtained by interpolation from the values given in reference (3).[3] In the case of curve $E$ and 63 Mc the value of $D_1$ shown in Table I required extrapolation beyond the maximum value of 4 for $\lambda$ treated in reference (3). As a check, $D_1$ was recomputed by the perturbation method and a value of $-1.05+1.97i$ was obtained. This method also yielded a convergent value for $U_1(0)$ of $-0.043+1.17i$. With these constants the differential equation for the height-gain function of the first mode $U_1(z)$

$$\frac{d^2U(z)}{dz^2}+Q(z)U(z)=0,\quad Q(z)=z+D+\alpha e^{-\lambda z}\quad(7)$$

was integrated using an interval $\Delta z=0.1$ and the

TABLE II. Data for 170 Mc, $\lambda=176$ cm, $H=228$ feet, $L=18.5$ n. miles.

| Curve | $\alpha$ | $\lambda$ | $D_1$ | Theor. decrement d.b./n. mile | Obs. decrement d.b./n. mile | Obs. decrement range miles |
|---|---|---|---|---|---|---|
| $C$ | 6.23 | 1 44 | $-1\ 84+0.69i$ | 0.32 | 0.61 | 32–71 |
| $D$ | 8.77 | 1.96 | $-1.48+0\ 72i$ | 0.34 | 0.41 | 32 100 |
| $E$ | 8.84 | 2.28 | $-1.22+0\ 94i$ | 0.44 | 0.17 | 71–100 |

---

*** Not to be confused with the $\lambda$ in (4) which denotes wave-length.

recursion formula

$$\left[1+\frac{(\Delta z)^2Q_1}{12}\right]U_1=2U_0-U_{-1}$$
$$-\frac{(\Delta z)^2}{12}(10U_0Q_0+U_{-1}Q_{-1}),\quad (8)$$

which is correct to within $[(\Delta z)^2/240]\delta^4(QU)$, where $\delta^4$ denotes the fourth difference. The perturbation method also gives for the second mode $D_2=-1.965+3.450i$, $U'_2(0)=0.041+1.084i$, and these were used to obtain $U_2(z)$ by (7) and (8). The results for the first two modes are shown in Figs. 4 and 5. Clearly, for 63 Mc the trapping of the modes is small, so that for the application in view it would have been sufficient to use the solutions for a standard atmosphere.

In the case of 170 Mc and curve *E*, values of $D_1=-1.22+0.94i$ and $U'_1(0)=1.14+1.04i$ were obtained by interpolation from the "method II" values tabulated in reference (3). With these, the height-gain function $U_1(z)$ was integrated using (7) and (8), and the result is shown in Fig. 6. Here the trapping is considerable, the theoretical decrement being less than half the standard value. From the perturbation method one obtains the approximate values $D_2=-2.01+3.12i$, $U'_2(0)=-0.36+1.05i$.

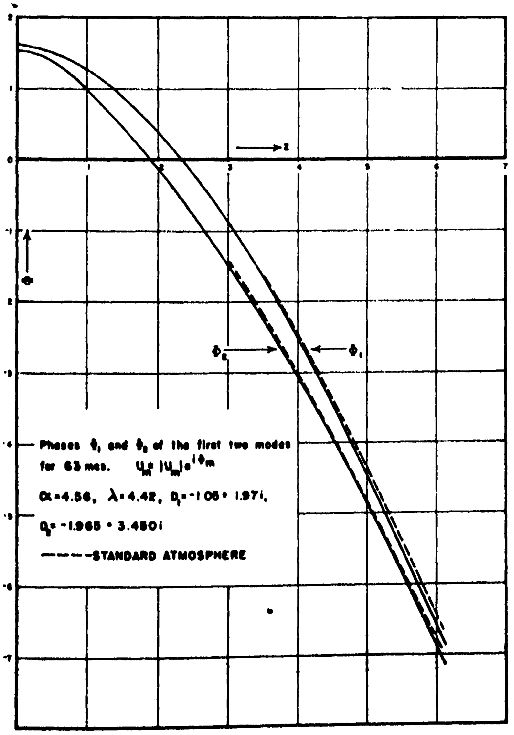

FIG. 5.

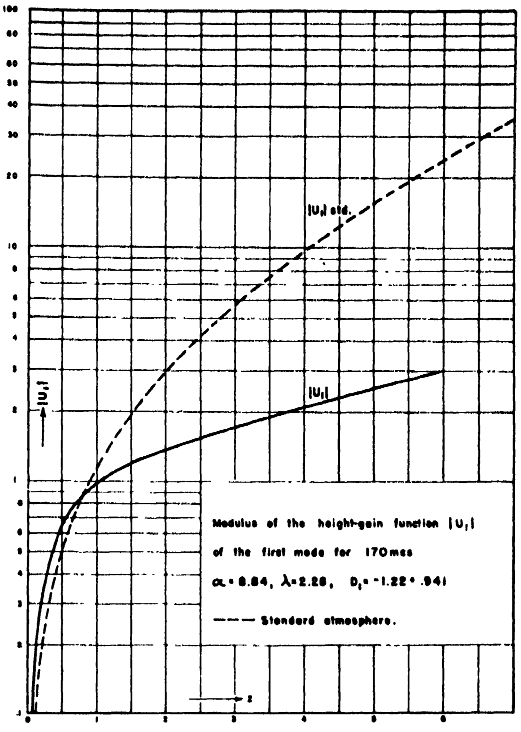

FIG. 6.

### 3. DISCUSSION OF RESULTS

Figure 7 shows a comparison of observed field intensities relative to free space with theoretical. The first two modes were used in the calculations, and where the second mode contributed more than 50 percent to the total field the theoretical curves were terminated. The observed increase of intensity with height, as well as the detailed distribution of intensity with height, shows satisfactory agreement with theory out to a range of 71 miles, but the observed decrement is greater than the theoretical (which is close to the standard value) by about 0.1 d.b./n. mile. In the case of 170 Mc shown in Fig. 8 there is again good agreement at a range of 32 n. miles, and satisfactory agreement in the variation of intensity with height out to 49 n. miles. The observed

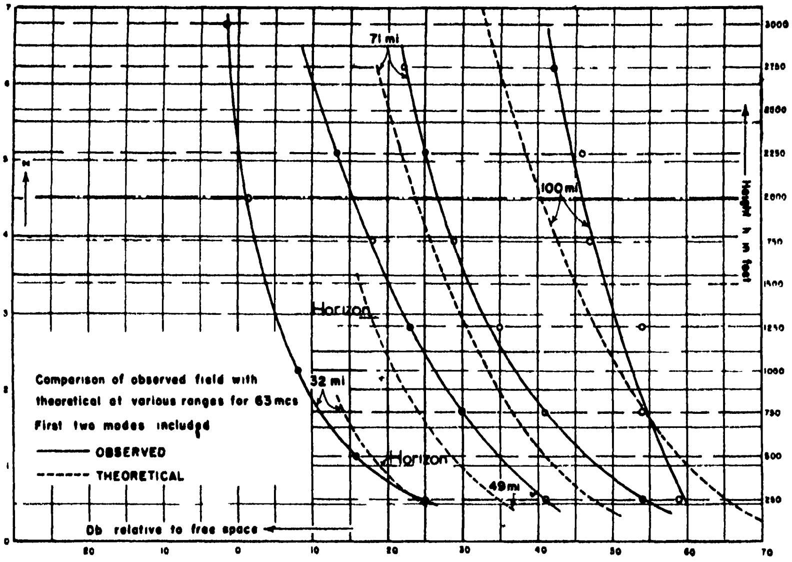

FIG. 7.

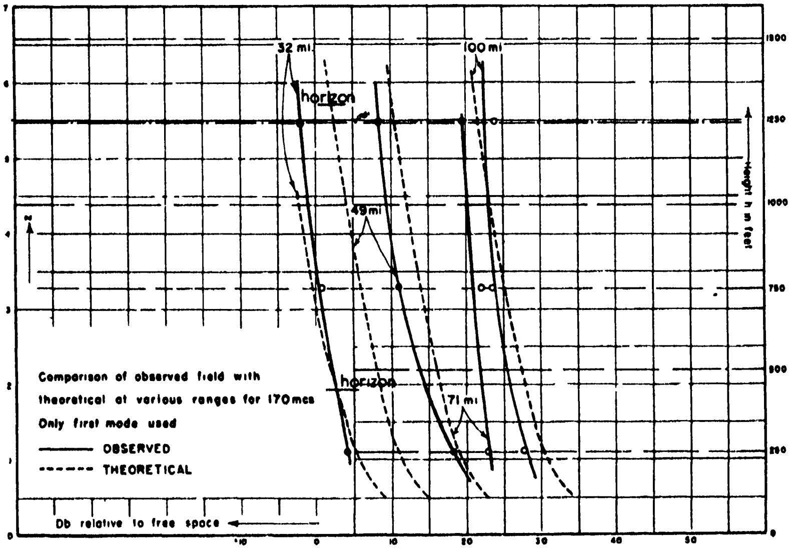

FIG. 8.

decrement, however, while only 0.7 of standard, exceeds the theoretical value by about 0.3 d.b./n. mile at this range.

It is possible that a weaker surface duct than the one adopted in this preliminary analysis would bring the theoretical decrements to closer agreement with observation, while not materially affecting the shape of the height-gain curve. Part of the excessive observed attenuation no doubt originates from scattering by inhomogeneities in the atmosphere. However, the tendency of the observed field to assume a uniform distribution with height, with little horizontal attenuation beyond about 70 miles, is probably an effect which cannot be accounted for by the present formulation of the normal mode theory.

## Modified Cavity Oscillator for the Generation of Microwaves

GEORGE G. BRUCK
*Specialties, Inc., Syosset, New York*
March 13, 1947

THE cavity consists of two co-axial cylinders and two end-plates. $N$ longitudinal slots in the wall of the inner cylinder are used to create the proper type of field. This layout resembles the well-known "turbator." A qualitative picture of the field can be given easily although an exact calculation is rather laborious. Figure 1 shows a probable aspect related to the $\pi$-mode of the magnetron. Figure 2 is a probable configuration similar to the $TE_{01}$ mode of a cylindrical guide.

Electrons may be made to describe circular orbits in the region between the two cylinders by applying a positive potential to the inner one. As in the orbital beam tube (RCA) there is no need for a magnetic field. Because of progressive sorting, $N$-electron clouds are formed. This is explained in the following way: the fringing field near the slots has an electric component in the direction of the flight-path of the electrons. This component of the field accelerates or decelerates the electrons. The accelerated ones, which absorb energy from the field, fly outward, while the decelerated ones, which give up energy to the field, approach the inner cylinder because of loss in velocity. At the following slot the unfavorable electrons, the faster ones, pass through a weaker fringing field than the favorable ones. They extract less energy from the field than the favorable ones are adding to it. The effect obtained is quite pronounced because the intensity of the fringing field declines exponentially with the distance from the slot. The in-phase electrons spiral inward. The out-of-phase electrons spiral outward. There exists an added tendency of proper phasing because of the difference in path length for the fast and slow electrons. The angular displacement required to give proper phasing can be progressively approached by the faster electrons because of the increasing radius of their orbit.

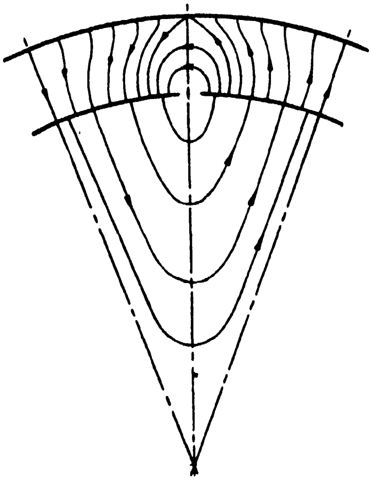

FIG. 1. Probable electric field $\pi$-mode.

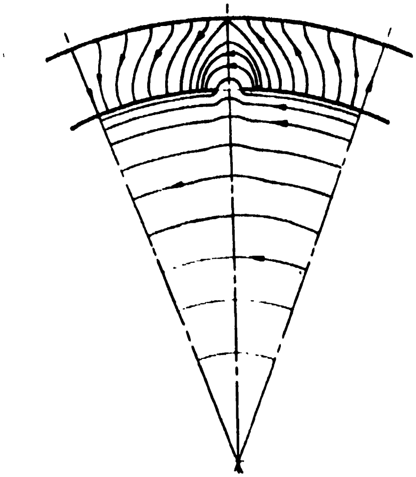

FIG. 2. Probable electric field corresponding to $TE_{01}$ mode.

The cathode and accelerating grid are both parallel to the cylinder axis. Their location is such as to create minimum interference with the orbits of the electron. There are no slots provided in their immediate neighborhood (Fig. 3). The voltage on the accelerating grid is related to the potential between the inner and outer cylinders in order to produce initially circular orbits.

Microwave power is extracted from the inner cavity by any approved method probe, loop, or window.

For modes of the $TE_{01}$ type, the cavity may be split along a plane, perpendicular to the axis. This permits the insertion of a dielectric vacuum-tight window and location of the electron stream in the sealed and evacuated part. The output iris and simple means for frequency adjustment are located in the non-evacuated section.

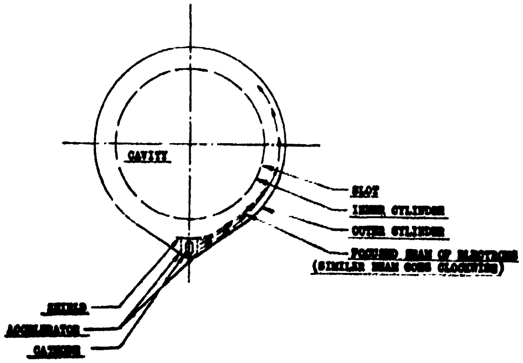

FIG. 3. Potential distribution: cathode, shield, outer cylinder . . . negative; accelerator, inner cylinder . . . positive.

No evaluation of the specific properties of this tube has as yet been made. It is anticipated that high output at higher frequencies will be obtainable, particularly above 30 kmc. It is further believed that this type of oscillator may be made to work at frequencies exceeding 100 kmc.

## Particle "Growth" in the Electron Microscope

V. E. COSSLETT*
*Cavendish Laboratory, Cambridge, England*
June 9, 1947

IT has recently been observed by Watson[1] that carbon black particles appear to increase in size when used as objects in an electron microscope. He rightly stresses the importance of this disturbing effect in particle-size determinations, and calls for an exchange of experience in order to clear it up.

We observed a similar effect some months since with the smallest zinc-oxide crystals obtainable by burning zinc in air in a coal-gas flame (see Fig. 1); they were being used as test specimens in investigating the performance of a Siemens electron microscope. We have now obtained similar results with zinc, molybdenum, and magnesium oxides in the RCA Type-B microscope. Figure 2 shows a typical series of photographs from zinc oxide supported on an RCA nickel grid. Plates (a), (c), and (e) were taken at intervals of 2 minutes after bringing the needles into the field of view, in critical illumination, i.e., with the source imaged on the specimen, which was thus exposed to maximum energy flux. Plate (b) is of a field lying within 10 microns of that first examined, and plate (d) is of a field lying on the opposite side of the grid hole containing these two fields, i.e., about 75 microns from them and outside the focused image of the source. It is clear that the effect is confined to the region covered by the latter, and its very immediate neighborhood.

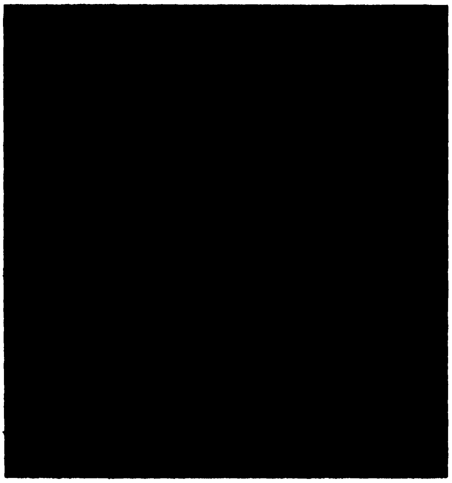

FIG. 1. Zinc-oxide smoke particles (20,000×) after *ca.* 3-minutes exposure to electron beam in Siemens electron microscope (on nickel grid).

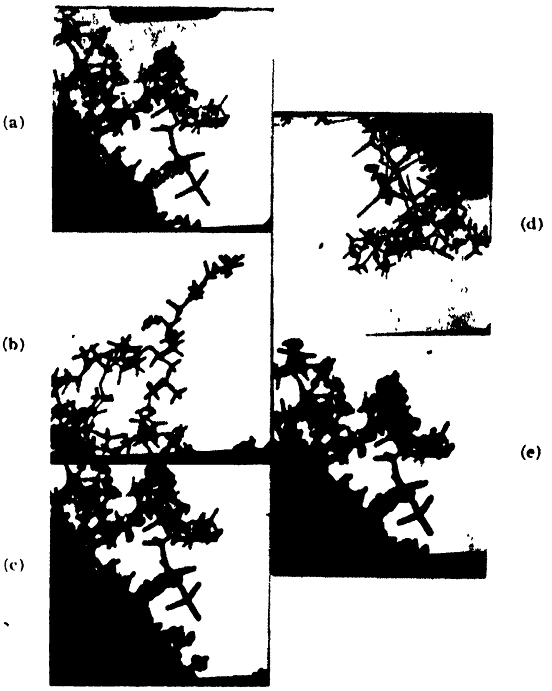

FIG. 2. Zinc-oxide smoke particles in RCA Type B electron microscope 12,000× (on nickel grid).

a. After *ca.* 2 minutes in beam.
b. Adjacent field to (a) (within 10μ), after *ca.* 3 minutes in beam.
c. Field (a) after a further 2 minutes in beam.
d. Field *ca.* 75μ distant from field (a).
e. Field (a) after a further 2 minutes in beam.

Observation of crystals supported on long chains of their like from the opposite side of a grid hole, or by adventitious, loosely-adhering material on the near side, shows that such growth does not occur when there is a poorly conducting path between specimen and grid. Watson found little effect on particles supported in the center of a grid space on a collodion film, but considerable effect after shadowing with chromium. We find little effect at all in such supported specimens, wherever they be with respect to the grid, and no enhancing influence of a thick gold deposit (*ca.* 100 atomic layers). This is of importance for the estimation of the size of virus and 'phage particles, which cannot be observed otherwise than on a supporting film. We have not been able to find any increase in size of gold-shadowed turnip virus particles, nor of the flagella of bacteria, after exposures in the beam up to 10 minutes.

In contradistinction to Watson, who suggests that the growth arises from the deposition of organic material from the vapor state in the form of ion clusters, we incline to the view that the effect is due to ejection of adsorbed matter, and perhaps of metal itself, from the grid wires under electron bombardment. The local temperature, since the beam image is of the order of 10 microns only in diameter, will be very high and may well reach 1000°C; in the Siemens microscope it is possible to fuse the nickel grid if the filament is a little over-run. Prior cleaning of the grids with organic solvents, and heating in the electron beam in vacuum before depositing the specimen, bring about a small improvement only, making it very doubtful that organic impurities on the grid are responsible. The fact that magnesium oxide, a highly refractory material, shows more rapid growth than either zinc or molybdenum oxides, suggests that it cannot be due to recrystallization or the growth of some crystals at the expense of others; in any case a diminution in size is never observed.[2] We have used copper and platinum-gold object holders, as well as nickel, and find the growth slightly less rapid on the platinum-gold and slightly more so on the copper disks. This gradation is in the order of the melting points of these metals, but it is not necessarily the case that this is the same as that of ease of sputtering. As a working hypothesis, however, we put forward the view that the observed increase in size of particles in good electrical contact with the grid arises from the deposition of charged metal and other particles ejected from the supporting holder by the electron beam. If it were from organic vapors, it should be observable in gold-shadowed viruses and similar specimens. In Watson's case it may be that contamination comes also from the carbon black itself under electron bombardment, and hence affects gold-shadowed specimens.

---

[1] Watson, J. App. Phys. 18, 153 (1947).

[2] The original plates of Figs. 1 and 2 show the accretions of material to be of lower opacity to electrons than the zinc-oxide needles; this may, however, arise from loose agglomeration rather than from a smaller physical density.

# Ultrasonic Modulation of a Light Beam*

R. F. Humphreys, W. W. Watson, and D. L. Woernley**
*Sloane Laboratory, Yale University, New Haven, Connecticut*

June 23, 1947

THE use of a light beam as a carrier of intelligence has the obvious military advantage of high collimation, hence a low probability of detection by an enemy not in the direct line of the beam. If the wave-length of the light is outside the visible region, the chance of direct line-of-view detection by an enemy is still further reduced. However, there are three major limitations to the use of such a communication device: (a) attenuation of the carrier light beam by atmospheric absorption, (b) attenuation by the infra-red (or ultraviolet) filter, and (c) the difficulty in obtaining a satisfactory signal-to-noise ratio. Evidently, these limitations are somewhat interdependent. If, furthermore, it is desired that the equipment be portable, the limitation of power and space must be considered. This note is concerned with the performance of an experimental infra-red communication unit designed for the Army Signal Corps.

The most direct method of light modulation involves varying the intensity of the source of light in accord with the signal frequency. The very appreciable thermal inertia of light sources, however, permits only a relatively small signal-to-noise ratio. That an ultrasonic grating, formed by a traveling sound wave in a liquid medium, will serve as an almost inertia-less modulator has been pointed out by Jeffree[1] and Becker,[2] and the method has been employed successfully in the Scophony Television system.[1]

A beam of parallel light falls on a glass cell (Fig. 1) at the bottom of which is a 7-megacycle quartz crystal. The cell is filled with xylol and capped with a plug of glass wool to prevent the formation of standing sound waves. (The cell performs equally well as a modulator with either traveling or standing waves; however, it is not desirable to have a mixture of the two.) The waves traveling up the cell form moving regions of increased and decreased density, hence, are similar to a moving diffraction grating. The diffraction pattern which results when light is directed normally to the sound waves has an order spacing proportional to the wave-length of the crystal excitation (approximately 0.4° for the frequency used). The distribution of light intensity in the various orders depends on the amount of crystal excitation; the light in the zero order is nearly inversely proportional to the excitation of the crystal.[3] Thus, an ultrasonic grating corresponds somewhat to an optical grating whose groove shapes are variable at will. If the crystal excitation is modulated by a signal, the light received in the zero order will have the same modulation. It should be noted that orders higher than zero are likewise modulated, though 180° out of phase with the undeviated light; the advantage gained by using the zero order lies in its greater intensity.

The light source found most satisfactory was a 6-volt

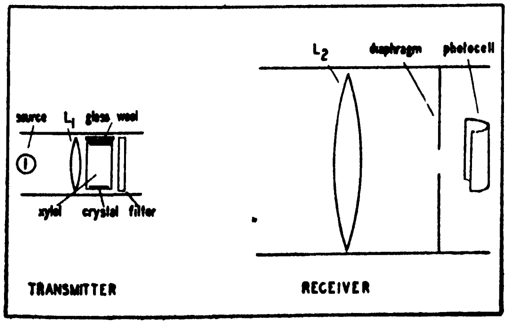

FIG. 1. Schematic diagram of the transmitter-receiver unit for modulating an infra-red light beam.

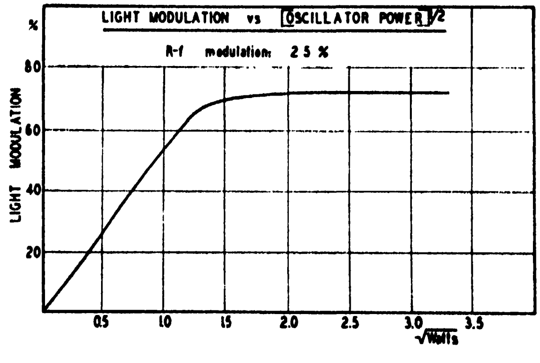

FIG. 2. Light modulation of the zero-order diffraction image as a function of sound intensity (assumed proportional to the voltage on the crystal).

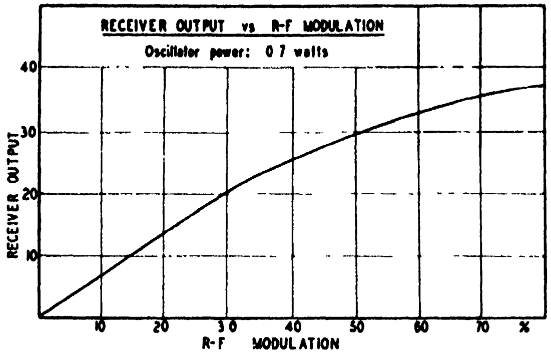

FIG. 3. The curve of audio-signal output as a function of percentage r f modulation indicates the approximate linearity of the ultrasonic modulator. At 70 percent modulation the deviation is only 2 db.

Mazda ribbon lamp, operated at 8 volts; at this latter voltage the infra-red energy was doubled, while the life of the lamp was not seriously shortened. An achromatic lens ($L_1$), of 60-mm diameter, formed parallel light which completely filled the cell. The infra-red filter (Corning "Heat Resistant") was made removable to allow daytime signaling. The collection lens ($L_2$) at the receiver should be as large as conveniently possible to obtain the maximum signal-to-noise ratio. An eight-inch diameter lens was used in the present work with a quarter-inch diaphragm placed at its principle focus, slightly in front of the photocell. A rifle telescope (magnification 4×) was mounted on the unit to aid initial contact between the two communicators.

A 7-megacycle x-cut quartz crystal rested on the stainless-steel base of the liquid cell; on the crystal's upper surface was evaporated copper and then a layer of gold. Contact with this electrode was made with a spring-bronze fork, soldered to the gold surface with Wood's metal to eliminate contact sparking. The crystal was driven at its fundamental frequency by a conventional electron-coupled oscillator with one stage of amplification; a 6V6GT tube served to plate-modulate the amplifier stage. The receiver contained an RCA 918 photo-cell with three 6Sj7 stages of audio-amplification; earphones were used in the output circuit. For the portable unit a 6-volt vibrator pack supplied the necessary power; the vibrator, transmitter, receiver, and optical system were contained in a single, well-shielded unit. The total power consumption was approximately 40 watts. The r-f power delivered to the crystal was of the order of one watt.

The linearity of the ultrasonic cell as a modulator is indicated in Fig. 2, where the sound intensity is taken to be proportional to the square root of the oscillator power. The degree of r-f modulation is held constant (25 percent). It is seen that from zero to 70 percent the modulation is reasonably linear. A curve of r-f modulation (constant r-f power) *versus* receiver output confirms this relation (Fig. 3). The shape of the curve conforms with that predicted by the theory of Raman and Nath.[4]

The most severe operating conditions occur, of course, in bright sunlight, where the signal-to-noise ratio is low. With the red filter removed, the limiting distance for satisfactory two-way conversation was found to be about 3000 yards. Night communication using the filter was very clear at 3000 yards and was still possible at 5000 yards. Beyond this the background noise became prohibitive. If the restriction of low power consumption is removed, a more intense source of light and a larger modulating crystal should easily double this maximum range.

## Films, Resistant to Organic Solvents, for Use in the Electron Microscope

S. G. Ellis
*Department of Physics, University of Toronto, Canada*

June 28, 1947

FILMS of Alkathene,* insoluble in ether and suitable for specimen supports in the electron microscope have been made from hot xylene solutions of the plastic.

A suitable strength for the solution is 0.2 g of Alkathene grade 2 in 100 cc of xylene. It is convenient to use the solution in such a quantity (75 cc) that, when placed in a bottle with a wide neck, a clean glass microscope slide can be half-immersed in the bottle, and a ground glass stopper inserted. The bottle is heated in a water bath at 100°C until the solution is clear. The bottle may then be removed from the bath, the slide lifted from the solution and held vertically just above its surface for a few seconds and then removed from the bottle. The film of Alkathene left on the slide is suitably cut with a needle and then floated off on the clean surface of some hot distilled water at a

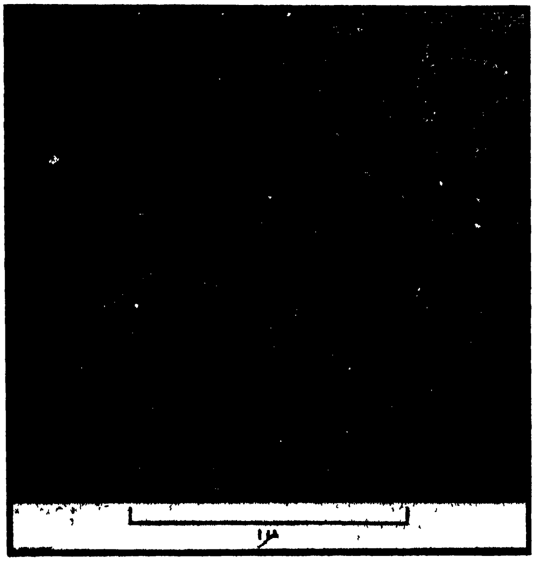

FIG. 1. Alkathene film shadow cast with chromium

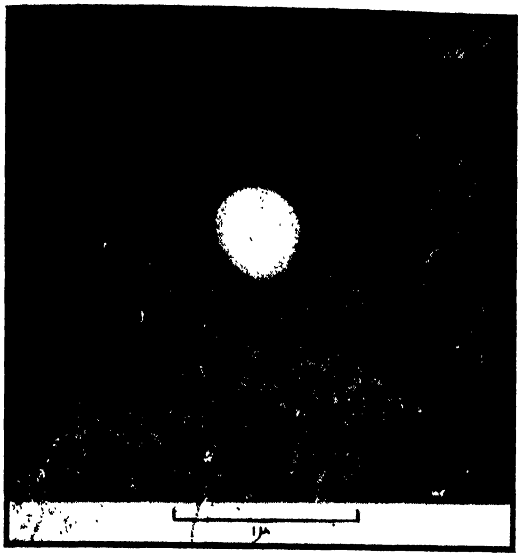

FIG. 2. Unidentified particle on Alkathene film shadow cast with chromium.

temperature above 50°C. A mesh can then be placed on the film and mesh lifted from the water and allowed to dry in the usual manner. When another microscope slide has been placed in the Alkathene solution it should be allowed to come to the temperature of the solution before being removed.

These Alkathene films, when examined in the electron microscope, show a characteristic structure (see Fig. 1). There are many applications in which the structure will not interfere with the observations since adequate contrast can be obtained in the micrographs (Fig. 2). The strength of these films, for a given transparency to the electron beam, is comparable with that of Formvar films. The films, when mounted on a mesh, have been flooded with either suspensions, both of soaps and carbons, without any apparent solvent action on the Alkathene.

In the studies made to date it has not been possible to prevent the formation of the characteristic structure in these films either by varying the strength of the xylene solution or by changing the conditions under which the xylene evaporates. Attempts to form a film by rapidly dipping and withdrawing a cold microscope slide into the hot xylene solution failed.

Similarly attempts to cast the films on the surface of hot water failed, since with the solvents used the solutions of the plastic spread in an irregular and unsatisfactory manner.

We are indebted to Mr. F. G. Rice of Canadian Industries Limited, for samples of Alkathene and for information on its use.

---

* "Alkathene" (registered trademark of I.C.I. in Canada and most of the important countries in the world) is a straight low polymer of ethylene formed at high pressure. Its properties are described in a series of papers by E. Hunter and W. G. Oakes, R. B. Richards and E. L. Midwinter, in British Plastics for March, April, and May, 1945. It is available from: Plastics Division, Canadian Industries, Ltd., P. O. Box 10, Montreal, Canada, for delivery in Canada only, and Plastics Division, Imperial Chemical Industries, Ltd., Welwyn Garden City, Hertfordshire, England.

# Note on the Reduction of Microphonics in Triodes[1]

VICTOR W. COHEN AND ABRAHAM BLOOM
*Ordnance Development Division, National Bureau of Standards, Washington 25, D. C.*

June 2, 1947

UNDER the above title, Mr. Waynick has considered the behavior of a simple triode with a vibrating grid and developed, as a consequence of the motion, a relationship between the microphonic output and the grid bias. This relationship indicates that under certain conditions the microphonic response can be appreciably reduced by a suitable choice of grid bias. The application of this effect to high gain amplifiers with fixed bias may be of importance. In the application of the theory however to the 6A3 tube, he has failed to consider two very important factors both of which pertain to this type of tube. These are: (a) The effect of symmetry in a plane symmetrical triode, and (b) the importance of motion of the cathode in filamentary tube types.

Consider an idealized symmetrical plane triode with the cathode in the center and two grid planes attached to a pair of side rods so that they vibrate with their separation fixed. Then as the grid-cathode distance *increases* on one side, it will *decrease* on the other. To a first-order approximation, therefore, the vibration of the grid side rods will result in no change in $I_p$. For a more accurate evaluation of the microphonic output, one must consider the second-order approximation. We have made such a calculation and find that, depending upon the spacings, there may or may not be a point between negative cut-off and zero grid bias at which the microphonic output is zero. A rough approximation of the second-order term is:

$$I-I_0=\Delta I=G_m\Delta d^2\left[\frac{4}{d^2}\left(E_g+\frac{K}{b}E_p\right)+\frac{(d-2b)}{bd}\,\frac{2}{b^2}KE_p\right.$$
$$\left.+\tfrac{1}{2}\frac{K^2E_p{}^2}{b^4}\left(E_g+\frac{K}{b}E_p\right)^{1}\right],$$

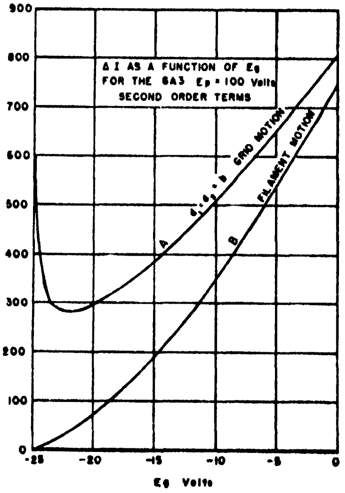

FIG. 1. The second-order term for the change in plate current due to (A) grid motion and (B) filament motion, as a function of grid bias. The curves are calculated for the 6A3, with 100 volts applied to plate.

where $G_m = 3C/2d^2[E_g+(KE_p/b)]^{\frac{1}{2}}$, where $d$ = grid-cathode spacing, $b$ = grid-plate spacing, $C = 2.33\times10^{-6}A$ amperes, $\Delta d$ = grid displacement, and $K = 1/2\pi n \log 1/2\pi np$.

The behavior of this second-order term for $\Delta I$ as a function of grid bias is shown in Fig. 1 curve A, where the term $\Delta Id^4/C(\Delta d)^2$ is plotted against $E_g$, for the special case of the 6A3 in which $d=b$, $u=4$, $E_p=100$ v.

This function goes to infinity at cut-off and has a minimum not far from cut-off.

Since in practice the tube is not perfect in its assembly, the symmetry may not be exact. The microphonic output due to grid vibration may, therefore, contain components of both first and second orders. The first-order term will obey a function similar to Waynick's but will have an amplitude dependent upon the degree of asymmetry.

For a single plane triode the first-order term of $\Delta I$ as a function of $E_g$ is shown in Fig. 2 curve A, in which $\Delta Id^3/C\Delta d$ is plotted against $E_g$ for the same case as Fig. 1A. If the vibration is harmonic, the first-order term of the output will be a sine wave which will reduce to zero amplitude at a particular bias as shown. The second-order term, however, since it depends upon the square of the grid displacement, will have a wave form of the second harmonic of the vibration frequency since $\sin^2\omega t = \frac{1}{2} - \frac{1}{2}\cos 2\omega t$.

While it is true that for indirectly heated cathodes the important cause of microphonics will be the grid vibration, in filamentary types the resonant vibration of the cathode is very important. We have subjected a 6A3 to vibration tests and find very distinct resonant vibration of the filament legs visible with the naked eye. Each leg had its own resonant frequency, most of these being near 800 cycles. The grid vibration was of smaller amplitude and was not visible in a binocular microscope of 36×, using stroboscopic illumination. It was detectable with a r-f capacity vibration pick-up.

The cathode of each section of the 6A3 is formed from a narrow ribbon, in the shape of a letter M. The plane of the ribbon in each leg is designed to be perpendicular to the idealized cathode plane. One would expect, therefore, that appreciable vibrations would occur only in the cathode plane. However, since in assembly the cathode ribbon may be warped slightly, there may be a component of vibration normal to the cathode plane. A rough calculation of the change in plate current due to filament motion gives to a second-order approximation:

$$I-I_0=\Delta I=-2\frac{C}{d_1^3}\left(E_g+\frac{K}{b_1}E_p\right)^{\frac{3}{2}}d_1+\frac{2C}{d_2^3}\left(E_g+\frac{KE_p}{b_2}\right)^{\frac{3}{2}}d_1$$
$$+3\frac{C}{d_1^4}\left(E_g+\frac{K}{b_1}E_p\right)^{\frac{3}{2}}(d_1)^2+\frac{3C}{d_2^4}\left(E_g+\frac{K}{b_2}E_p\right)^{\frac{3}{2}}(d_2)^2,$$

where the subscripts 1 and 2 refer to opposite sides of the triode.

Clearly all four terms of this expression are $\frac{3}{2}$ power curves and have minima only at cut-off, i.e., where $E_g = -K/bE_p$. The form of the second, and first-order terms are illustrated in Fig. 1 curve B and Fig. 2 curve B, respectively.

With the foregoing considerations in mind, one can explain some of Waynick's observations on the 6A3 which appear to depart from his theory.

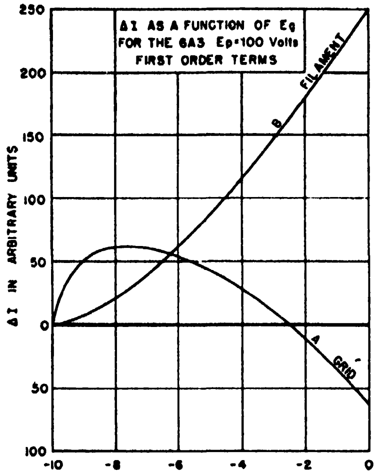

FIG. 2. The first-order term for the change in plate current due to motion of (A) grid and (B) filament as a function of grid bias. The curves are calculated for the 6A3, with 100 volts applied to plate.

1. Case 2 and 8 may be explained as due to resonances either of a filament leg or of the grid in a symmetrical section of the tube.
2. Case 6 was undoubtedly due in part to a second-order term giving rise to a second harmonic of the vibration frequency which did not pass through zero as the fundamental component did.
3. The residual output near the minima which appeared to contain the second harmonic of the driving frequency was probably due to second-order effects.

The apparent close agreement observed in some cases may have been due to a grid vibration in a highly asymmetrical section of the tube.

A more detailed discussion of calculations of the effects of vibration of triode elements as well as experimental methods and observations is contained in a manuscript now nearing completion.[2]

## Comments on "Sound-Velocity Determination of Molecular Weights"

G. J. DIENES
*Development Laboratories, Bakelite Corporation, Bound Brook, New Jersey*

June 24, 1947

In a recent paper in this journal, A. Weissler, S. W. Fitzgerald, and I. Resnick[1] described a method of molecular-weight determination for liquid polymers based on sound-velocity, density, and refractive-index measurements. The essential relation for calculating molecular weights by their method is an empirical linear correlation between molar sound velocity and molar refraction.

It occurred to the writer that there is no necessity for making the sound-velocity measurements since the mo-

TABLE I.

| Glycol | Theoretical mole wt. | No. ave. mole wt. from specific refractivity | Deviation. % |
|---|---|---|---|
| Ethylene | 62.1 | 62.1 | 0.0 |
| Diethylene | 106.1 | 101.5 | −4.3 |
| Triethylene | 150.1 | 144.8 | +3.5 |
| Tetraethylene | 194.2 | 192.9 | +0.7 |
| Pentaethylene | 238.2 | 245.7 | −3.1 |
| Poly 200 | 200 ± 10 | 193.0 | 0.0 |
| Poly 300 | 300 ± 15 | 316.9 | +0.6 |
| Poly 400 | 400 ± 20 | 408.6 | 0.0 |
| Poly 600 | 600 ± 30 | 576.2 | 0.0 |
| | | Ave: | 1.4% |

lecular weights are easily calculable from molar refractions, as pointed out recently by E. Warrick.[2] Calculation of molecular weights from molar refractions is based on the well-accepted concept of group additivity and the additional step of an empirical correlation between molar velocity and molar refraction is eliminated. Since the molar-refraction method is physically analogous to a chemical end-group determination, the resulting molecular weight, in the case of a heterogeneous polymer, will evidently be a number average. This can also be readily shown mathematically using additivity of molar refractions on the basis of mole fractions.

In the system of polyethylene glycols, treated by the above authors, the average experimental molar-refraction increment for each $-CH_2-CH_2-O-$ structural unit, based on the first five pure members of the series, is 10.97. From the general formula for the polyethylene glycols, $HO-(CH_2-CH_2-O-)_n-H$, the molecular weight, $M$, of any member may be written

$$M = 44.05i + 62.07, \qquad (1)$$

where

$i$ = number of $CH_2-CH_2-O$ units in compound, 44.05 = molecular weight of $CH_2-CH_2-O$ unit, and 62.07 = molecular weight of ethylene glycol.

Similarly, the molar refraction, on the basis of additivity of groups, may be expressed

$$R = (n^2-1/n^2+2)M/d = rM = 10.97i + 14.47,$$

or

$$r(44.05i + 62.07) = 10.97i + 14.47, \qquad (2)$$

where

$r = (n^2-1/n^2+2)1/d$ = specific refractivity of compound, and 14.47 = molar refraction of ethylene glycol.

Equation (2) is easily solved for $i$, and substitution of $i$ in Eq. (1) gives the molecular weight. From the density and refractive-index data reported by Weissler, Fitzgerald, and Resnick, the molecular weights given in Table I were calculated.

The agreement between theoretical molecular weight and molecular weight calculated from the experimental specific refractivities is actually better than that obtained by the molar-velocity method (1.4 percent *vs.* 2.0 percent). Since the molar-refraction method depends essentially on differences between the molar refractivity of the chain and the end-groups, it is evidently only applicable to compounds of relatively low degree of polymerization. This same limitation, however, applies to the molar-velocity method. For low molecular-weight liquid polymers the molar-refraction method is very useful and convenient as the necessary density and refractive-index measurements are easily made to a high degree of accuracy.

# Preliminary Measurements Relative to the Onset of Thermal Convection Currents in Unconsolidated Sands*

H. L. MORRISON
*North Carolina State College of Agriculture and Engineering, Raleigh, North Carolina*

July 10, 1947

TO assess a recently advanced theory[1] for the minimum temperature gradient necessary to cause the onset of convection in a viscous liquid in a porous medium, a series of appropriate measurements has been initiated using several different liquids separately in unconsolidated sands of known permeability. These measurements are reported here in a preliminary form because of their interesting bearing upon the theory itself and upon its application to geophysical problems. The measurements were made on mixtures (depth 10 cm) of liquid and sand in a 400-cc beaker (diameter 7.0 cm) which was heated from below; temperatures were observed at various depths in the mixture, as functions of time; and microscopic observations were made of the onset of motion in small suspended solid particles (impurities) which were visible near the wall of the beaker. Precautions were taken to assure the horizontal uniformity of temperature (maximum deviation about ¼°C to ½°C) throughout the mixture; and subsidiary measurements of upward motions of the liquids, caused by diffusion, were made using suitable soluble dyes so as to assure that this possible disturbing effect was negligible. A further subsidiary series of measurements was made using a beaker of 15.0-cm diameter, to exhibit the effects of vessel radius; there were no appreciable effects on the temperature gradient required for onset of convection. Typical observations are recorded in Table I. In Table I, the data in columns 4 to 6 are cast in the form used in reference 1, so that $z$ column 4+column $6 = z + \theta$; the column 3 refers to the gradient at $z$ (distance into mixture

TABLE I.

| | | Temperatures and gradients at onset of convection | | | |
|---|---|---|---|---|---|
| Liquid | Permeability of sand (d'Arcy's) | Local gradient (°C/cm) estimated | β-gradient (°C/cm) | Temperature at $z = 0$ (°C) | Approximate θ temperature function (°C) |
| Glycerol | 95 | −80 | −8.4 | 125 | $-47\frac{1}{2}\sin(\pi z/10)$ |
| $CCl_4$ | 127 | −0.8 | −0.8 | 31½ | 0 |
| $H_2O$ | 127 | −6.0 | −6.0 | 57 | 0 |

from bottom) = 2 cm, the usual point of location of the microscope.

In attempting to compare the data in Table I with the theory,[1] one meets definite difficulties. Thus, the $\theta$-function for the $CCl_4$ and $H_2O$ data, does not accord with the sinusoidal one assumed in developing the theory, though this may not be too significant, for the theory might use a more general series of sine functions which could correlate with the zero used in the measurements. Again, the theory does not contemplate a variation of viscosity with temperature, a situation which is far from acceptable for the liquids used in these measurements. Finally, the finite horizontal extent of the mixture in these measurements implies, at least in principle, boundary conditions which the theory does not contemplate. Nevertheless, any attempted application of the Eq. (26) in reference 1 to these experiments appears to indicate that for the glycerol test, the calculated gradient is at least on order of magnitude in excess of the observed, and for the other two, the calculated gradient is slightly in excess of the observed. Apart then, from the possibility that it is not correct to identify the onset of motion in suspended matter in the present series of measurements with the onset of convection, it can only be concluded at the moment that the theory[1] predicts excessive values for the minimum temperature gradient but that it deserves such extensions as to render it applicable to materials, dimensions, and $\theta$-function having actual, rather than ideal, characters.

This work was suggested to the author by Dr. F. T. Rogers, Jr., to whom, with Mr. C. W. Horton, the author is also indebted for continuing conversations and correspondence relating to it. Further measurements are in progress, and will be reported when and if it is possible to extend the theory suitably.

# Attachments for Aligning a Console Electron Microscope

HENRY C. FROULA
*Armour Research Foundation of Illinois Institute of Technology, Chicago, Illinois*

July 8, 1947

THE alignment of the electron gun and anode aperture in our RCA console electron microscope was greatly simplified through the use of the two devices described below.

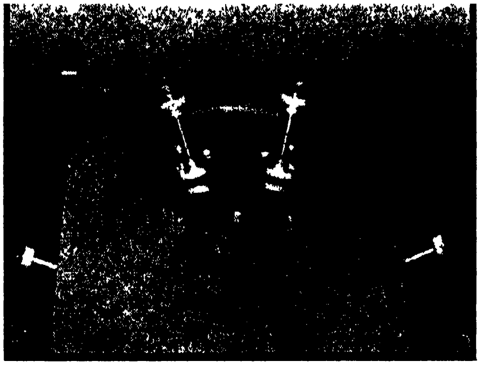

FIG. 1. Rear view of console electron microscope, showing external controls for alignment of electron gun and anode aperture.

The first of these two devices provides for the alignment of the electron gun. Three arms mounted 120° apart on the front rim of the gun extend forward to overhang the fixed column by about one-half inch. One of these arms (on the underside of the gun) is a flat spring whose free end presses upward against the column, tending to lower the gun. Each of the other two arms has a tapped hole through which a screw is driven against the fixed column. Manipulation of the screws provides a two-dimensional adjustment of the gun position. The two screws can be turned externally by means of the removable extension shafts which project through the sides of the hood as shown in Fig. 1.

The second of the two devices provides for the external adjustment of the anode aperture. The regular cover of the specimen chamber is replaced temporarily by one having two sealed passages holding a pair of metal rods. These rods can be seen projecting upward in the figure. Their lower ends are articulated with the two screws which adjust the anode aperture. The vacuum seals through which the rods pass, permit a liberal amount of movement of the rods so that adjustments can be made during actual operation of the microscope.[1]

Both of these devices have had considerable use in our laboratory and have given very satisfactory service in establishing and maintaining suitable alignment of the microscope.

---

[1] The seals are of the type described by D. B. Cowie, Rev. Sci. Inst. 15, 46 (1944).

# New Books

## Radium Therapy; Its Physical Aspects.

By C. W. Wilson. Pp. 224, Figs. 97, 30 tables, and 4 mathematical appendices. Chapman and Hall, Ltd., London, 1945. Price $6.00 plus postage.

This book supplies an excellent practical survey of the physical aspects of radium therapy, more complete and detailed than anything hitherto available. The basic theories of radioactivity are passed over rather briefly, but the interaction of high energy radiations with matter is discussed in detail. The development of methods and theory of dosimetry receives considerable attention. Detailed descriptions are given of the air-wall ionization chamber, and of various practical vacuum-tube dosimeters, with instructions for their use.

A large part of the book is devoted to dosage calculations, with many examples. For surface therapy, the Paterson and Parker charts are followed. In intracavitary treatments, various systems for treatment of cancer of the cervix are compared in detail. For interstitial dosage calculations, the Memorial Hospital and Paterson and Parker techniques are discussed, with numerous examples for the latter. A chapter devoted to dosage in teleradium therapy will find few readers in America, since this method is now little used here. The matter of protection is adequately covered.

One might wish that more attention had been devoted to the matter of integral dose, or total energy absorbed by the patient, since this had been more thoroughly studied in England than in the United States.

Each chapter contains a good list of references, specific and general. The appendix consists of useful mathematical tables.

Radiologists have long felt a need for such a book; there has been no satisfactory text covering this field. It should be welcomed by students, teachers, and all practicing radiologists and radium therapists.

Edith H. Quimby
*Columbia University*

## Introduction to Atomic Physics

By Henry Semat. Revised Edition. Pp. 412+xi, Figs. 169, Tables 27, 23×15.5 cm. Rinehart and Company, Inc., New York, 1946. Price $4.50.

The first edition of Semat, appearing in 1939, at once became a standard undergraduate text on atomic physics and won a place of respect on the shelves and desks of physicists and chemists of experience. This second edition is substantially the earlier Semat, though it presents an altered appearance. The page size, type, paper, and some of the subdivision of text into chapters have been changed along with the corporate title of the publisher. The effect of the new format is one of increased elegance and modernity, but not all users will approve the change to paper of half the former thickness.

Getting down to subject matter, one finds that a large number of small, first-edition errors have been corrected, data have been brought up to date, several diagrams have been redrawn, and new paragraphs inserted to clarify or supplement previous treatments. This piecemeal modernization has been accomplished smoothly without serious impairment of the unity of the book. Some new problems have been constructed and some old ones improved. The statement that 94 elements are found in nature is not yet correct.

The book begins and ends with nuclear energy, the frontispiece comprising photographs of the first atomic bomb explosion, and the final chapter being devoted entirely to a discussion of nuclear energy. This chapter, the only completely new one in the book, starts with the stellar energy reactions of Bethe and proceeds through a careful history of nuclear fission researches to nuclear chain reactions, fast and slow. Some of the latter discussion is taken sentence for sentence from the Smythe report, without quotation marks, but with a preceding statement that the discussion is based on the report. The reviewer dislikes and disbelieves statements that mass is converted into energy, or even "other forms of energy." This common stereotype will do no harm to physicists but may interfere with students' understanding of the equivalence equation since it suggests that after the event the total mass is less than it was before.

Other topics which make their first appearance in this edition are the measurements of nuclear magnetic moments, the discovery and production of new elements, electron optics, and the design and use of the betatron. Semat's first edition was distinguished by an unpretentious clarity of statement and a consistent awareness of the capacity and limitations of the chosen audience. These characteristics are preserved in the current modifications and extensions. It is a sad circumstance that enables a book on atomic physics to be brought up to date after seven years with no more enlargement than Semat has found necessary. It is to be hoped that the third edition will require the inclusion of much more new material.

Paul Kirkpatrick
*Stanford University*

# New Booklets

The National Research Council calls attention to *Mathematical Tables and Other Aids to Computation*, a quarterly journal published by the Council at 2101 Constitution Avenue, Washington 25, D. C. It is edited by Raymond C. Archibald and Derrick H. Lehmer and is an international publication which serves as an information center of published and unpublished mathematical tables and material dealing with other aids to computation. Because of the continuous pagination in each volume and a system of constant cross references, new subscribers will find it desirable to begin their subscriptions with the first issue of the year. Subscription is $4 per year; single issues $1.25.

Jarrell-Ash Company, 165 Newbury Street, Boston 16, Massachusetts, announce their new 20-page catalog *I-3* describing their stigmatic grating spectrographs and accessories.

*Interchemical Review*, 432 West 45th Street, New York 19, New York, features in its Spring 1947 issue articles on the application of filters in photography, methods of printing on vinyl film, and the wartime development in Britain of a non-metallic conductive coating for paper.

The most recent issue (Volume 9, Number 2) of *Philips Technical Review*, published by Philips Laboratories in Holland, contains the following articles, according to North American Philips Company, Inc., 100 East 42 Street, New York 17, New York: "A new electron microscope with continuously variable magnification," by J. B. le Poole; "Electronic conductivity of non-metallic materials," by E. J. W. Verwey; "Installations for improved broadcast reception," by P. Cornelius and J. van Slooten.

RCA Victor Division, Camden, New Jersey, has issued a 16-page booklet, for distribution to consumers, entitled *What's Your Television I.Q.?*

Dover Publications, 1780 Broadway, New York 19, New York, has published a new 1947 catalog of scientific books published by it. 38 pages.

Burrell Technical Supply Company, 1942 Fifth Avenue, Pittsburgh 19, Pennsylvania, has issued an *Announcer* of scientific equipment. It is published quarterly and describes various laboratory instruments and equipment. Each edition also contains a dissertation on the history of some instrument or process now used in industrial research.

Cannon Electric Development Company, 3209 Humboldt Street, Los Angeles 31, California, has issued *Cannon Plugs*, a 78-page booklet containing many photographs and describing the uses of its products in industry.

Microfilm Service, a new affiliate of the American Council on Public Affairs, located at 2153 Florida Avenue, Washington 8, D. C., is publishing through the microfilm medium scholarly manuscripts on specialized subjects, documents of historical value, and out-of-print studies.

The Editorial Service Bureau of Kodak, 343 State Street, Rochester 4, New York, has issued the first edition of *Shorts*, a 4-page digest of new uses of photography.

Foster D. Snell, Inc., 29 West 15th Street, New York 11, New York, has released a 1947 edition of its brochure under the heading *The Chemical Consultant and Your Business*. Available without charge.

Distillation Products, Inc., 755 Ridge Road West, Rochester 13, New York, has published a 16-page booklet entitled *Information on High Vacuum Distillation*.

Fischer and Porter Company, Hatboro, Pennsylvania, has released a new, larger catalog section No. 95-D describing the company's line of precision bore glass specialties. Address Department 6F-D in requesting a copy.

# Here and There

### New Appointments

Cleveland Norcross, formerly executive secretary of the Office of Scientific Research and Development, is now assistant director of the American Institute of Physics.

Captain Robert D. Conrad, U. S. Navy retired, has been named assistant director of Brookhaven National Laboratory for atomic research.

Effective September 1, T. Keith Glennan, recently an executive of Ansco Division of General Aniline and Film Corporation and wartime director of the U. S. Navy Underwater Sound Laboratory, became president of Case Institute of Technology, Cleveland, Ohio, succeeding William E. Wickenden, who has retired.

*Science* reports that Henry N. Russell, professor of astronomy and director of the observatory, Princeton University, retired July 1. Lyman Spitzer, Jr., professor of astrophysics, Yale University, has been appointed director of the observatory, and Martin Schwarzschild, Columbia University, has become professor of astronomy.

William E. Good has been granted a year's leave of absence from the Westinghouse Research Laboratories to aid in atomic energy investigation at the Argonne National Laboratory near Chicago.

Louis N. Ridenour, formerly assistant professor of physics, University of Pennsylvania, has been appointed dean of the Graduate School, University of Illinois.

### New Casting Resin

P. J. Franklin and M. Weinberg of the National Bureau of Standards issued recently a report on a casting resin developed by the Bureau. Their report says, "During the war, exacting mechanical and electrical stability requirements of special electronic applications—such as the radio proximity fuze—necessitated the potting of the circuit components. Because of the high impedance of the circuits involved, the electrical loss factor or the dissipation of the available energy in the casting or 'potting' compound became a matter of major importance. An extensive investigation of various available casting resins at the National Bureau of Standards revealed none suitable for the particular applications because of the high loss factor. The few materials with adequate electrical properties were deficient mechanically. In addition, the applications required a resin of such viscosity that the potting compound would encompass all the circuit elements when poured into a container housing the electronic device, and then harden to a rigid solid without adversely affecting circuit operation.

"Many casting resins have been developed, but few have the vital electrical properties for proper operation of high-impedance, high-frequency equipment. As a result of experience gained in the fuze-development program at the National Bureau of Standards, a new casting resin embodying the required properties of mechanical and electrical stability, was formulated through a systematic variation of resin constituents. Various applications at the Bureau indicate that, with slight modifications to suit the intended use, the new potting compound—known as NBS Casting Resin—can be readily employed in many high-frequency devices requiring such mechanical-electrical insulation.

"The most important properties specifically desired of a casting resin when utilized at high frequencies in high-impedance circuits are low power factor, low dielectric constant, short polymerization period at low temperature and atmospheric pressure, high impact strength, small volume shrinkage on polymerization, dimensional and electrical stability, and low moisture absorption. The NBS Casting Resin not only meets these requirements but fulfills the additional requirements of low viscosity and low surface tension, and hence may be poured through small openings."

### New Research Laboratory in Texas

In April a new research laboratory was officially opened on a 3000-acre strip eight miles west of San Antonio, Texas. The project, made possible by the gift of a valuable oil property by Tom B. Slick, San Antonio oil and ranch man, consists of two separate but closely associated units: the Foundation of Applied Research, utilizing the Essar Ranch as part of its laboratory, and the Institute of Industrial Research, including a development service for inventors. While the Foundation of Applied Research was incorporated by its trustees as a non-profit undertaking, it has been designed to make its own way financially, after a development period, from sales of Essar Ranch's blooded cattle and from earnings by the Institute of Industrial Research through fees and patent proceeds.

Dr. Gregory Pincus, head of the Worcester Foundation for Experimental Biology at Worcester, Massachusetts, is selecting the research men and scientists who will staff the Foundation and the Institute.

Objectives of the projects have been outlined by Mr. Slick as follows: "The only limitation to the scope of work to be undertaken by the Foundation is that it has in view a distinctly practical application. The value of pure scientific study is fully realized, but it is felt that the Foundation's greatest contribution can be realized by concentration on the field lying between pure scientific study as carried out by universities and similar institutions, and completely industrial research of limited range as conducted by the average industrial corporation."

The Institute of Industrial Research, under separate management from the Foundation, will undertake, on a fee basis for industrial corporations, programs similar to the services rendered by the Mellon, Armour, and Midwest Institutes, and in addition will provide inventors with a complete processing service should their projects be determined worthy of development.

### New Computer at California Institute of Technology

*Science* reports that an electric analog computer will be part of the new analysis laboratory now being established at the California Institute of Technology. Gilbert D. McCann, Associate Professor of Electrical Engineering at the Institute, is setting up the laboratory.

The new calculator, which will be made available to all interested industrial and engineering organizations as well as being used for research at the Institute, is expected to be completed by August. Weighing approximately 33,000 pounds, the machine, including its control desk, will occupy some 1000 square feet of floor space. The device was designed for the solution of complex mathematical problems in the field of algebra and calculus requiring an accuracy of the order of 1 percent. It is particularly suited to solving engineering problems, including those of electrical circuits; applied mechanics; self-induced mechanical oscillations, such as airplane structure flutter, car shimmy, rail car stability; problems in thermodynamics, such as a general analysis of heat flow problems; speed controllers, voltage regulators; and angle position controllers, such as airplane stabilizers, guided missiles, gyro pilots, etc.

### Physical Society Acoustics Group

The Acoustics Group of the Physical Society was formed at an inaugural meeting at the Royal Institute of British Architects in February 1947. Dr. Alex Wood gave an address entitled "The Contribution of Acoustical Science to Allied Studies." The meeting was attended by some 170 persons. The principal object of the Group is to provide an opportunity for the varied types of workers engaged on acoustical problems to meet and discuss the scientific and technical implications of their work. Membership is open both to members and also to non-members of the Physical Society. For further particulars inquire of the Joint Honorary Secretaries of the Acoustics Group, The Physical Society, 1 Lowther Gardens, Prince Consort Road, London S. W. 7.

### Sound Apparatus Company

The Sound Apparatus Company announces the opening of its production plant in Stirling, New Jersey. The company's research laboratories are in Millington, New Jersey, and the main offices are at 233 Broadway, New York City.

### High Vacuum Symposium

National Research Corporation, in cooperation with the Division of Industrial and Engineering Chemistry, American Chemical Society, has announced plans for a High Vacuum Symposium to be held in Cambridge, Massachusetts, October 30 and 31. Secretary for the event is Stanley Heck, National Research Corporation, Boston 42, Massachusetts.

### Kodak Fellowships

Sixteen educational institutions have been offered one or more of twenty-two Eastman Kodak fellowships in chemistry, physics, engineering, and business administration for the school year 1947–48. In addition six similar fellowships are to be sponsored by Tennessee Eastman Corporation, Kodak subsidiary.

### National Electronics Conference

A National Electronics Conference will be held at the Edgewater Beach Hotel, Chicago, Illinois, November 3–5, 1947. Dr. George D. Stoddard, new president of the University of Illinois, will deliver the keynote address. The complete program for the Conference includes twenty technical sessions with a total of about fifty papers.

### Taylor Elected Radiology Fellow

Lauriston S. Taylor, chief of the x-ray section at the National Bureau of Standards, has been elected an associate fellow in the American College of Radiology.

### Institute of Navigation Officers

The institute of Navigation has elected the following national officers for the academic year 1947–48: president, Commodore G. G. McLintock, USMS, Special Assistant to the Commandant, U. S. Maritime Service; vice president, Captain P. V. H. Weems, USN (*Retired*), Annapolis, Maryland; technical adviser, Paul Rosenberg, president of Paul Rosenberg Associates, New York City; executive secretary, Samuel Herrick, professor of astronomy, University of California at Los Angeles.

### Chicago Physics Club Officers

The following are the new officers of the Physics Club of Chicago, elected May 1947: president, W. F. Einbecker; vice president, H. A. Carter; treasurer, J. W. Juvinall; secretary, H. C. Froula.

### Conference on Administration of Research

A conference on "Administration of Research" will be held at The Pennsylvania State College on Monday and Tuesday, October 6 and 7. The main purpose of the conference is to provide free discussion on the organization, administration, and operation of research laboratories.

Discussion will be led by Prof. Philip M. Morse, Brookhaven National Laboratories, and Dr. Jesse E. Hobson, Armour Research Foundation. The following men will be the principal speakers:

Dr. Maurice Holland, New York, Consultant
Dr. R. L. Jones, Bell Telephone Laboratories
Dr. G. H. Young, Mellon Institute of Industrial Research
Dr. Dwight E. Gray, Applied Physics Laboratory
Dr. L. Warrington Chubb, Westinghouse Electric Corporation
Dr. Edw. U. Condon, National Bureau of Standards
Hon. James H. Duff, Governor, Commonwealth of Pennsylvania
Commodore Henry A. Schade, Director, Naval Research Laboratory
Dr. Paul D. Foote and Dr. Blaine B. Westcott, Gulf Research Laboratories
Dr. Albert W. Hull, General Electric Company

For further information and a copy of the program, address Dr. Eric A. Walker, Head, Electrical Engineering Department, The Pennsylvania State College, State College, Pennsylvania.

# Fringing Flux Corrections for Magnetic Focusing Devices

NORMAN D. COGGESHALL
*Gulf Research and Development Company, Pittsburgh, Pennsylvania*

(Received March 27, 1947)

When a charged particle approaches a region of uniform magnetic field its trajectory is affected by the fringing field. Compensation for the effect of the fringing field may in some cases be achieved by the use of virtual field boundaries which are outwardly displaced from the actual boundaries. A definition of the virtual boundary in terms of the effect of the fringing field upon the trajectories is formulated. A procedure for calculating the displacement *d* of the virtual from the actual field boundary is given using the methods previously developed for calculating ion trajectories in non-uniform magnetic fields. Using this procedure several values of the displacement for various magnet dimensions and conditions have been calculated. A method of altering the geometry of sector-type mass spectrometers to correct for the effects of the fringing fields is proposed. It is shown that the angular and spatial separations of the individual ion trajectories in an ion beam of small angular spread as it approaches a uniform field region through a fringing field are approximately the same as for the ideal case wherein the magnet field changes discontinuously at the boundary.

IT is well known that the magnetic field of a magnet does not discontinuously go from its maximum value to zero as the boundary of the region between the pole faces is passed. Rather the field falls off gradually in conformation with the laws of potential theory, and the result is an appreciable amount of fringing flux for some distance away from the pole-face boundaries.

In the sector-type mass spectrometer, schematically illustrated in Fig. 1, the ions proceed from the ion source through a magnetic-field-free region to the magnetic analyzer. The magnetic analyzer consists of a uniform magnetic field perpendicular to the plane of the figure and with the shape of a truncated sector. After passing through the magnetic analyzer the ions again pass through a magnetic-field-free region on their way to the ion collector. In the derivation[1] of the focusing properties of this system, it is assumed that the magnetic field region has sharp boundaries such as delineated in Fig. 1. Actually no magnet provides sharp boundaries to the magnetic field region, and in calculating the geometrical arrangement of ion source, magnetic analyzer, and ion collector, the effects of fringing magnetic field must be taken into account. One means of doing this is to use virtual boundaries of the sector-shaped field region which are displaced outwards from the actual boundaries. In this method it is assumed that fringing flux corrections can be effectively made by such a simple displacement of field boundaries. It is the purpose of this article to provide an analytical method for the determination of *d*, the displacement of the

---

[1] W. E. Stephens, Phys. Rev. 45, 513 (1934).

virtual field boundaries from the actual field boundaries. This displacement is considered under various conditions and several numerical cases evaluated. It is a further purpose of this article to consider the effectiveness of such a procedure as the use of virtual field boundaries for fringing flux corrections and to provide an alternative procedure which is believed to be more effective.

If we consider the magnetic field on the median plane, i.e., the plane parallel to and midway between the pole faces, the flux on it may to a reasonable approximation be regarded as a function of only one variable, the perpendicular distance from the boundary of the uniform field region. Thus the methods previously developed[2] for the calculation of ion paths in non-uniform magnetic fields may be used to determine analytically the trajectories of the central ray and others between the ion source and their penetration into the uniform field region.

In the past there have been indicated approximate methods of correcting for stray fields,[3–5] but they do not allow the exact calculations of the trajectories as will be described below.

In reference 2 it was shown that the exact determination of ion paths could be readily achieved for such cases where the ions move in a plane through a non-uniform magnetic field which is a function of only one coordinate and is everywhere perpendicular to this coordinate and to the orthogonal coordinate in the same plane. This was shown to be true for both Cartesian and polar coordinate systems, the magnetic field being a function of the radial distance in the latter. For the case at hand we may use the distance from the uniform field region and on a line normal to its boundary as the $x$ coordinate in a Cartesian system and apply these methods.

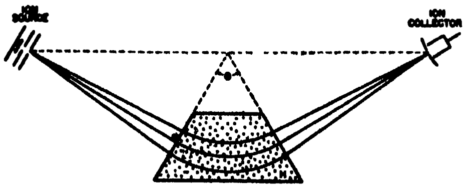

FIG. 1. Focusing scheme used in sector-type spectrometer.

In reference 2 it was shown that the ion trajectory is determined from the differential equation:

$$dy/dx = \pm f/(1-f^2)^{\frac{1}{2}}, \qquad (1)$$

where $f=f(x)$ and is defined as:

$$f = (e/vmc)\int H(x)dx,$$

and $v$ = velocity of ion in cm/sec., $c$ = velocity of light, $e$ = electrical charge of the ion in e.s.u., and $m$ the mass of the ion in grams. For convenience in the present applications we define a function $h(x)$ as follows:

$$H(x) = H_0 h(x).$$

The function $h(x)$ then specifies the ratio of the magnetic field at any point to the maximum field $H_0$ in the uniform field region. With this we may rewrite (1) as:

$$dy/dx = \pm f/(r^2-f^2)^{\frac{1}{2}}, \qquad (2)$$

where

$$f = f(x) = \int h(x)dx \quad \text{and} \quad r = (vmc/H_0 e).$$

The quantity $r$ is the radius of curvature of the ion path in the uniform field $H_0$.

It is to be noticed that the right-hand portion of Eq. (2) is a function of $x$ only. Therefore, an integration, either numerical or analytical, may be made to determine $y$ as a function of $x$ and thus obtain the trajectory. If the function $h(x)$ is known only experimentally then $f(x)$ may be determined by numerical integration and the resulting values used in a numerical integration of Eq. (2).

The application of the foregoing equations may be seen in Fig. 2. Here is plotted the trajectory of an ion as it passes from the ion source to and through a uniform magnetic field. Although the ion source is so oriented that its axis is perpendicular to the boundary of the magnetic field region, the fringing flux causes the central ray to actually enter the uniform field region with an angle other than 90° and at a

point considerably displaced from the entrance point of the axis. The net effect of the fringing field is to so determine the trajectory that as the ion passes through the uniform field region the center of curvature is a distance $d$ normal to the pole-face boundary. This is in contrast to the ideal case wherein the magnetic field would be discontinuous at the boundary and the center of curvature would be on the boundary. We may therefore define a virtual boundary as one parallel to the actual boundary and displaced from it so as to include as a point the center of curvature for that part of the trajectory in the uniform field region. We shall consider $d$ at present only for the case wherein the axis of the ion source is perpendicular to the pole-face boundaries. As will be discussed in more detail later, $d$ depends upon the distance of the ion source from the uniform field region and upon the angle of emergence of the ions from the source. In Fig. 2 the virtual boundary is represented by the dashed line which contains the center of curvature as a point. It is useful to know the displacement $d$, although as we shall see later these virtual boundaries do not allow the use of the ideal geometrical arrangements considered in reference 1.

The determination of the displacement $d$ is readily made from Eq. (2). We note that $dy/dx = \infty$ for a value $\bar{x}$ such that $f(\bar{x}) = \pm r$. Suppose the actual pole-face boundary is taken as the line $x=0$, then since in the $x$-coordinate system the center of curvature will be located $r$ units from $\bar{x}$, it follows that:

$$d = (r - |\bar{x}|). \qquad (3)$$

The absolute value is used here since $\bar{x}$ may have a negative value, depending on manner of using the coordinate system. To obtain $\bar{x}$ we must use the relationship

$$\int_{x_0}^{\bar{x}} h(x)dx = \pm r, \qquad (4)$$

where $x_0$ is the value of the $x$ coordinate at the ion source exit slit.

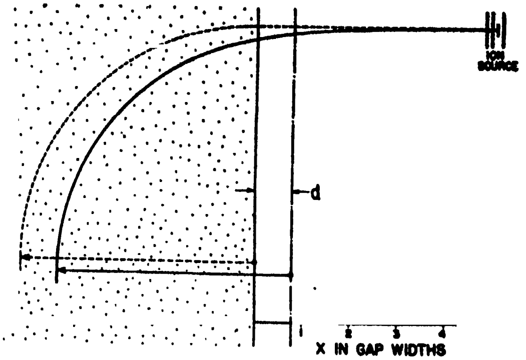

FIG. 2. Comparison between ion trajectories for the ideal case and for the actual case wherein the fringing flux is effective.

Thus the problem of determining $d$ reduces to obtaining the function $h(x)$ and to carrying out the integration of Eq. (4). Actually for any particular magnet $h(x)$ should be determined experimentally. We may, however, get some idea of the order of magnitude of $d$ and its change with variations of magnets by using the Schwarz-Christoffel transformation[6] to obtain $h(x)$. Figure 3 shows the type of magnet pole considered and the differential equation used for the conformal transformation. Here the magnet poles are considered to extend to $\infty$ in both directions perpendicular to the paper. They are in the form of jaws with the outer surface of each jaw being $n$ times further from the median plane than the inner surface. For simplicity the transformation is made for the case shown by the cross-hatching in Fig. 3, i.e., one magnet pole as one surface of constant magnetic potential and the median plane as the other. The differential equation shown transforms the edge of the upper magnet pole onto the left-hand half of the real axis in the $\omega$ plane and transforms the edge of the other region of constant magnetic potential onto the right-hand half of the real axis. In the differential equation $T$ is the usual orientation factor necessary for the transformation. The constants in the equation shown in Fig. 3, which expresses $z$ in terms of $\omega$, are given by:

$$a = (n + (n^2 - 1)^{\frac{1}{2}})/\pi,$$
$$b = (n - (n^2 - 1)^{\frac{1}{2}})/\pi,$$
$$c = -(((a+b)/2)\log(a-b) - (ab)^{\frac{1}{2}}\log(a-b)).$$

The transformation given in Fig. 3 allows the flux on the median plane to be calculated for various values of $n$. Changing the value of $n$

corresponds to changing the thickness of the pole pieces relative to the gap width. The function $h(x)$ has been evaluated for several values of $n$, and the results are shown in Fig. 6.

In addition to the evaluation of $h(x)$ for several values of $n$ the two extreme cases of $n=1$ and $n=\infty$ have been treated. Figure 4 shows the boundaries to be transformed and the differential equation for the extreme case of $n=1$. This case which is physically impossible corresponds to the pole pieces being thin sheets of magnetic material. The other extreme case of $n=\infty$, illustrated in Fig. 5, is also physically impossible but may be representative of magnets which have a large ratio of thickness to gap width. The results of the evaluation of $h(x)$ for these two extreme cases are also shown in Fig. 6.

It is somewhat surprising in inspecting Fig. 6 to see how little effect the variation of pole piece thickness has on the fringing flux. In this figure $h(x)$ is plotted against distance from pole-face boundary with the unit of distance as one gap width. Values of $d$ obtained from using these evaluations of $h(x)$ cannot be expected to give true values of $d$ for actual magnets. This is because an actual magnet will have finite dimensions in all directions and for it $h(x)$ will fall to zero more rapidly for large values of distance from pole-face boundary than shown in Fig. 6.

TABLE I. Variation of $d$ with various values of $n$ and $r$.

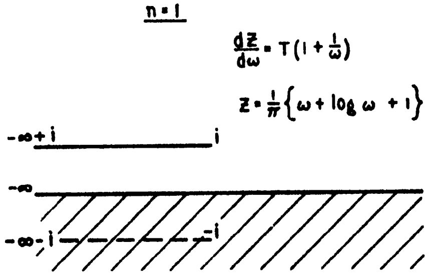
| $r$ $n$ | 1 | 2 | 5 | 10 | $\infty$ |
|---|---|---|---|---|---|
| 5 | 0.69 | 0.84 | 0.92 | 0.95 | 0.98 |
| 10 | 0.81 | 0.97 | 1.07 | 1.14 | 1.20 |

If the dimensions are, however, reasonably large compared to the gap width, then the obtained values of $h(x)$ may be expected to be fairly accurate throughout the region wherein its greatest reduction in value occurs, i.e., up to about 2 gap widths.

In order to appraise the value of $d$ obtainable for the two-dimensional cases discussed above the necessary integrations as in Eq. (4) were carried out. The results are given in Table I. Here $d$ is given in gap widths as a function of the two variables $n$ and $r$. In each case it applies to the central ray. Actually $d$ is not directly dependent on $r$ but rather on the distance of the ion source from the uniform field region. For the cases evaluated in Table I this distance was taken as equal to $r$, a situation which exists in a sector-type spectrometer when the sector angle is 90°. The values considered were: $r=5$ gap widths and $r=10$ gap widths.

As is evident from Table I, a large change in ion source distance will cause considerable change in $d$. Although the magnetic field strength is small at large distances it has a large cumulative effect. In determining $h(x)$ experimentally for a determination of $d$ by numerical integration it is important to take the measurements under as near operating conditions as possible. For example, if an auxiliary magnet is used with the ion source to align the beam of ionizing electrons the experimental determination of $h(x)$ must include its effects.

It has sometimes been assumed that effective corrections for the influence of the fringing flux could be made by the simple use of the virtual field boundaries. Thus in locating the ion source and ion collector relative to the magnetic field the apex formed by the virtual field boundary is



n = 1
$\frac{dz}{d\omega}=T(1+\frac{1}{\omega})$
$z=\frac{1}{\pi}\{\omega+\log\omega+1\}$

$-i$

FIG 4. Extreme case of magnet pole construction wherein $n=1$.

obtained by some approximate or graphical method. Such a method of correction assumes that the central ray will have its center of curvature located on the virtual sector apex.

We now wish to show that this method is not exact and that not only must the displacement of virtual field boundaries be taken into account but also the deviation of the trajectory from a straight line in the region between the ion source and the magnetic analyzer.

Figure 7 represents the geometry such as found in a 90° sector-type spectrometer with symmetrical location of ion source and collector. Here $A$ represents the position of an ion source with its axis coincident with line $AB$. The effect of the fringing field is to cause the ions emerging from the source on the line $AB$ to move away from it as they approach the magnetic analyzer. In the scale of dimensions used in constructing this figure $AB$ is 5 gap widths which would be proper for a 90° instrument utilizing trajectories with radii of curvature also of 5 gap widths. The center of curvature for that portion of the central ray within the uniform field region is at $D$, the intersection of the virtual field boundaries $DH$ and $DI$. Now if one were to use $DH$ and $DI$ as the new boundaries of an ideal magnetic field region, the ion source would be located at $F$ which will be 5 gap widths from $DH$ and which lies on the line perpendicular to $ED$, the bisector of the sector angle. However, it is clear that the location of the ion source at $F$ will give a central ray with a center of curvature below and slightly to the right of $D$ as the fringing field will still be operative. Thus the assumption that the use of virtual field boundaries would allow the use of the exact geometrical relations prescribed for this type of instrument (reference 1) is seen not to be true. It is to be noticed that this result does not depend on the numerical value of $d$ or of the sector angle, i.e., the use of virtual field boundaries and the exact geometrical relationships described above will always yield a center of curvature of the central ray offset from the virtual field boundary apex.

A method of correcting for fringing flux which depends upon an assumption concerning optimum focusing is now suggested. It is assumed that optimum focusing conditions are achieved when the ion source and ion collector are located the same distance from the actual field boundaries as would be used for the ideal case wherein there were no fringing flux and are so located relative to the sector apex that the central ray leaves the ion source in a direction normal to one pole-face boundary and enters the ion collector in a direction normal to the other pole-face boundary. Such a condition is illustrated in Fig. 7. There the distances $AB$ and $CG$ are equal to the radius of curvature for the uniform field region which is a condition necessary for the ideal 90° sector-type analyzer. One basis for the above

assumption about optimum focusing conditions is the close correspondence between the geometry stated and the geometry of the ideal case which was used in the derivation of the focusing properties of this type of analyzer. Another basis for the assumption is that as an ion beam of small angular spread reaches the actual pole-face boundary, after passing from the ion source through the fringing flux, the angular and spatial separations of the individual trajectories are approximately the same as would be obtained in the ideal case wherein there were no fringing field. Also the centers of curvature of the trajectories as they pass through the uniform field region will be separated by approximately the same distances as for the ideal case. These latter statements will be seen to be true later when we consider the changes in Eqs. (2) and (3) for ion trajectories of different angles of emergence from the source.

By way of demonstrating the above assumption concerning optimum fringing flux corrections let us suppose it is desired to make the corrections for a 90° sector-type instrument with symmetrical location of ion source and collector. Referring to Fig. 7, $AB$ will be the distance of the ion source from the actual field boundary and will be equal to the radius of curvature chosen for operation. Supposing $h(x)$ to be available it will be possible to obtain $f(x)$ and to use it in the integration of Eq. (2), which will give the deviation of the central ray trajectory from the line $AB$ and will trace its entry into the uniform field region. When the trajectory reaches a point deep enough in the uniform field region that $h(x)=1$, the slope $dy/dx$ may be evaluated and the location of point $D$, the center of curvature, determined. Now it is clear that we may expect the ion to leave the field in a trajectory exactly similar to the entry one if symmetrical conditions are provided. To do so a line which is at 45°, half the sector angle, with $DH$, the virtual field boundary, is projected to the actual field boundary. This locates $E$, the actual sector apex. Now it is seen that exactly symmetrical conditions are provided. The dimension of significance now is $EB$ which locates the distances of the ion source and ion-collector axes from the actual sector apex. This is readily obtained in simple steps, using the location of point $D$ relative to points $A$ and $E$ and to the point of entry of line $AB$ into the uniform field region.

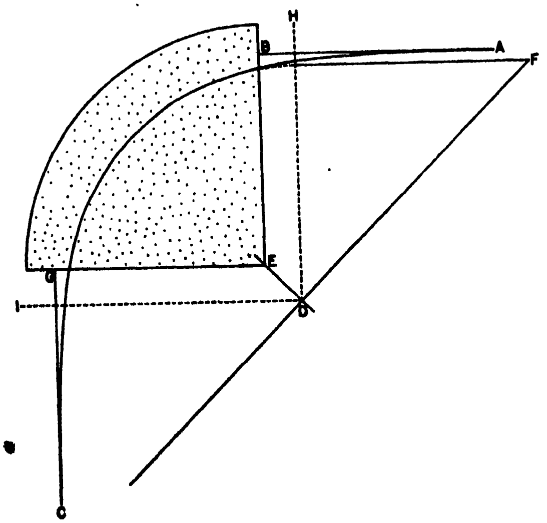

FIG. 7. Geometry of fringing flux corrections for sector-type instrument.

If it is desired to determine the flux corrections for an unsymmetrical system such that the angles $\theta$ and $\gamma$, as defined in reference 1, are unequal it may be done using the methods of above. In this case it would be necessary to determine the trajectories for two fringing field conditions, i.e., for the ion source and ion-collector sides, and match them in the uniform field region.

For the trajectories and geometry considered so far

$$f(x)=\int_{x_0}^{x} h(x)dx,$$

that is $f(x_0)=0$ so that $(dy/dx)x_0=0$. This is the condition imposed on the central ray, i.e., that it leave the ion source normal to the slits (using such a case as in Fig. 7 where the ion source axis is parallel to the $x$ axis and the pole-face bounary is parallel to the $y$ axis). However, for ions emerging from the ion source at a small angle $\alpha$ with the normal to the slits we will have:

$$f(x)=\int_{x_0}^{x} h(x)dx+\tilde{c},$$

where $\tilde{c}$ is a constant to be correlated with the initial slope.[2]

From Eq. (1) we have then:

$$(dy/dx)x_0 = \tan\alpha = \bar{c}/(r^2 - \bar{c}^2)^{\frac{1}{2}}.$$

Since for small $\alpha$ (as would be true for an actual ion beam) $r \gg \bar{c}$ we obtain $\bar{c} = r\tan\alpha$.

The virtual boundary displacement for such a trajectory will be obtained from:

$$r = \pm\int_{x_0}^{\bar{x}} h(x)dx + r\tan\alpha.$$

Since $h(x)$ is equal to unity in the uniform field region we have for the virtual boundary displacement $d(\alpha)$ for a trajectory of starting angle $\alpha$

$$d(\alpha) = d(0) + r\tan\alpha.$$

The separation then between the virtual boundary effective for a trajectory of starting angle $\alpha$ and the virtual boundary effective for the principal ray is seen to be $r\tan\alpha$ which is the same as is obtained for the ideal case. This result is part of the basis for the assumption above concerning optimum focusing conditions.

The separation in the $y$ direction at the pole-face boundary between the central ray and one emerging from the ion source with angle $\alpha$ may be seen to be approximately the same as for the ideal case. To calculate this difference we integrate Eq. (2) for the two cases. We get then for the separation

$$\Delta y = \bar{c}\int_{x_0}^{0} \frac{dx}{(r^2 - (\bar{f} + \bar{c})^2)^{\frac{1}{2}}}.$$

However, since $r \gg \bar{c}$ and since $\bar{f}(x)$ is always found to be small enough so that $(r^2 - (\bar{f} + \bar{c})^2)^{\frac{1}{2}} = r$ to within about 2 percent or better for all of $0 < x < x_0$ we have $\Delta y = \bar{c}x_0/r$ which is equal to $x_0\tan\alpha$, the same value as for the ideal case.

By use of Eq. (2) and the approximations above we may show that the angular spread of the trajectories as they enter the uniform magnetic field region is approximately the same for the actual case as for the ideal one. We shall denote the slope angle at $x = 0$ as $\beta$. Then from Eq. (2) we have:

$$\tan\beta = (\bar{f}(0) + \bar{c})/(r^2 - (\bar{f}(0) + \bar{c})^2)^{\frac{1}{2}}. \qquad (5)$$

By differentiation we get

$$(1 + \tan^2\beta)\Delta\beta = r^2\Delta\bar{c}/(r^2 - (\bar{f}(0) + \bar{c})^2)^{\frac{1}{2}}.$$

Using Eq. (5) and the approximation of above this reduces to $\Delta\beta = \Delta\bar{c}/r$. For the central ray and one emerging from the source at a small angle $\alpha$ we have $\Delta\bar{c} = \bar{c} = r\tan\alpha = r\alpha$ so that $\Delta\beta = \alpha$; i.e., the trajectories will have approximately the same angular divergence at $x = 0$ as at the ion source. An actual calculation of the angular spread at $x = 0$ for one of the cases for which $d$ was evaluated above is illuminating. The conditions used were: $n = 10$, $r = 5$, and $\alpha = 3°40'$. For this case $\bar{f}(x)$ was calculated for the region between the ion source and the actual field boundary using the values of $h(x)$ shown in Fig. 6. From this and from Eq. (5) it was determined that the angle at $x = 0$ between the tangents of the two trajectories, was $3°44'$, i.e., the same as the starting angle to within less than 2 percent discrepancy.

The author is indebted to Dr. M. Muskat for several discussions of this problem and to Dr. P. D. Foote, Executive Vice-President of Gulf Research and Development Company, for permission to publish this material.

Wilbur L. Pritchard

(Received March 24, 1947)

This paper considers the theory of band-pass wave-guide filters formed by cascading rectangular cavities separated by quarter guide wave-lengths. Formulas for resonant frequency, loaded $Q$, and insertion loss in the pass band are derived for a single stage using matrix theory and are in a form suitable for design purposes.

The general theory of "$n$" stages is worked out using matrix algebra, and it is shown that the insertion loss and phase shift of "$n$" stages are given by:

$$L_n = 1 + x^2 Un^2(x) \qquad \phi = \tan^{-1}[Tn(x)/Un(x)],$$

where $Tn(x)$ and $Un(x)$ are the first and rationalized second kind Tschebyscheff polynomials.

The specific design procedure is outlined including the design of a finite thickness inductive aperture.

## I. INTRODUCTION

THE filters considered here are of the band-pass type, formed by rectangular cavities in cascade and separated from each other by quarter wave sections of line. The complete problem is divided into three sections. First, analysis of a single stage to find resonant frequency, phase shift, loaded $Q$, and loss in the pass band; second, study of the behavior of cascaded stages to find insertion loss out of the pass band, phase shift, and loss in the pass band for "$n$" stages; and third, the final design procedure.

The theory of a single stage is handled by use of matrix theory of four terminal networks[1] and the combined lumped element-transmission line equivalent circuit for the cavity. The cavity proper is represented by a length of ideal line, and the coupling apertures are represented by pure shunt susceptances The latter representation is not strictly accurate, and a slight correction is necessary in the final design. The analysis of "$n$" stages in cascade is also handled by matrix theory and involves taking the "$n$th" power of a matrix.

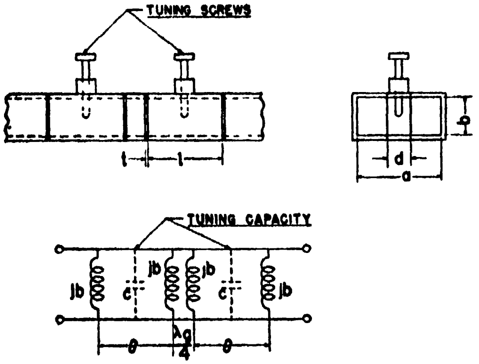

Fig. 1. Two stage filter and network equivalent.

Figure 1 shows the wave-guide configuration along with the equivalent circuit used in the analysis.

## II. PRELIMINARY NETWORK THEORY

A few brief relations based on the general circuit matrix of a quadripole are now derived. If the box in Fig. 2 represents any linear, passive network we can write:

$$E_1 = AE_2 + BI_2, \tag{1}$$

$$I_1 = CE_2 + DI_2. \tag{2}$$

The coefficients $A$, $B$, $C$, and $D$ completely determine the network behavior. Evidently $A$ and $D$ are numerics, $B$ is an impedance, and $C$ is an admittance. Actually there are only three independent coefficients, since application of the reciprocity theorem to Eqs. (1) and (2) yields the relation.

$$AD - BC = 1. \tag{3}$$

Furthermore in the case of symmetrical networks we also have

$$A = D. \tag{4}$$

---

* The author wishes to acknowledge his indebtedness to R. M. Fano of M.I.T. for a preview of the manuscript of Vol. XXII of the Rad. Lab. Series which deals with the same problem from a different approach.

[1] L. A. Pipes, "Matrix theory of four terminal networks," Phil. Mag. 30, 370–395 (November 1940); L. Brillouin, Revue Generale de L'Electricite 55, 3–16 (January 4, 1946).

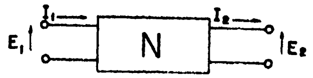

FIG. 2.

Since all the networks considered in the subsequent analysis are symmetrical, Eq. (4) will prove quite useful.

Rewriting Eqs. (1) and (2) in matrix form yields:

$$\begin{bmatrix} E_1 \\ I_1 \end{bmatrix} = \begin{bmatrix} A & B \\ C & D \end{bmatrix} \begin{bmatrix} E_2 \\ I_2 \end{bmatrix}. \quad (5)$$

The matrix $\begin{bmatrix} A & B \\ C & D \end{bmatrix}$ is called the general circuit matrix and will henceforth be designated as $[u]$. The general circuit matrices for several basic network elements used in this paper are shown in Fig. 3.

In Fig. 4 we have a generator and load, normally matched to each other, separated by some four terminal network. The normalized generator and load impedances are assumed to be real and equal to one, since this is the condition commonly met in wave-guide problems. Since the impedances are all normalized, the following equations will not be dimensionally homogeneous.

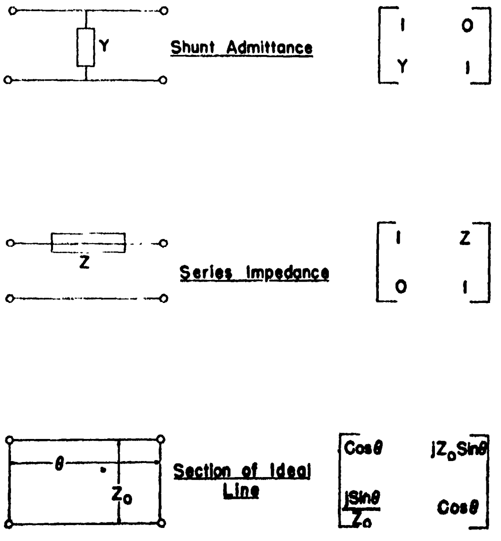

FIG. 3. General circuit matrices of several common networks.

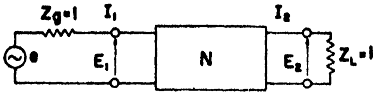

FIG. 4.

From Eqs. (1) and (2) we have:

$$Z_1 = E_1/I_1 = (AZ_L+B)/(CZ_L+D) = (A+B)/(C+D). \quad (6)$$

Using simple network theory we can find $R$, the ratio of the voltages across $Z_L$ when directly connected to the generator and when connected through the network,

$$R = \tfrac{1}{2}(A+B+C+D). \quad (7)$$

$R$ will be a complex quantity in general. The insertion loss, defined as the ratio of available power to the power delivered through the network, is found from the magnitude of $R$.

$$L = |R|^2. \quad (8)$$

The insertion phase shift, or phase shift in the voltage across the load resulting from the insertion of the network, is found from the real and imaginary components of $R$.

$$\tan\phi = [I(R)/R_e(R)]. \quad (9)$$

Equations (7)–(9) will enable us to determine the attenuation and phase characteristics of both single and multiple stage filters from the general circuit matrix.

## III. ANALYSIS OF A SINGLE STAGE

Figure 5 shows the equivalent circuit for a single stage. We proceed with the analysis of a single stage by first determining the general circuit matrix. Since the circuit of Fig. 5 can be considered as a cascade combination of two shunt susceptances and a section of ideal line we find $[u]$ by matrix multiplication in the same order as the order of connection.

Referring to the table in Fig. 3

$$[u] = \begin{bmatrix} 1 & 0 \\ jb & 1 \end{bmatrix} \begin{bmatrix} \cos\theta & j\sin\theta \\ j\sin\theta & \cos\theta \end{bmatrix} \begin{bmatrix} 1 & 0 \\ jb & 1 \end{bmatrix}. \quad (10)$$

Performing the indicated multiplication we have:

$$[u] = \begin{bmatrix} \cos\theta - b\sin\theta & j\sin\theta \\ j[(1-b^2)\sin\theta + 2b\cos\theta & \cos\theta - b\sin\theta \end{bmatrix}. \quad (11)$$

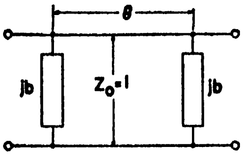

FIG. 5. Network equivalent of single stage filter.

From Eq. (7) we find $R$

$$R=(\cos\theta-b\sin\theta)$$
$$+j[(1-b^2/2)\sin\theta+b\cos\theta]. \quad (12)$$

Taking the sum of the squares of the components of $R$ and simplifying gives for the insertion loss:

$$L=1+b^2[\cos\theta-(b/2)\sin\theta]^2 \quad (13)$$

and for phase shift:

$$\tan\phi=\frac{[1-(b^2/2)]\sin\theta+b\cos\theta}{\cos\theta-b\sin\theta}. \quad (14)$$

Since the network is lossless a first definition for the resonant frequency is that frequency at which $L=1$. We have from Eq. (13)

$$1=1+b^2[\cos\theta-(b/2)\sin\theta]^2$$

Solving for $\theta$

$$\theta=\text{arc}\tan(2/b). \quad (15)$$

Equation (15) determines the resonant length of the filter in terms of the aperture susceptance. For large values of $b$ which represent physically small apertures, $\theta$ is almost 180° or one-half wave-length. Equation (15) is plotted in Fig. 6, curve (2).

A second definition of resonance, and one which will be useful in the subsequent determination of the filter $Q$, is that frequency at which the input admittance is zero if the load admittance is zero. From Eq. (6) we have for the input admittance when $Y_L=0$

$$Y_1=C/A.$$

Substituting from the matrix in Eq. (11) yields

$$Y_1=j\frac{(1-b^2)\sin\theta+2b\cos\theta}{\cos\theta-b\sin\theta}.$$

Equating the numerator to zero we have:

$$(1-b^2)\sin\theta=-2b\cos\theta$$
$$\tan\theta=-2b/(1-b^2)$$
$$\theta=\text{arc}\tan[2b/(b^2-1)]. \quad (16)$$

Equations (15) and (16) provide two different design relations for resonant frequency. For values of $b$ corresponding to values of $Q$ usually met in practice (treated in next section) the two formulas give the same result for $\tan\theta$ within normal slide-rule discrepancies.

To determine the physical length $l$ of the cavity we use the relation

$$\theta=\beta l, \quad \text{where} \quad \beta=2\pi/\lambda_g. \quad (17)$$

$\beta$ is the propagation constant of the guide and $\lambda_g$ is the guide wave-length.

Thus

$$\tan 2\pi l/\lambda_g=2/b \text{ where } \lambda_g=\lambda/[1-(\lambda/\lambda_c)^2]^{\frac{1}{2}}. \quad (18)$$

In terms of $\omega$, the angular velocity we have:

$$\tan\frac{\omega_0 l}{c}\left[1-\left(\frac{\omega_c}{\omega_0}\right)^2\right]^{\frac{1}{2}}=2/b, \quad (19)$$

where $l$ = cavity length, $b$ = aperture susceptance, $\lambda$ = air wave-length, $\lambda_c$ = cut-off wave-length, $\omega_0$ = resonant angular velocity, $\omega$ = cut-off angular velocity, and $c$ = velocity of light in vacuum.

Equation (19) is a design equation for determining the length of the resonant cavity. However, since there is an infinite number of pairs of values of $b$ and $l$ which satisfy Eq. (19) a second condition is required. This is the relation between the operating or loaded $Q$ of the cavity and the aperture susceptance. To derive such a relation we find a lumped parallel resonant cir-

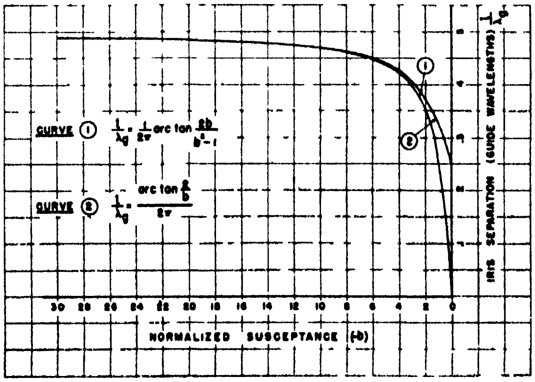

FIG. 6.

cuit which closely approximates the filter's behavior in the vicinity of resonance. In determining the filter's behavior near resonance we assume that the frequency consciousness of the apertures is negligible compared to the frequency consciousness of the length of line. In other words we assume constant $b$ and consider variations in $\theta$ with frequency and their effects on the filter characteristics. Physically this assumption corresponds to neglecting the effect of the coupling holes in considering the characteristics *versus* frequency of a resonant cavity. Naturally this assumption is most valid for small coupling holes or large susceptances. Subsequently it will be seen that for usual values of $Q$ the aperture susceptance will be high enough to make the above assumption quite justifiable.

Referring to Fig. 3 and the general circuit matrix we have for the input impedance, when the load impedance is infinite, from Eq. (1) and (2)

$$Z_1=(A+B/Z_L)/(C+D/Z_2)=A/C.$$

On an admittance basis we have from Eq. (11)

$$Y_1=C/A=j\frac{2b+(1-b^2)\tan\theta}{1-b\tan\theta}. \qquad (20)$$

We assume $\theta=\theta_0+K\Delta f$, where $\theta_0$ is the resonant wave-length and $K=d\theta/df$. By using the identity for the tangent of the sum of two angles and making the approximations $\tan K\Delta f=K\Delta f$ and $bK\Delta f<1$ Eq. (20) can be reduced to the form:

$$Y_1=jK\Delta f(b^2+1). \qquad (21)$$

In Fig. 7 the input admittance with zero load admittance is the well-known relation:

$$Y_1=j(C/L)^{\frac{1}{2}}(\omega/\omega_0-\omega_0/\omega), \qquad (22)$$

or for small frequency deviations $(\omega/\omega_0-\omega_0/\omega)=2\Delta\omega/\omega_0=\epsilon$,

$$Y_1=j(C/L)^{\frac{1}{2}}\epsilon. \qquad (23)$$

Equating the two input admittances we have:

$$j(C/L)^{\frac{1}{2}}2\Delta f/f_0=jK\Delta f(b^2+1) \qquad (24)$$

$$(C/L)^{\frac{1}{2}}=(Kf)(b^2+1)/2. \qquad (25)$$

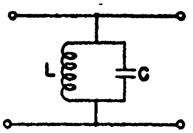

FIG. 7.

If we take the cavities as non-dissipative, then the $Q$ for any given type of aperture depends only on the loading. Since there is a matched load $Z_0=1$ on each side of the cavity the shunt loading resistance in the equivalent resonant circuit is taken equal to $\frac{1}{2}$. Since

$$\begin{aligned}R_{\text{shunt}}&=Q(L/C)^{\frac{1}{2}}=\tfrac{1}{2}\\ Q&=\tfrac{1}{2}(C/L)^{\frac{1}{2}} \qquad (26)\\ Q&=(Kf)(b^2+1)/4.\end{aligned}$$

To find $K$ we take the first derivative of the function relating $\theta$ to $f$

$$\theta=\frac{2\pi lf}{c}[1-(fc/f)^2]^{\frac{1}{2}}. \qquad (27)$$

After differentiating and simplifying

$$K=\frac{d\theta}{df}=\frac{2\pi l}{c}[1-(fc/f)^2]^{-\frac{1}{2}}. \qquad (28)$$

Also, from Eq. (27)

$$f_0=\frac{c\theta_0}{2\pi l}[1-(fc/f)^2]^{-\frac{1}{2}}. \qquad (29)$$

Substituting Eqs. (28) and (29) in Eq. (26) we find:

$$Q=(b^2+1)\theta_0/4[1-(fc/f)^2], \qquad (30)$$

but

$$\theta_0=\tan^{-1}2b/(b^2-1).$$

Therefore:

$$Q=\frac{b^2+1}{4[1-(fc/f)^2]}\tan^{-1}\frac{2b}{b^2-1}. \qquad (31)$$

For large values of $b$

$$\tan^{-1}\frac{2b}{b^2-1}=\pi \quad\text{and}\quad b^2\gg 1.$$

$$Q=\frac{b^2}{4[1-(fc/f)^2]}. \qquad (32)$$

Equation (31) is plotted in Fig. 8. The calculation of $Q$ using this expression neglects the effects of dissipative losses in the cavity. These

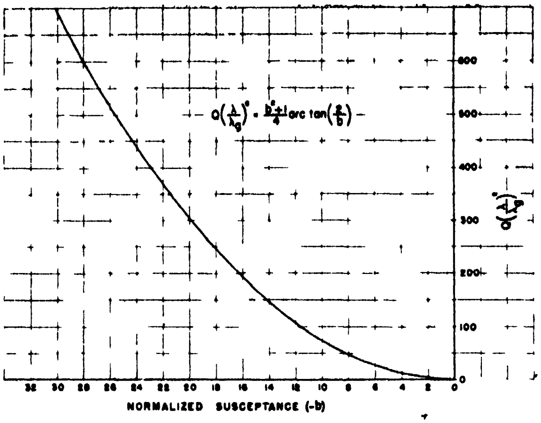

FIG. 8.

losses will have two chief effects on the filter performance. One will be to produce a slight lowering of the loaded $Q$ according to

$$1/Q^1 = 1/Q + 1/Q_0, \qquad (33)$$

where $Q^1$ is the actual operating $Q$, and $Q_0$ is the unloaded $Q$ of the rectangular cavity which can be calculated from ordinary resonant cavity theory.[2] The second effect will be to produce losses in the pass band. These losses can also be calculated from the unloaded $Q$ in the following manner:

From the general circuit matrix for a shunt admittance we have:

$$R = (A+B+C+D)/2 = (2+Y)/2$$
$$R = 1 + Y/2. \qquad (34)$$

For a dissipative cavity $Y$ is equal to the equivalent shunt conductance at resonance or:

$$Y = G_0 = (1/Q_0)(L/C)^{\frac{1}{2}}. \qquad (35)$$

But $(L/C)^{\frac{1}{2}} = \frac{1}{2}Q$, where $Q$ is the loaded $Q$ (Eq. (26)). Therefore

$$G_0 = 2Q/Q_0$$

and

$$R = 1 + Q/Q_0$$
$$L = |R|^2 = (1+Q/Q_0)^2 \qquad (36)$$

or

$$L_{\text{db}} = 20 \log(1+Q/Q_0). \qquad (37)$$

Equations (33) and (37) can be used to correct for the effects of incidental dissipation in the cavity.

## IV. QUARTER WAVE CASCADING OF FILTER SECTIONS

The simple filter of the previous section is only applicable where the desired response is approximately the same as that of a parallel resonant circuit. In many applications this is not sufficient, since the insertion ratio off resonance may not be high enough, or the width of the pass band may not be sufficiently great. In such cases it becomes necessary to cascade several filter sections. This cascading can be done in several ways. Either direct connection can be utilized, or the separate sections can be isolated by quarter wave sections. The successive sections can be tuned to the same frequency, or they can be stagger tuned. This report will consider only quarter wave coupled identical sections.[3]

We continue to use the lumped circuit equivalent for a single stage and consider the case of three quarter wave coupled stages (see Fig. 9).

The associated matrix is given by (refer to chart in Fig. 3):

$$[u] = \begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix} \begin{bmatrix} 0 & j \\ j & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix} \begin{bmatrix} 0 & j \\ j & 0 \end{bmatrix} \begin{bmatrix} 1 & 0 \\ Y & 1 \end{bmatrix}, \qquad (38)$$

Performing the indicated multiplication we have for $[u]$

$$[u] = \begin{bmatrix} 1+Y^2 & Y \\ Y(2+Y^2) & 1+Y^2 \end{bmatrix}. \qquad (39)$$

In Fig. 10a we have a simple $\pi$ section. To find its associated matrix we again multiply the matrices of its components.

$$[u]_\pi = \begin{bmatrix} (Z_p+Z_s)/Z_p & Z_s \\ (2Z_p+Z_s)/Z_p^2 & (Z_p+Z_s)/Z_p \end{bmatrix}. \qquad (40)$$

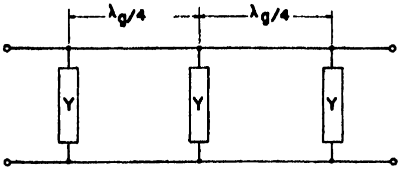

FIG. 9. Network equivalent of three cascaded stages.

---

[2] See, for instance, Sarbacher and Edson, *Hyper and Ultra High Frequency Engineering* (John Wiley and Sons, Inc., New York, 1943).

[3] Quarter wave coupled filters were first developed by R. M. Fano at Rad. Lab.

To find the equivalent $\pi$ section for Fig. 9 we equate the elements of the two matrices given in Eqs. (39) and (40)

$$\begin{aligned} (Z_p+Z_s)/Z_p&=1+Y^2 & Z_s&=Y\\ Z_s/Z_p&=Y^2 & Y_s&=1/Y\\ Z_p=Z_s/Y^2&=1/Y\\ Y_p&=Y. \end{aligned}$$

Using the above relations we have a $\pi$ section lumped circuit equivalent to the three section filter of Fig. 9. The value of $Y$ is given by Eq. (23).

$$\begin{aligned} Y&=j(C/L)^{\frac{1}{2}}\epsilon=Y_p\\ Y_s&=1/Y=-j(L/C)^{\frac{1}{2}}/\epsilon. \end{aligned} \tag{41}$$

The admittance of a lossless series resonant circuit is given by:

$$\begin{aligned} Y_{\text{series}}&=1/j(L^1/C^1)^{\frac{1}{2}}\epsilon\\ &=-j(C^1/L^1)^{\frac{1}{2}}/\epsilon. \end{aligned} \tag{42}$$

By comparing Eq. (42) to Eq. (41) we see that $Y_s$ can be replaced by a series resonant circuit where $C^1=L$ and $L^1=C$. Therefore we have for the final lumped equivalent the circuit of Fig. 10b.

This equivalent is evidently a band-pass filter with a center frequency given by $W_0=1/(LC)^{\frac{1}{2}}$ at which both series and shunt arms are resonant.

Similar lumped equivalents can be developed for any number of cascaded sections.

### V. THEORY OF "$n$" SECTIONS IN CASCADE

The brief considerations of Section IV served to yield an equivalent lumped circuit for the particular case of three cascaded stages. The general case, to be considered now, involves "$n$" stages, and we propose to obtain an exact expression for insertion loss and phase shift. We proceed with this problem by considering the typical stage in a quarter wave coupled cascade. Fig. 11 shows the resonant circuit equivalent of the cavity with eighth wave lines on each side. Evidently a cascade of this type section will result in resonant circuits separated by quarter wave lines.

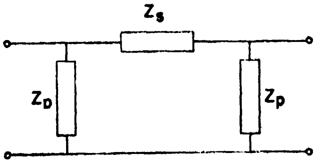

FIG. 10a.

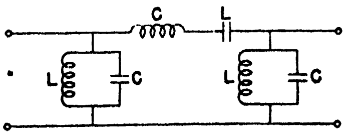

FIG. 10b. Lumped circuit equivalent of three cascaded stages.

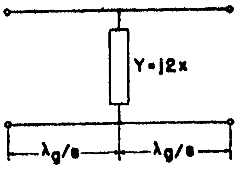

FIG. 11.

Again referring to Fig. 3 we have for the general circuit matrix:

$$[u]=\begin{bmatrix}\cos45° & j\sin45°\\ j\sin45° & \cos45°\end{bmatrix}\begin{bmatrix}1 & 0\\ Y & 1\end{bmatrix}\times\begin{bmatrix}\cos45° & j\sin45°\\ j\sin45° & \cos45°\end{bmatrix}. \tag{43}$$

Substituting $Y=j2X$ where $X=Q\epsilon$, $\cos45°=\sin45°=(2^{\frac{1}{2}}/2)$, and performing the matrix multiplication yields

$$u=\begin{bmatrix}-X & j-jX\\ j+jX & -X\end{bmatrix}. \tag{44}$$

To raise the matrix $[u]$ to the $n$th power we must reduce it to the form

$$[u]=[K]\begin{bmatrix}\lambda_1 & 0\\ 0 & \lambda_2\end{bmatrix}[K]^{-1}. \tag{45}$$

In this form $[u]^n$ becomes:

$$[u]^n=[K]\begin{bmatrix}\lambda_1{}^n & 0\\ 0 & \lambda_2{}^n\end{bmatrix}[K]^{-1}. \tag{46}$$

$\lambda_1$ and $\lambda_2$ turn out to be the eigenvalues of the matrix $[u]$ and are found from the characteristic equation of $[u]$. The characteristic equation is formed by subtracting $[u]$ from the scalar matrix $[\lambda]$ and equating the principal determinant of the difference to zero. The roots of the

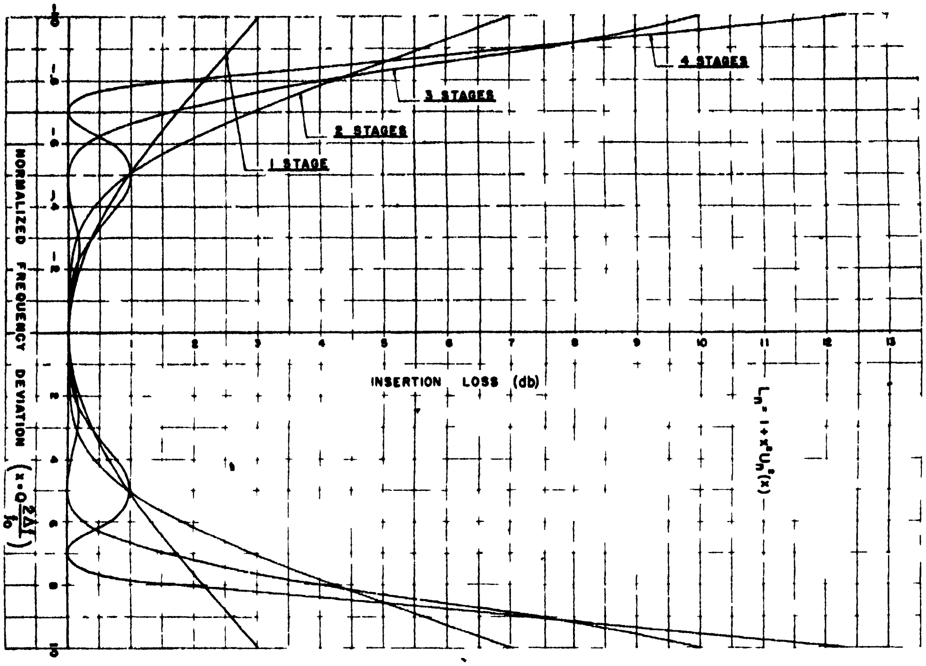

FIG 12

resultant quadratic (Eq. 47) then become:

$$\begin{gathered}\lambda^2+2x\lambda+1=0,\\ \lambda_1=-x+(x^2-1)^{\frac{1}{2}},\quad \lambda_2=-x-(x^2-1)^{\frac{1}{2}},\end{gathered}\tag{47}$$

Also:

$$\lambda_1+\lambda_2=-2x,\quad \lambda_1\lambda_2=1$$

We make the substitutions $\lambda_1=\epsilon^a$ and $\lambda_2=\epsilon^{-a}$ which give:

$$\lambda_1+\lambda_2=2\cosh a,\quad a=\cosh^{-1}(-x).\tag{48}$$

The matrix $[u]$ can now be written in the form:[4]

$$[u]=\begin{bmatrix}\lambda_1+x & \lambda_2+x\\ j(1+x) & j(1+x)\end{bmatrix}\begin{bmatrix}\lambda_1 & 0\\ 0 & \lambda_2\end{bmatrix}$$

$$\times\begin{bmatrix}\dfrac{1}{\lambda_1-\lambda_2} & -\dfrac{\lambda_2+x}{j(1+x)(\lambda_1-\lambda_2)}\\ -\dfrac{1}{\lambda_1-\lambda_2} & \dfrac{\lambda_1+x}{j(1+x)(\lambda_1-\lambda_2)}\end{bmatrix}.\tag{49}$$

The first and third matrices in the above product are inverses of each other, while the center matrix is a scalar matrix. That the product in the right-hand member of Eq (49) is actually equal to $[u]$ can be verified by multiplication.

We now raise $[u]$ to the $n$th power by taking the $n$th power of the elements of the diagonal matrix, multiply the three matrices together and simplify to get:

$$[u]^n=\begin{bmatrix}\cosh an & -j\dfrac{\sinh a}{1+x}\sinh an\\ j\dfrac{1+x}{\sinh a}\sinh an & \cosh an\end{bmatrix}$$

$$=\begin{bmatrix}A_n & B_n\\ C_n & D_n\end{bmatrix}.\tag{50}$$

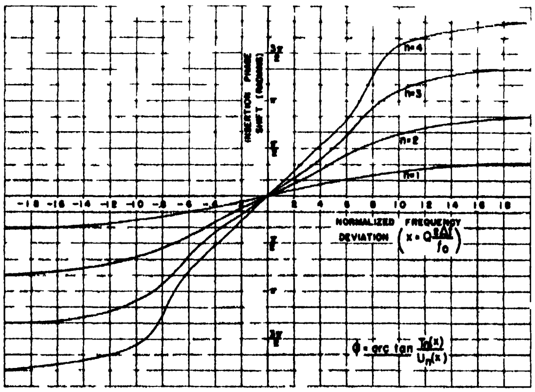

FIG. 13.

---

[4] The transformation and diagonalizing of a matrix carried out above are described in detail in Margenau and Murphy, *Mathematics of Physics and Chemistry* (D. Van Nostrand Company, Inc., New York 1943).

Equation (50) gives the general circuit matrix for "$n$" cascaded stages. Note that $A_n = D_n$ and $A_nD_n - B_nC_n = 1$ which is to be expected. From $[u]^n$ we can now find the general expression for insertion less and phase shift: From Eq. (7) we have:

$$R_n = (A_n + B_n + C_n + D_n)/2.$$

Substituting from the matrix $[u]^n$ yields

$$R_n = \cosh an + j\frac{\sinh an}{\sinh a}. \qquad (51)$$

For insertion loss we take the square of the magnitude:

$$L_n = |R_n|^2 = \cosh^2 an + \sinh^2 an/\sinh^2 a. \qquad (52)$$

Using the identity $\cosh^2 an - \sinh^2 an = 1$ and substituting for Sinh$a$ we can write Eq. (52) in the form:

$$L_n = 1 + x^2\,\mathrm{Sinh}^2 an/(x^2-1) \qquad (53)$$

or

$$L_n = 1 + x^2 \times [\mathrm{Sinh}\{n \operatorname{arc}\cosh(-x)\}]^2/(x^2-1). \qquad (54)$$

The expression in the bracket of Eq. (54) is equivalent to the rationalized Tschebyscheff polynomial of the second kind.[5] Rewriting Eq. (54) we have (see Appendix I):

$$L_n = 1 + x^2 U_n^2(x). \qquad (55)$$

Equation (56) gives the specific polynomials for $U_n(X)$ and $L_n$ for values of "$n$" up to four along with a recurrence formula for $U_n$ in case higher values of "$n$" are desired:

$$\begin{aligned} L_1 &= 1 + x^2, & U_1 &= 1,\\ L_2 &= 1 + 4x^4, & U_2 &= 2x,\\ L_3 &= 1 + x^2 - 8x^4 + 16x^6, & U_3 &= 4x^2 - 1,\\ L_4 &= 1 + 16x^4 - 64x^6 + 64x^8, & U_4 &= 8x^3 - 1, \end{aligned}$$

$$U_{n+1}(x) = 2xU_n(x) - U_{n-1}(x). \qquad (56)$$

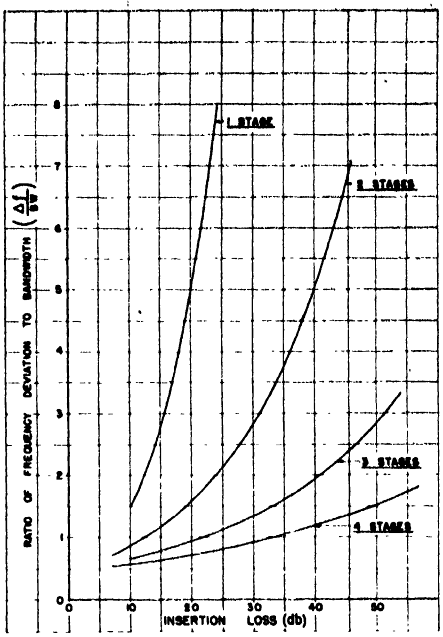

FIG. 14a.

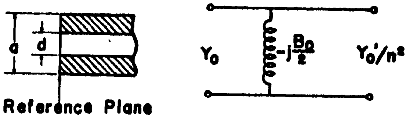

FIG. 14b. Network equivalent of inductive change in wave guide cross section.

Figure 12 is a plot of Eq. (55) in decibels for $n = 1, 2, 3, 4$. From the complex expression for $R_n$ we can also determine the phase shift for "$n$" stages:

$$\phi_n = \tan^{-1}\frac{\sinh an/\sinh a}{\cosh an} = \tan^{-1}\frac{\sinh[n\cosh^{-1}(-x)]/(x^2-1)^{\frac{1}{2}}}{\cosh[n\cosh^{-1}(-x)]}. \qquad (57)$$

The expression in the denominator for Eq. (57) is a Tschebyscheff polynomial of the first kind, while the numerator is again a rationalized second kind polynomial. Rewriting Eq. (57) we have (see Appendix I):

$$\phi_n = \tan^{-1}\frac{-U_n(x)}{T_n(x)}. \qquad (58)$$

Since the typical stage used in considering "$n$" stages cascaded had eight wave line sections on each end, when a particular number of stages is considered there is an extra eighth wave on

---

[5] E. Modelung, *Die Mathematischen Hilfsmittel des Physikers* (Dover Publications, New York, 1943).

each end of the composite filter. This total extra quarter wave introduces an added 90° phase shift. Since this added phase shift is not pertinent to the filter operation we subtract it from the expression in Eq. (58) yielding:

$$\phi_n = \tan^{-1}\frac{-T_n(x)}{U_n(x)}. \tag{59}$$

Specific expressions for $\phi_n$ and $T_n$ for values of "$n$" up to four are given in Eq. (60) along with a recurrence formula for $T_n$

$$\phi_1 = \tan^{-1}x, \qquad T_1 = x,$$

$$\phi_2 = \tan^{-1}(2x^2-1)/2x, \qquad T_2 = 2x^2-1,$$

$$\phi_3 = \tan^{-1}(4x^3-3x)/(4x^2-1), \quad T_3 = 4x^3-3x,$$

$$\phi_4 = \tan^{-1}(8x^4-8x^2+1)/(8x^3-4x),$$

$$T_4 = 8x^4-8x^2+1,$$

$$T_{n+1}(x) = 2xT_n(x) - T_{n-1}(x). \tag{60}$$

Figure 13 is a plot of Eq. (59) for values of "$n$" up to four. In computing phase shift it is assumed that the phase shift at resonance is zero. Actually it will be some multiple of 90° because of the quarter wave sections and the lengths of guide composing the cavities. Also, if the individual stages are designed on an input match basis there will be a very slight extra phase shift at resonance. Generally this is negligible. Since one is usually only interested in phase shift variation about an arbitrary constant value, for f-m distortion considerations, etc., plotting $\phi_n$ about zero is quite useful.

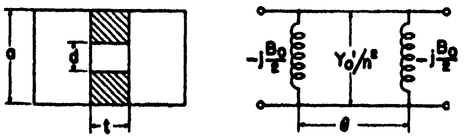

FIG. 15. Network equivalent of finite thickness inductive aperture.

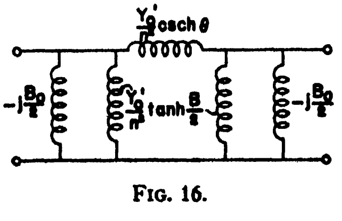

$\frac{Y_0'}{n^2}\operatorname{csch}\theta$
$-j\frac{B_0}{2}$
$\frac{Y_0'}{n^2}\tanh\frac{\theta}{2}$
$-j\frac{B_0}{2}$

FIG. 16.

An approximate relation for the insertion loss of $n$ stages, which will be accurate for values of $x$ far off resonance, can be found from the Tschebyscheff polynomial by neglecting all but the highest power of $x$. This yields:

$$L_{n(\mathrm{db})} = 6(n-1)+20n\log x. \tag{60}$$

Equation (60) can be used to determine if a particular number of stages will have sufficient attenuation far out of the pass band.

## VI. DESIGN PROCEDURE

In designing a filter for a particular application the first step is the choice of the proper number of stages. This is done with the aid of Fig. 14a. The ratio to band width of frequency deviation for a particular attenuation is plotted in Fig. 14 for $n=1, 2, 3, 4$. We define the band width of the filter as the difference between the frequencies of the half-power points. As an example, if an attenuation of 40 decibels is desired at a frequency two band widths removed from resonance, Fig. 14 shows that three stages are necessary. The curves in Fig. 14 can only be used to select the number of stages if band width is considered as distance between the half-power points.

After the number of stages has been determined the $Q$ of a typical stage is found from Fig. 12. That is, from the normalized frequency deviation $X$ which gives the desired band width, and from the band width and resonant frequency, $Q$ is determined using the relation

$$X = Q[(f/f_0)-(f_0/f)] \tag{61}$$

or approximately

$$X = Q(2\Delta f/f_0). \tag{62}$$

The approximation in Eq. (62) is reasonably valid for values of frequency deviation as high as 10 percent which, at microwave frequencies, is much larger than normally considered.

Once $Q$ is chosen and knowing $\lambda/\lambda_g$ the aperture susceptance is found using Fig. 8, and then the aperture separation using Fig. 6. From the guide wave-length the actual mechanical cavity length is readily determined.

The last step in the design procedure is the determination of the actual aperture opening which will produce the desired susceptance.

Unfortunately this is a rather tedious process, since it is absolutely necessary to consider the finite thickness of the window.

The method is based on the equivalent circuit for a symmetrical change in cross section of a rectangular guide. This equivalent was derived by N. Marcuvitz at Radiation Lab.[6] Figure 14b shows the wave guide configuration, and the network equivalent referred to the indicated reference plane:
"$a$" is the cut-off controlling dimension of the guide, $Y_0$ the characteristic admittance of the first section and $Y_0^1/n^2$ the characteristic admittance of the second section of width $d$. $B_0$ is the susceptance of an infinitely thin aperture of opening "$d$" and can be found from Eq. (63) or from curves in the Wave Guide Handbook.

$$B_0/Y_0=\frac{\lambda_g}{a}\left[\cot^2\frac{\pi d}{2a}\right], \qquad (63)$$

$$n^2=\frac{4}{\pi}\cdot\frac{\cos\pi d/2a}{1-(d/a)^2}, \qquad (64)$$

$$\lambda_g'=j2a/(1-(2d/\lambda)^2)^{\frac{1}{2}}, \qquad (65)$$

$$Y_0'=Y_0[-j\lambda_g a/|\lambda_g'|d]. \qquad (66)$$

$|\lambda_g^1|$ is the magnitude of the wave-length in the below cut-off section of guide of width $d$. Equation (65) for the imaginary wave-length in the cut-off guide is the usual expression for guide wave-length modified to take care of $(\lambda/\lambda_c)^2$ greater than one.

The above equivalent circuit can be extended to the case of a finite thickness aperture. Figure 15 shows the wave guide configuration and the equivalent circuit for symmetric inductive apertures.

In the above network the two lumped susceptances represent the abrupt changes in cross section at each end of the window, and the line section represents the short length of below cut-off line produced by the thickness of the window. This line section can be replaced by its exact $\pi$ equivalent,[7] as shown in Fig. 16.

$\theta$ is given for a dissipationless line by Eq. (67)

$$\theta=j\beta l=\frac{2\pi}{|\lambda_g'|}t. \qquad (67)$$

The network of Fig. 16 can be further simplified by combining the shunt susceptances of the $\pi$ equivalent with $-jB_0/2$. The equivalent for the composite aperture is shown in Fig. (17).

$$B_a=B_0/2+|Y_0'/n^2|\tanh\pi t/|\lambda_g'|, \qquad (68)$$

$$B_b=|Y_0'/n^2|\ \operatorname{csch}2\pi t/|\lambda_g'|. \qquad (69)$$

Equations (68) and (69) completely determine the equivalent network for a finite thickness symmetric inductive aperture. To proceed with the design of the filter it is convenient to convert this $\pi$ section to an equivalent $T$. This equivalent is shown in Fig. (18).

$$B_1=2B_b+B_a, \qquad (70)$$

$$B_2=2B_a+B_a^2/B_b. \qquad (71)$$

The shunt arm ($B_2$) of the $T$ equivalent may now be used in determining the $Q$ of the filter stage, and the series arm $B_1$ is used to make a slight correction in the resonant length of the filter. This correction is made by simply shortening the cavity an amount equal to the line length represented by the series susceptance $B_1$.

As a practical consideration it is generally desirable to design the filter at a frequency slightly higher than desired and then tune it down to the desired frequency with a capacitive tuning screw as shown in Fig. 1. This capacity will lower the resonant frequency as much as 5 percent without seriously changing the loaded $Q$.

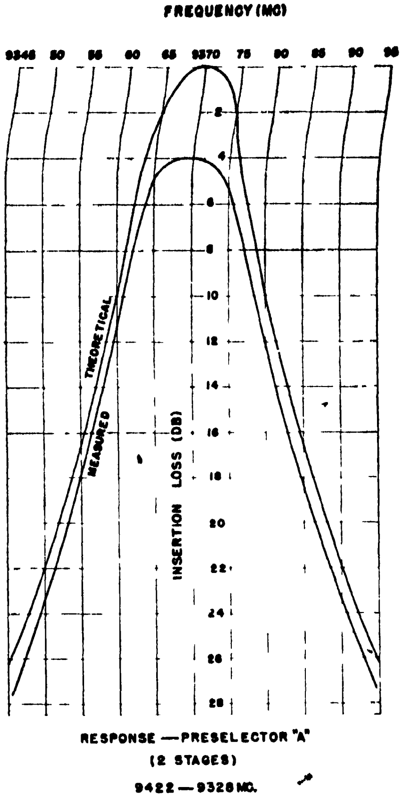

FIG. 19.

## VII. EXPERIMENTAL RESULTS

Figure 19 shows a comparison between the calculated and measured characteristics *vs.* frequency of a two stage filter designed using the method outlined. The filter was designed for a frequency of 9422 Mc in 1″×½″ wave guide and then tuned down to 9370 Mc with two capacitive probes mechanically ganged. The experimental curve is displaced downward from theoretical because of finite losses in the pass band, but its shape is substantially unaltered. It is important to note that the filter can easily be tuned 50 Mc below its natural frequency without materially altering its response.

## Conclusions

A general theory for an "*n*" stage filter has been developed using matrix theory which, along with the design formulas for a single stage and the procedure outlined in the last section, can be used to design a composite filter.

## APPENDIX I

We define the Tschebyscheff function of the first kind as follows:

$$T_n(x)=\cosh(n\cosh^{-1}x), \qquad (1)$$

Letting $y=\cosh^{-1}x$ we have:

$$T_n(x)=\cosh ny \qquad (2)$$

$$T_{n+1}(x)=\cosh(ny+y)=\cosh ny\cosh y+\sinh ny\sinh y \qquad (3)$$

$$T_{n-1}(x)=\cosh(ny-y)=\cosh ny\cosh y-\sinh ny\sinh y. \qquad (4)$$

Adding Eqs. (3) and (4) yields:

$$\begin{aligned}T_{n+1}(x)&=2\cosh ny\cosh y-T_{n-1}(x)\\ T_{n+1}(x)&=2T_n(x)T_1(x)-T_{n-1}(x).\end{aligned} \qquad (5)$$

Equation (5) is a recursion formula from which the Tschebyscheff polynomials can be formed, starting with $T_0(x)=1$ and $T_1(x)=x$. If $-x$ is substituted for $x$ then the sign of $T_n(x)$ changes for $n$ odd and remains the same for $n$ even. In Eq. (57) for phase shift the function in the denominator is actually $T_n(-x)$.

The second kind Tschebyscheff function is defined as follows:

$$U_n(x)=\frac{\sinh(n\cosh^{-1}x)}{(x^2-1)^{\frac{1}{2}}}. \qquad (6)$$

The term $(x^2-1)^{\frac{1}{2}}$ is a rationalizing factor since $U_1(x)=\sinh(\cosh^{-1}x)=(x^2-1)^{\frac{1}{2}}$ and polynomials formed from a recursion formula will always have this radical as a multiplier. The recursion formula for $U_n(x)$, derived in exactly the same manner as the one for $T_n(x)$, is given by:

$$U_{n+1}(x)=2xU_n(x)-U_{n-1}(x). \qquad (7)$$

If $-x$ is substituted for $x$ then the sign of $U_n(x)$ changes for $n$ even and remains the same for $n$ odd. In Eq. (54) giving the insertion loss for an "$n$" stage filter the rationalizing factor is already present in the denominator of the second term of the right-hand member, and since this term is squared the changes in sign of $U_n(-x)$ have no effect and we can write

$$U_n^2(x)=\left[\frac{\sinh(n\cosh^{-1}-x)}{(x^2-1)^{\frac{1}{2}}}\right]^2. \qquad (8)$$

In Eq. (57) for phase shift the inverse tangent of $\phi$ is given by $(U_n(-x)/T_n(-x))$, which is equal to $-(U_n(x)/T_n(x))$ for $n$ either odd or even. Since only relative phase shift is of interest this minus sign has been neglected in plotting $\phi$.

# A Computational Method Applicable to Microwave Networks

R. H. Dicke
*Palmer Physical Laboratory, Princeton University, Princeton, New Jersey*

(Received March 20, 1947)

A method is devised for computing the properties of a complex microwave network in terms of the properties of the circuit elements which in combination form the network. It is particularly suited to machine computation of the properties of circuits of such complexity that simpler, more direct methods fail. It is also applicable to low frequency networks. The elements of such networks may be regarded as interconnected by transmission lines of zero length. A numerical example is used to illustrate the method.

## INTRODUCTION

In the past the engineering of microwave circuits has consisted largely of a method of cut and try. It seems likely that microwave circuits of the future will consist of combinations of microwave elements each of whose properties are known. These microwave elements will probably be interconnected by transmission lines to form complex networks. Among the microwave elements used to synthesize a complex network one may mention tuners, line stretchers, tees, magic tees, directional couplers, and terminations. Figure 1 shows a block diagram of such a microwave circuit.

It is desired to calculate the properties of such a complex network in terms of the known properties of the various sub-elements which in combination form the network. In particular it is desired to calculate the amplitudes and phases of the waves leaving the network at each of the five feeding transmission lines in terms of the amplitudes and phases of the waves entering the network. For some purposes it is also necessary to know the amplitudes and phases of waves in the various interconnecting transmission lines.

As is well known, the complex amplitudes of waves leaving a junction of one or more transmission lines are linearly related to the amplitudes of waves entering the junction. This linear relation can be conveniently expressed by means of a matrix algebra formulation. See Eq. (1). The matrix algebra formulation will be used throughout the remainder of the discussion without going into a discussion of matrix algebra per se. (A concise development of matrix algebra can be found in Margenau and Murphy.[1])

$$\begin{pmatrix} b_1 \\ b_2 \\ \cdot \\ \vdots \\ b_n \end{pmatrix} = \begin{pmatrix} S_{11} & \cdots & S_{1n} \\ \cdot & & \cdot \\ \vdots & & \vdots \\ S_{n1} & \cdots & S_{nn} \end{pmatrix} \begin{pmatrix} a_1 \\ \cdot \\ \vdots \\ a_n \end{pmatrix}. \tag{1}$$

Equation (1) is concerned with a junction of $n$-transmission lines. These lines are numbered consecutively from 1 through $n$. Reference planes are chosen in each of these lines. The complex number $a_j$ represents the amplitude and phase of the wave incident on the junction in the $j$th line, the phase being measured at the reference plane. In a similar way $b_j$ is a complex number representing a wave leaving the junction. The square matrix with elements $S_{jk}$ is called the scattering matrix of the junction. Equation (1) expresses the fact that the $b$'s are linearly related to the $a$'s; Eq. (1) may be written formally as

$$\mathbf{b} = \mathbf{Sa}. \tag{2}$$

It should be noted that $\mathbf{a}$ and $\mathbf{b}$ in Eq. (2) are descriptions of the waves entering and leaving the junction, but that the matrix $\mathbf{S}$ is dependent only on the properties of the junction. The scattering matrix is simply related to the more familiar impedance and admittance matrices.[2]

## DISCUSSION

The problem to be considered is the following: Given a set of microwave circuit elements, with scattering matrices $\mathbf{S}_1, \mathbf{S}_2, \cdots \mathbf{S}_n$, interconnected to form a complex network, what is the scattering matrix of the combined network? A

---

[1] H. Margenau and G. P. Murphy, *The Mathematics of Physics and Chemistry* (D. Van Nostrand Company, Inc., New York, 1943).

[2] Radiation Laboratory Technical Series, *The Principles of Microwave Circuits* (McGraw-Hill Book Company, Inc., New York, to be published), gives a discussion of the scattering matrix formalism and its application to microwave problems.

method will be presented for the calculation of the scattering matrix of a network composed of two interconnected junctions. It is clear that by iteration the method may be used to calculate a network with an arbitrary number of interconnected junctions.

*Problem*: To calculate the scattering matrix of two interconnected microwave elements.

*Element No. 1* has scattering matrix $\mathbf{S}_1$ and is fed by $p$ transmission lines.

*Element No. 2* has scattering matrix $\mathbf{S}_2$ and is fed by $q$ transmission lines.

Let there be $r$ interconnections between the two elements. Number the transmission lines feeding the element (1) in such a way that the terminals of junction (1) number from 1 to $p$. Let the terminals of element (2) be numbered to run from $p-r+1$ to $p-r+q$. Let terminals in the range

$$p-r<n<p+1$$

be interconnected. For an example see Fig. 2. The scattering matrix for element (1) can be written

$$\mathbf{S}_1=\left[\begin{array}{c|c|c} & & 0\\ \hline & & 0\\ \hline 0 & 0 & 0\\ \underbrace{\qquad}_{\substack{p-r\\ \text{columns}}} & \underbrace{\qquad}_{\substack{r\\ \text{columns}}} & \underbrace{\qquad}_{\substack{q-r\\ \text{columns}}}\end{array}\right]\begin{array}{l}\}\,p-r\text{ rows}\\ \}\,r\text{ rows.}\\ \}\,q-r\text{ rows}\\ \phantom{0}\end{array}\qquad(3)$$

Note that zeros have been added to make $\mathbf{S}_1$ a square matrix of order $p-r+q$. Equation (2) applied to junction (1) will be written as

$$\mathbf{S}_1\mathbf{a}_1=\mathbf{b}_1.\qquad(4)$$

In a similar way

$$\mathbf{S}_2\mathbf{a}_2=\mathbf{b}_2,\qquad(5)$$

where

$$\mathbf{S}_2=\left[\begin{array}{c|c|c} 0 & 0 & 0\\ \hline 0 & & \\ \cline{2-2} 0 & & \\ \underbrace{\qquad}_{p-r} & \underbrace{\qquad}_{r} & \underbrace{\qquad}_{q-r}\end{array}\right]\begin{array}{l}\}\,p-r\\ \}\,r\\ \}\,q-r\\ \phantom{0}\end{array}\qquad(6)$$

Introduce an auxiliary matrix

$$\mathbf{A}=\left[\begin{array}{c|c|c} 0 & 0 & 0\\ \hline 0 & \begin{matrix}1_1 & & 0\\ & \ddots & \\ 0 & & 1\end{matrix} & 0\\ \hline 0 & 0 & 0\end{array}\right].\qquad(7)$$

It is characterized by having zeros everywhere but along the diagonal of the central block. Also introduce

$$\mathbf{B}=\mathbf{I}-\mathbf{A}\qquad(8)$$

where $\mathbf{I}$ is the identity matrix.

The matrix $\mathbf{A}$ is useful in representing the connections between the two elements of the network. To see this, note that in Fig. 2 waves leaving junction (1) along transmission lines (4), (5) and (6) are also waves entering junction (2) and *vice versa*. This may be expressed formally in the following way:

$$\mathbf{A}\mathbf{a}_1=\mathbf{A}\mathbf{b}_2,\qquad(9)$$

$$\mathbf{A}\mathbf{b}_1=\mathbf{A}\mathbf{a}_2.\qquad(10)$$

From Eqs. (4), (5), (8)–(10) one obtains

$$\begin{aligned}\mathbf{b}_1&=\mathbf{S}_1\mathbf{a}_1\\ &=\mathbf{S}_1\mathbf{I}\mathbf{a}_1=\mathbf{S}_1\mathbf{A}\mathbf{a}_1+\mathbf{S}_1\mathbf{B}\mathbf{a}_1\\ &=\mathbf{S}_1\mathbf{A}\mathbf{S}_2\mathbf{a}_2+\mathbf{S}_1\mathbf{B}\mathbf{a}_1\\ &=\mathbf{S}_1\mathbf{A}\mathbf{S}_2\mathbf{A}\mathbf{a}_2+\mathbf{S}_1\mathbf{A}\mathbf{S}_2\mathbf{B}\mathbf{a}_2+\mathbf{S}_1\mathbf{B}\mathbf{a}_1.\end{aligned}\qquad(11)$$

Let

$$\mathbf{M}=\mathbf{S}_1\mathbf{A}\mathbf{S}_2\mathbf{A},\quad \mathbf{N}=\mathbf{S}_1\mathbf{A}\mathbf{S}_2.\qquad(12)$$

Then

$$\mathbf{b}_1=\mathbf{M}\mathbf{a}_2+\mathbf{N}(\mathbf{B}\mathbf{a}_2)+\mathbf{S}_1(\mathbf{B}\mathbf{a}_1).\qquad(13)$$

It should be noted that the last two terms on the

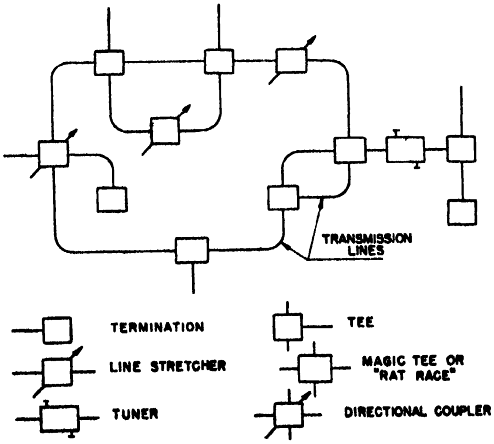

FIG. 1.

right side of (13) contain $\mathbf{Ba}_2$ and $\mathbf{Ba}_1$ as column vectors. From (7) and (8) it may be seen that $\mathbf{B}$ has all zeros in the central block. Hence if $\mathbf{B}$ operates on a column vector it replaces the $r$ rows whose indices run from $p-r+1$ through $p$ by zeros. Thus $\mathbf{B}$ has the effect of removing from $\mathbf{a}_1$ and $\mathbf{a}_2$ those elements which are unknown, namely, the wave amplitudes in the interconnecting transmission lines. The remaining elements of $\mathbf{a}_1$ and $\mathbf{a}_2$ are the incident waves in the transmission lines feeding the combined network and are assumed known.

The procedure which leads from (4) to (13) may be iterated to give the following sequence of equations:

$$\begin{aligned}
\mathbf{b}_1 &= \mathbf{Ma}_2+\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1),\\
\mathbf{b}_1 &= \mathbf{M}^2\mathbf{a}_2+\mathbf{MN}(\mathbf{Ba}_2)+\mathbf{MS}_1(\mathbf{Ba}_1)\\
&\qquad +\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1),\\
\mathbf{b}_1 &= \mathbf{M}^3\mathbf{a}_2+\mathbf{M}^2\mathbf{N}(\mathbf{Ba}_2)+\mathbf{M}^2\mathbf{S}_1(\mathbf{Ba}_1)\\
&\quad +\mathbf{MN}(\mathbf{Ba}_2)+\mathbf{MS}_1(\mathbf{Ba}_1)\\
&\qquad +\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1),\\
&\ \ \vdots \qquad\qquad \vdots \qquad\qquad \vdots
\end{aligned}\tag{14}$$

Note that in this sequence of equations, with the exception of the 1st term, all terms on the right side have column vectors operated on by $\mathbf{B}$.

The Eq. (14) may be rearranged as follows:

$$\begin{aligned}
\mathbf{b}_1 &= \mathbf{Ma}_2+[\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1)],\\
\mathbf{b}_1 &= \mathbf{M}^2\mathbf{a}_2+(\mathbf{M}+\mathbf{I})[\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1)],\\
\mathbf{b}_1 &= \mathbf{M}^3\mathbf{a}_2+(\mathbf{M}^2+\mathbf{M}+\mathbf{I})[\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1)].\\
&\ \ \vdots \qquad\qquad \vdots \qquad\qquad \vdots
\end{aligned}\tag{15}$$

Let the characteristic equation of the matrix $\mathbf{M}$ be

$$\sum_n C_n\lambda^n = 0. \tag{16}$$

It will be shown in the appendix that the term $C_0$ vanishes in (16) and furthermore that there can be no more than $r+1$ non-vanishing terms.

By Cayley-Hamilton's theorem the matrix $\mathbf{M}$ satisfies its characteristic equation and

$$\sum_n C_n\mathbf{M}^n = 0. \tag{17}$$

If possible, it is convenient to normalize the coefficients in (16) in such a way that

$$\sum C_n = 1. \tag{18}$$

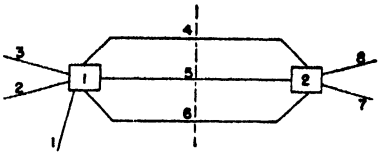

FIG. 2. $p=6$, $q=5$, and $r=3$.

If the sum of the coefficients of the characteristic equation vanishes, this normalization is impossible. This case will be discussed in the appendix.

Multiply Eqs. (15) by the coefficients $C_n$ and sum over the index $n$.

$$\sum_{n=1}^{r+1} C_n\mathbf{b}_1 = \left[\sum_{n=1}^{r+1} C_n\mathbf{M}^n\right]\mathbf{a}_2+\sum_{n=1}^{r+1} C_n\mathbf{S}_1(\mathbf{Ba}_1)$$
$$+\sum_{n=1}^{r+1} C_n\mathbf{N}(\mathbf{Ba}_2)+\sum_{n=2}^{r+1} C_n\mathbf{MN}(\mathbf{Ba}_2)+\cdots. \tag{19}$$

Substituting (17) and (18) in (19)

$$\begin{aligned}
\mathbf{b}_1 = [\mathbf{I}+(1-C_1)\mathbf{M}+(1-C_1-C_2)\mathbf{M}^2+\cdots]&\\
\times[\mathbf{N}(\mathbf{Ba}_2)+\mathbf{S}_1(\mathbf{Ba}_1)].&
\end{aligned}\tag{20}$$

It should be noted that $\mathbf{a}_1$ and $\mathbf{a}_2$ appear in (20) only in combination with $\mathbf{B}$. Equation (20) is part of the solution as it expresses the amplitudes of waves leaving the junction number (1) as a linear combination of the amplitudes of waves entering the combined network.

Since

$$\mathbf{S}_1\mathbf{Ba}_2 = 0 \tag{21}$$

and

$$\mathbf{NBa}_1 = 0,$$

Eq. (20) can be written as

$$\begin{aligned}
\mathbf{b}_1 = [\mathbf{I}+(1-C_1)\mathbf{M}+(1-C_1-C_2)\mathbf{M}^2+\cdots]&\\
\times(\mathbf{N}+\mathbf{S}_1)\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2).&
\end{aligned}\tag{22}$$

The amplitudes of waves leaving the junction number (2) remain to be calculated. This is easily done making use of (22). From (5) and (10)

$$\mathbf{b}_2 = \mathbf{S}_2\mathbf{a}_2 = \mathbf{S}_2(\mathbf{A}+\mathbf{B})\mathbf{a}_2 = \mathbf{S}_2\mathbf{Ab}_1+\mathbf{S}_2\mathbf{Ba}_2. \tag{23}$$

Substitute (22) in (23)

$$\begin{aligned}
\mathbf{b}_2 = \mathbf{S}_2\mathbf{A}[\mathbf{I}+(1-C_1)\mathbf{M}+(1-C_1-C_2)\mathbf{M}^2+\cdots]&\\
\times(\mathbf{N}+\mathbf{S}_1)\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2)+\mathbf{S}_2\mathbf{Ba}_2,&
\end{aligned}\tag{24}$$

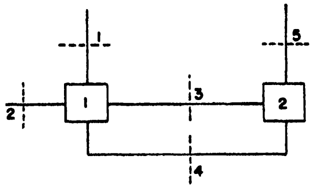

FIG. 3.

which may be written as

$$\mathbf{b}_2=\{\mathbf{S}_2+\mathbf{S}_2\mathbf{A}[\mathbf{I}+(1-C_1)\mathbf{M}+\cdots](\mathbf{N}+\mathbf{S}_1)\}\times\mathbf{B}(\mathbf{a}_1+a_2).\quad(25)$$

Equations (22) and (25) may be combined to form the scattering equation for the combined network.

$$\mathbf{B}(\mathbf{b}_1+\mathbf{b}_2)=\mathbf{S}\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2)\quad(26)$$

where

$$\mathbf{S}=\mathbf{B}\{\mathbf{S}_2+(\mathbf{I}+\mathbf{S}_2\mathbf{A})[\mathbf{I}+(1-C_1)\mathbf{M}+(1-C_1-C_2)\mathbf{M}^2+\cdots](\mathbf{N}+\mathbf{S}_1)\}\mathbf{B}.\quad(27)$$

**S** as given by (27) is the scattering matrix of the combined network.

The network scattering matrix **S** has the following form:

$$\mathbf{S}=\left[\begin{array}{c|c|c} & 0 & \\ \hline 0 & 0 & 0 \\ \hline & 0 & \\ \underbrace{\hphantom{000}}_{p-r} & \underbrace{\hphantom{0}}_{r} & \underbrace{\hphantom{000}}_{q-r} \end{array}\right]\begin{matrix}\}p-r\\ \}r\\ \}q-r\\ \phantom{0}\end{matrix}.$$

The $r$ rows and columns which are zero may be removed to form a matrix of order $p+q-2r$. In a similar way the column vectors $\mathbf{B}(\mathbf{b}_1+\mathbf{b}_2)$ and $\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2)$ have zeros in $r$ rows beginning at the $p-r+1$ row. These zeros may be removed to form $p+q-2r$ rowed vectors. This process of removing zeros reduces the matrices to a dimension equal to the number of transmission lines feeding the combined network. The rows and columns removed are the ones associated with the interconnecting transmission lines.

For some purposes it is desirable to know the amplitudes of waves in the interconnecting transmission lines in terms of amplitudes of waves incident upon the network. These amplitudes are contained in $\mathbf{b}_1$ and $\mathbf{b}_2$ and may be expressed as

$$\mathbf{A}\mathbf{b}_1=\mathbf{A}[\mathbf{I}+(1-C_1)\mathbf{M}+(1-C_1-C_2)\mathbf{M}^2+\cdots]\times(\mathbf{N}+\mathbf{S}_1)\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2)\quad(28)$$

and

$$\mathbf{A}\mathbf{b}_2=\mathbf{A}\{\mathbf{S}_2+\mathbf{S}_2\mathbf{A}[\mathbf{I}+(1-C_1)\mathbf{M}+\cdots]\times(\mathbf{N}+\mathbf{S}_1)\}\mathbf{B}(\mathbf{a}_1+\mathbf{a}_2).\quad(29)$$

The left-hand side of Eqs. (28) and (29) consists only of the amplitudes of waves in interconnecting transmission lines of the network.

To recapitulate, Eqs. (26)–(29) express the unknown complex wave amplitudes of waves in the transmission lines of a microwave network of the type illustrated in Fig. 2 as functions of the known amplitudes. In particular the left side of (26) consists of the amplitudes of waves leaving the network (along the lines 1, 2, 3, 7, and 8 of Fig. 2) expressed as a linear combination of the complex amplitudes, assumed known, of waves entering the network. In a similar way Eqs. (28) and (29) express the complex amplitudes of waves in the interconnecting transmission lines (4, 5, and 6, Fig. 2) as linear combinations of the known complex amplitudes of waves entering the network (along lines 1, 2, 3, 7, and 8 of Fig. 2).

## EXAMPLE

As an example of the application of the formalism, consider the microwave network illustrated schematically in Fig. 3.

The "magic tee" has the property of dividing the power incident upon it in any one of its four feeding transmission lines equally between the two adjacent lines. For example, if a wave is sent in on line 2, it leaves the junction No. 1 *via* lines 1 and 4. Of course, the wave which leaves junction No. 1 *via* line 4 returns again after interacting with junction No. 2. This leads, in turn, to a new set of waves scattered by junction No. 1 and so on. By locating the terminals in (1), (2), (3), or (4) properly, the scattering matrix of the junction No. 1 may be written as

$$\mathbf{S}_1=\frac{1}{\sqrt{2}}\left[\begin{array}{cc|cc|c} 0 & 1 & 1 & 0 & 0 \\ 1 & 0 & 0 & 1 & 0 \\ \hline 1 & 0 & 0 & -1 & 0 \\ 0 & 1 & -1 & 0 & 0 \\ \hline 0 & 0 & 0 & 0 & 0 \end{array}\right].\quad(30)$$

As an example of the meaning of $\mathbf{S}_1$ note that the third column of $\mathbf{S}_1$ indicates that a wave of amplitude 1 incident on the junction in transmission line 3 leaves the junction along lines 1 and 4 with amplitudes $1/\sqrt{2}$ and $-1/\sqrt{2}$, respectively. The phases of these waves are to be taken at their respective reference planes.

In a similar way the junction No. 2 is a matched symmetrical tee. Its scattering matrix is assumed to be

$$\mathbf{S}_2=\left[\begin{array}{c|cc|c} 0 & 0 & & 0 \\ \hline 0 & 0 & 1/\sqrt{2} & 1/\sqrt{2} \\ & 1/\sqrt{2} & \frac{1}{2} & -\frac{1}{2} \\ \hline 0 & 1/\sqrt{2} & -\frac{1}{2} & \frac{1}{2} \end{array}\right]. \quad (31)$$

It is possible to write the scattering matrix of any matched symmetrical tee in this way merely by locating the terminals correctly. However, the terminals 3 (or 4) have already been fixed in position. Therefore, it is necessary to assume that either the line 3 or the line 4 has been adjusted to have the correct length.

It may be noted that both $\mathbf{S}_1$ and $\mathbf{S}_2$ are symmetric and unitary. These are general properties and are characteristic of all scattering matrices.

Turning now to the two auxiliary matrices **A** and **B**, these have the following forms:

$$\mathbf{A}=\left[\begin{array}{c|cc|c} 0 & 0 & & 0 \\ \hline 0 & 1 & 0 & 0 \\ & 0 & 1 & \\ \hline 0 & 0 & & 0 \end{array}\right], \quad (32)$$

$$\mathbf{B}=\left[\begin{array}{cc|c|c} 1 & 0 & 0 & 0 \\ 0 & 1 & & \\ \hline 0 & & 0 & 0 \\ \hline 0 & & 0 & 1 \end{array}\right]. \quad (33)$$

The two matrices **M** and **N** may now be computed (see Eq. (12)).

$\mathbf{N}=\mathbf{S}_1\mathbf{A}\mathbf{S}_2$

$$=\frac{1}{2\sqrt{2}}\left[\begin{array}{c|cc|c} 0 & 0 & \sqrt{2} & \sqrt{2} \\ & \sqrt{2} & 1 & -1 \\ \hline 0 & -\sqrt{2} & -1 & +1 \\ & 0 & -\sqrt{2} & -\sqrt{2} \\ \hline 0 & 0 & & 0 \end{array}\right], \quad (34)$$

$\mathbf{M}=\mathbf{S}_1\mathbf{A}\mathbf{S}_2\mathbf{A}$

$$=\frac{1}{2\sqrt{2}}\left[\begin{array}{c|cc|c} 0 & 0 & \sqrt{2} & 0 \\ & \sqrt{2} & 1 & \\ \hline 0 & -\sqrt{2} & -1 & 0 \\ & 0 & -\sqrt{2} & \\ \hline 0 & 0 & & 0 \end{array}\right]. \quad (35)$$

Equation (16) may be obtained by using the method introduced in the appendix [see Eq. (45)]

$$0=\sum_n C_n\lambda^n=\lambda\det(\mathbf{R}-\mathbf{I}\lambda)=\lambda\begin{vmatrix} -(\lambda+\frac{1}{2}) & \dfrac{-1}{2\sqrt{2}} \\ 0 & -(\lambda+\frac{1}{2}) \end{vmatrix}$$

$$=\lambda(\lambda+\tfrac{1}{2})^2=\lambda^3+\lambda^2+\tfrac{1}{4}\lambda. \quad (36)$$

The coefficients $C_n$ must be normalized to satisfy Eq. (18). They then have the values

$$C_1=\frac{1}{9},\quad C_2=\frac{4}{9},\quad C_3=\frac{4}{9}. \quad (37)$$

The scattering matrix of the combined network may be computed by substituting in Eq. (27)

$$\mathbf{S}=\mathbf{B}\left\{\mathbf{S}_2+(\mathbf{I}+\mathbf{S}_2\mathbf{A})\left[\mathbf{I}+\frac{8}{9}\mathbf{M}+\frac{5}{9}\mathbf{M}^2\right](\mathbf{N}+\mathbf{S}_1)\right\}\mathbf{B}$$

$$=\frac{1}{3}\left[\begin{array}{cc|c|c} 0 & 2\sqrt{2} & 0 & 1 \\ 2\sqrt{2} & \frac{1}{3} & & -\dfrac{2\sqrt{2}}{3} \\ \hline 0 & & 0 & 0 \\ \hline 1 & -\dfrac{2\sqrt{2}}{3} & 0 & \dfrac{8}{3} \end{array}\right]. \quad (38)$$

If the two rows and columns which vanish are removed, the matrix becomes

$$\mathbf{S}=\frac{1}{3}\begin{bmatrix} 0 & 2\sqrt{2} & 1 \\ 2\sqrt{2} & \frac{1}{3} & -\dfrac{2\sqrt{2}}{3} \\ 1 & -\dfrac{2\sqrt{2}}{3} & \dfrac{8}{3} \end{bmatrix}. \quad (39)$$

It should be noted that this matrix is symmetric and unitary as it should be.

The matrices which can be used to calculate the amplitudes of waves in the connecting lines are obtained from Eqs. (28) and (29).

$$\mathbf{S}_c=\mathbf{A}\left[\mathbf{I}+\frac{8}{9}\mathbf{M}+\frac{4}{9}\mathbf{M}^2\right](\mathbf{N}+\mathbf{S}_1)\mathbf{B}$$

$$=\frac{1}{3}\left[\begin{array}{cc|c|c} \multicolumn{2}{c|}{0} & 0 & 0 \\ \hline \sqrt{2} & -\frac{1}{3} & & \frac{2\sqrt{2}}{3} \\ & & 0 & \\ 0 & \sqrt{2} & & -1 \\ \hline \multicolumn{2}{c|}{0} & 0 & 0 \end{array}\right]$$

$$\mathbf{S}_c'=\mathbf{A}\left\{\mathbf{S}_2+\mathbf{S}_2\mathbf{A}\left[\mathbf{I}+\frac{8}{9}\mathbf{M}+\frac{4}{9}\mathbf{M}^2\right](\mathbf{N}+\mathbf{S}_1)\right\}\mathbf{B}$$

$$=\frac{1}{9}\left[\begin{array}{cc|c|c} \multicolumn{2}{c|}{0} & 0 & 0 \\ \hline 0 & 3 & & 3\sqrt{2} \\ & & 0 & \\ 3 & \sqrt{2} & & -4 \\ \hline \multicolumn{2}{c|}{0} & 0 & 0 \end{array}\right]. \quad (41)$$

To illustrate the meaning of the matrices (38), (40), and (41), assume that a wave of unit amplitude is incident upon the combined network at terminals No. 1. The scattering matrix **S**, Eq. (39), states that the amplitudes of the waves leaving the network *via* lines (2) and (5) are $\frac{2}{3}\sqrt{2}$ and $\frac{1}{3}$, respectively. The matrix (40) states that there is a wave of amplitude $\sqrt{2}/3$ running in line (3) from junction No. 1 to No. 2. There is no wave moving in this direction along line (4). The matrix (41) states that there is no wave moving from junction No. 2 to No. 1 along (3), but that there is a wave of amplitude $\frac{1}{3}$ moving from right to left in line (4).

## APPENDIX

From Eqs. (3), (6), and (12) it is apparent that **M** has the form

$$\mathbf{M}=\left[\begin{array}{c|c|c} 0 & - & 0 \\ 0 & \mathbf{R} & 0 \\ 0 & 0 & 0 \\ p-r & r & q-r \end{array}\right]\begin{array}{l} \}p-r \\ \}r \\ \}q-r \end{array}. \quad (42)$$

The characteristic equation of **M** is defined as

$$\det(\mathbf{M}-\lambda\mathbf{I})=0. \quad (43)$$

Denote the middle square of **M** as a sub-matrix **R**. It is evident that

$$\det(\mathbf{M}-\lambda\mathbf{I})=\lambda^{q+p-2r}\det(\mathbf{R}-\mathbf{I}\lambda), \quad (44)$$

where the determinant on the right side of (32) is of order $r$. In order to reduce the characteristic polynomial to its lowest degree, Eq. (16) is defined by the relation

$$0=\sum_n C_n\lambda^n=\lambda\det(\mathbf{R}-\mathbf{I}\lambda). \quad (45)$$

Thus the characteristic polynomial is of degree $r+1$ and the index $n$ runs from 1 to $r+1$.

It will be remembered that the above described computational method depended for its validity on the non-vanishing of the sum of the coefficients of (33). A necessary and sufficient condition for the vanishing of this sum is the occurrence of

$$\lambda=1$$

as an eigenvalue of the matrix **M**. The values of the eigenvalues of **M** depend upon the scattering matrices $\mathbf{S}_1$ and $\mathbf{S}_2$. However, the locations of the reference planes or terminals in the interconnecting transmission lines are arbitrary. By changing their locations an accidental occurence of the root $\lambda=1$ can be eliminated.

# The Optics of Three-Electrode Electron Guns*

S. G. Ellis
*The McLennan Laboratory, Department of Physics, University of Toronto, Toronto, Canada*

(Received April 17, 1947)

The paper is concerned primarily with the electron guns employed in electron microscopy. The position of the image of the cathode, the magnification, and the divergence of the beam leaving the anode are calculated for a three-electrode electron gun with plane electrodes and circular apertures both for zero and battery bias. The simplifying assumption is made that the electrostatic lenses are thin. The results are compared with the experiments of Johannson. The extension of the results to the gun used in the transmission electron microscope is considered with the aid of electrolytic trough measurements. The case of a gun biased by a cathode resistor is also discussed.

## INTRODUCTION

THE illuminating system of the transmission electron microscope was first treated analytically by von Borries and Ruska.[1] They considered the electron gun as a source of electrons of fixed cross section and position and considered the dependence of the semi-angle of the illuminating beam at the specimen on the strength of the condenser lens. Marton and Hutter[2] extended this treatment to include the converging effect on the illuminating beam of that part of the objective field which lies between the specimen and the condenser lens. Finally, Hillier and Baker[3] have considered, semi-empirically, the influence of the filament height on the angular aperture of the illumination by treating the electron gun as a converging lens containing a physical aperture which may itself limit the aperture of the illumination.

Hitherto the electron gun has received either very general physical treatment,[4] or rather special semi-empirical treatment[5] in the literature. Since these treatments do not greatly clarify the behavior of the particular types of electron gun employed in electron microscopy, an attempt has been made in this paper to develop an analytic theory of a very simplified electron gun. The main simplifications are the treatment of the electrodes as plane, and the variations of axial potential as linear. The latter simplification is equivalent to treating the lenses as thin lenses. Later, this theory is used, in conjunction with electrolytic trough measurements, to describe the behavior of the guns employed in practice.

This analytic treatment is aided by a theorem attributed to Schlesinger[6] which may be called the "Transit Time Theorem." Consider an electron leaving an object (cathode or image) at $A$, Fig. 1, passing through a lens at $B$ and being focused to $C$. An axis $Oz$ is taken, coaxial with the lens, positive in the direction of electron motion and with origin at the lens. Take the zero of time as the epoch at which the electron passes through the lens $OB$. $T_0$ is the epoch at which the electron leaves $A$ and $T_I$ the epoch at which it arrives at $C$. It is supposed that the lens is thin so that radial forces act on the electron only while it is passing the $OB$ plane. If then a radial impulse $I$, positive if centrifugal, acts on the electron when passing through the lens at a distance $R$ from the center, then Schlesinger shows that the condition for image formation is:

$$I \propto R \tag{1}$$

and that under these conditions

$$(1/T_I)-(1/T_0)=-(I/mR) \tag{2}$$

$$=1/T_F \text{ say.} \tag{3}$$

In Eq. (2) $m$ is the mass of the electron. Equation (2) immediately leads to Gaussian dioptrics in the magnetic lens and the bipotential lens,

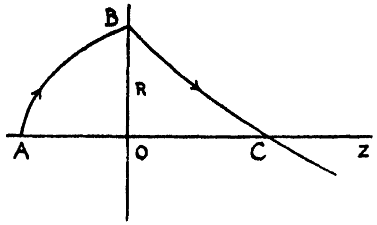

FIG. 1. General electron trajectory through a thin lens.

where the axial velocity of the electron is constant outside the lens and the trajectories are linear there. In the immersion objective the dioptrics will not be Gaussian, both because the axial velocity is continually changing and also because the strength of the lens (proportional to $I/R$) will depend on the object distance $OA$. The magnification, $M$, for the thin lens is, quite generally, given by

$$M = T_I/T_0. \tag{4}$$

## SIMPLIFYING ASSUMPTIONS AND DEFINITIONS

The filament or cathode is considered as a plane circular emitting area of radius $r_e$ (see Fig. 2). The shield, or grid, is considered as a thin sheet with a central aperture of radius $r_k''$, distant $d_2$ from a plane anode. An axis $O_s z$ with origin $O_s$ at the center of the shield aperture and positive in the direction of electron motion is chosen to coincide with the axis of symmetry of the electron gun. The assumed variation of axial potential is shown in Fig. 3.

The following factors have now to be taken into consideration. The electrons leave the filament with a velocity distribution both in magnitude and direction governed by the temperature of the filament. The electrostatic field in the vicinity of the shield exerts a convergent effect upon the electrons. The electron speeds are nowhere constant within the electron gun, and it is therefore convenient to use the transit time method of Schlesinger taking zero time as the instant at which the electron passes through the shield.

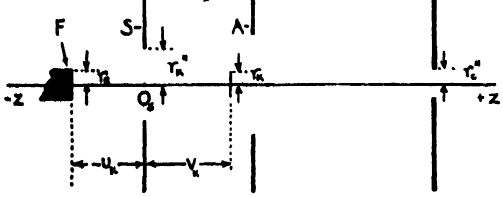

FIG. 2. Symbols used in text. $F$ represents the filament, $S$ the shield, and $A$ the anode.

To commence, consider an electron which leaves the filament at the axis with zero axial velocity and with transverse thermal velocity $v_T$ cm per sec. (or $V_T$ in electron volts). It describes a parabolic path (Fig. 4) until it reaches the shield aperture at a distance $R$ from the axis. At this point it receives a centripetal impulse $I_k$ and returns to the axis at a distance $v_k$ from the shield, following another parabola until it reaches the anode aperture where it receives a centrifugal impulse $I_A$ traveling thereafter in a straight line towards the condenser lens of the microscope.

## NOTATION

Where possible the notation employed by Hillier and Baker[3] has been used in this section.

$r_e$ = radius of emitting area, assumed plane
$r_k''$ = radius of hole in shield
$r_c''$ = radius of condenser aperture
$r_0'$ = radius of area of specimen plane illuminated by electrons
$V_k$ = potential at origin $O_s$
$V_k'$ = potential of shield
$V$ = potential of anode
$V_T$ = transverse (thermal) velocity of electron leaving filament in electron volts
$E_1$ = electrostatic field strength between filament and shield = $V_k/u_k$
$E_2$ = electrostatic field strength between shield and anode = $-V/d_2$ (if $V_k \ll V$)
$v_T$ = transverse (thermal) velocity of electron leaving filament in cm per sec.
$T_0$ = epoch at which electron leaves filament (negative with sign convention used here)
$T_I$ = epoch at which electron arrives at real image formed by cathode lens
$T_{SA}$ = transit time of electron from shield to anode
$T_0'$ = epoch at which electron leaves real image formed by cathode lens
$T_I'$ = epoch at which electron 'passes' virtual image formed by anode aperture
$u_k$ = distance from shield to filament (negative on above sign convention) commonly called the filament height
$v_k$ = distance from shield to image formed by cathode lens
$d_1$ = distance from shield to condenser aperture
$d_2$ = distance from shield to anode
$R$ = radial displacement of electron at shield
$\dot{R}$ = radial velocity of electron between shield and anode

$R_A$ = radial displacement of electron at anode
$I_k = I_k(R)$ = centripetal impulse acting on electron on passing shield
$I_A = I_A(R_A)$ = centrifugal impulse acting on electron on passing anode
$\alpha_c$ max. = maximum angular aperture of illumination at specimen
$\beta$ = angular aperture of beam at cathode side of anode
$\beta'$ = angular aperture of beam leaving the electron gun
$\gamma$ = angle between $O_sz$ and center of beam from off-axial point of cathode, see Fig. 8
$M_k$ = magnification produced by cathode lens
$M_A$ = magnification produced by anode lens
$M_G$ = over-all magnification produced by electron gun
$M_c$ = magnification produced by condenser lens
$e$ = charge of electron
$m$ = mass of electron.

## THEORY

From the transit time theory of Schlesinger

$$(1/T_I)-(1/T_0)=-(I_k/mR)=1/T_F. \qquad (5)$$

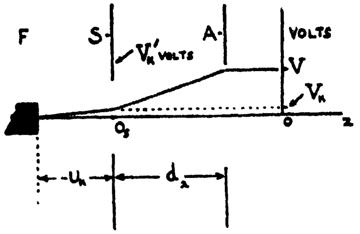

FIG. 3. Potential distribution assumed.

Further

$$-u_k=\frac{1}{2}\left(\frac{eV_k}{mu_k}\right)T_0^2. \qquad (6)$$

At the plane of the shield the electron will have gained an axial component of velocity $(-2eV_k/m)^{1/2}$. Hence

$$v_k=\left(-\frac{2eV_k}{m}\right)^{1/2}T_I-\frac{1}{2}\frac{eV}{md_2}\cdot T_I^2 \qquad (7)$$

and

$$T_I=\frac{2(-Ve/2md_2)^{1/2}\cdot[\lambda(1-\epsilon)]^{1/2}\pm\{4(-Ve/2md_2)\cdot[\lambda(1-\epsilon)]+4(-Ve/2md_2)v_k\}^{1/2}}{-2(-Ve/2md_2)}, \qquad (8)$$

where

$$\lambda=u_kr_k''/(\pi u_k-r_k'') \qquad (9)$$

and

$$\epsilon=-\pi(d_2/r_k'')\cdot(V_k'/V). \qquad (10)$$

Then with an obvious choice of sign

$$T_I=\{[\lambda(1-\epsilon)+v_k]^{1/2}-[\lambda(1-\epsilon)]^{1/2}\}/(-Ve/2md_2)^{1/2}. \qquad (11)$$

To obtain the value of $I_k/mR$ notice that if the lens may be treated as a thin lens[7]

$$\frac{I_k}{mR}=-\left(-\frac{2V_ke}{m}\right)^{1/2}\cdot\left[\frac{E_2-E_1}{4V_k}\right], \qquad (12)$$

but[8]

$$V_k=V\lambda(1-\epsilon)/d_2 \qquad (13)$$

and, therefore,

$$\frac{I_k}{mR}=\left[-\frac{Ve}{2md_2}\right]^{1/2}\cdot\left[\frac{1}{2[\lambda(1-\epsilon)]^{1/2}}+\frac{[\lambda(1-\epsilon)]^{1/2}}{2u_k}\right]. \qquad (14)$$

From Eqs. (6), (11), and (14)

$$\frac{1}{T_0}=\left(-\frac{Ve}{2md_2}\right)^{1/2}\cdot\frac{1}{u_k}\cdot[\lambda(1-\epsilon)]^{1/2} \qquad (15)$$

$$\frac{1}{T_I}=\left(-\frac{Ve}{2md_2}\right)^{1/2}\cdot\frac{1}{[\lambda(1-\epsilon)+v_k]^{1/2}-[\lambda(1-\epsilon)]^{1/2}} \qquad (16)$$

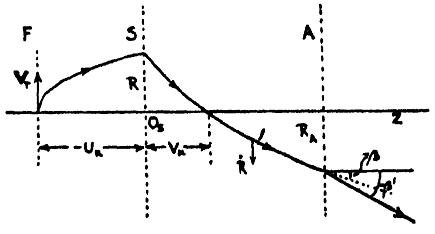

FIG. 4. An electron trajectory for the three-electrode electron gun.

[8] Zworykin, Morton, Ramberg, Hillier, and Vance, *Electron Optics on the Electron Microscope* (John Wiley and Sons, Inc., New York, 1945), pp. 383–385, particularly equation 11.95.

$$\frac{1}{T_F}=\left(-\frac{Ve}{2md_2}\right)^{\frac{1}{2}}$$

$$\cdot\left\{[\lambda(1-\epsilon)]^{\frac{1}{2}}\left[\frac{1}{2\lambda(1-\epsilon)}+\frac{1}{2u_k}\right]\right\}. \quad (17)$$

Substituting from Eqs. (15) to (17) into Eq. (5) and solving for $v_k$

$$v_k=4[\lambda(1-\epsilon)]\left\{\frac{1+(1+3[\lambda(1-\epsilon)]/u_k)}{(1+3[\lambda(1-\epsilon)]/u_k)^2}\right\}. \quad (18)$$

Values of $v_k$ are plotted in Fig. 5 for typical values of the other variables. The non-Gaussian dioptrics of the system is apparent from Eq. (18).

### DIVERGENCE OF THE BEAM

One of the factors controlling the intensity of illumination in the electron microscope will be the divergence of the electron beam leaving the electron gun, for this will determine the percentage of electrons leaving the electron gun which pass through the condenser diaphragm.

If $\beta$ is the angle to the axis $O_sz$ at which the peripheral beam approaches the anode then, from Fig. 4

$$\tan\beta=\frac{\dot{R}}{(-2eV/m)^{\frac{1}{2}}}=\frac{I_k/m+\mathbf{v}_T}{(-2eV/m)^{\frac{1}{2}}}, \quad (19)$$

but

$$I_k/m=-R/T_F \quad (20)$$

and

$$R=-\mathbf{v}_T T_0; \quad (21)$$

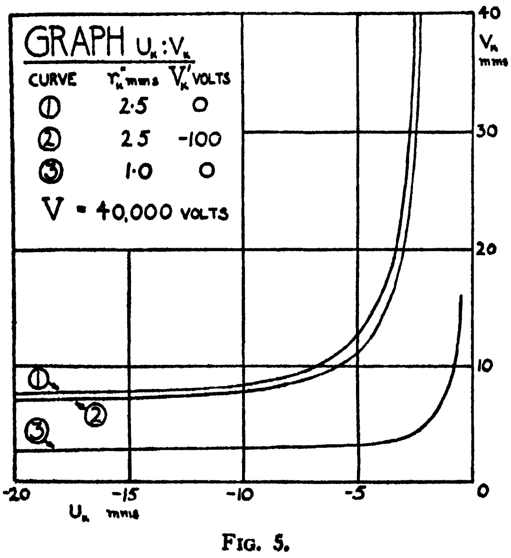

FIG. 5.

therefore

$$\tan\beta=\left(\frac{V_T}{V}\right)^{\frac{1}{2}}\left[1+\frac{T_0}{T_F}\right]. \quad (22)$$

Substituting in Eq. (22) from Eqs. (15) and (17)

$$\tan\beta=\frac{3}{2}\left(\frac{V_T}{V}\right)^{\frac{1}{2}}\left[1-\frac{1}{3(1-\epsilon)}+\frac{\pi u_k}{3r_k''(1-\epsilon)}\right]. \quad (23)$$

The further divergence produced in the electron beam by the change in field strength at the anode aperture may now be determined. Then

$$\tan\beta'=\frac{\dot{R}+I_A/m}{(-2eV/m)^{\frac{1}{2}}} \quad (24)$$

$$=\tan\beta+I_A/m(-2eV/m)^{\frac{1}{2}}. \quad (25)$$

But,[7]

$$\frac{I_A}{mR_A}=\left(-\frac{2eV}{m}\right)^{\frac{1}{2}}\cdot\frac{1}{4d_2} \quad (26)$$

$$\frac{I_A}{m(-2eV/m)^{\frac{1}{2}}}=\frac{R_A}{4d_2} \quad (27)$$

and

$$\tan\beta'=\tan\beta+R_A/4d_2. \quad (28)$$

Further

$$R+R_A=\dot{R}T_{SA} \quad (29)$$

and

$$T_{SA}=T_I \text{ (for } v_k=d_2), \quad (30)$$

that is

$$T_{SA}=(-2d_2m/Ve)^{\frac{1}{2}}\{[\lambda(1-\epsilon)+d_2]^{\frac{1}{2}}-[\lambda(1-\epsilon)]^{\frac{1}{2}}\} \quad (31)$$

and approximating

$$T_{SA}=(-2d_2m/Ve)^{\frac{1}{2}}\cdot d_2^{\frac{1}{2}} \quad (32)$$

giving

$$R_A=2d_2\tan\beta+2\left(\frac{V_T}{V}\right)^{\frac{1}{2}}\cdot\frac{d_2^{\frac{1}{2}}u_k}{[\lambda(1-\epsilon)]^{\frac{1}{2}}} \quad (33)$$

and

$$\tan\beta'=\frac{3}{2}\tan\beta+\frac{1}{2}\left(\frac{V_T}{V}\right)^{\frac{1}{2}}\frac{u_k}{[\lambda d_2(1-\epsilon)]^{\frac{1}{2}}}. \quad (34)$$

The negative values of $\beta'$ obtained from Eq. (34) indicate that the electrons from the filament cross the axis of the gun. Values of $\tan\beta'$ are plotted in Fig. 6. It has been assumed here that $R$ is less than the radius of the $-V_T$ equipotential surfaces at the cathode shield, which is true for the range of $u_k$ plotted in the graphs.

## MAGNIFICATION

It would appear from Fig. 5 that for the range of filament heights commonly employed in the electron microscope, the cathode lens forms a real image of the filament between the shield and the anode (i.e., $v_k < d_2$). First, therefore, the magnification $M_k$ produced by the cathode lens may be calculated.

By the transit time method of Schlesinger

$$M_k = T_I / T_0. \tag{35}$$

Negative values obtained for $M_k$ indicate inversion of the image with respect to the object. Using Eqs. (15) and (16)

$$M_k = [\lambda(1-\epsilon)]^{\frac{1}{2}}\{[\lambda(1-\epsilon)+v_k]^{\frac{1}{2}} - [\lambda(1-\epsilon)]^{\frac{1}{2}}\}/u_k. \tag{36}$$

The anode lens forms a virtual image of the real image mentioned above. For $v_k < d_2$ this virtual image lies between $v_k$ and $d_2$ and is demagnified. If $M_A$ is the magnification produced by the anode lens alone then

$$M_A = T_I' / T_0' \tag{37}$$

but

$$(1/T_I') - (1/T_0') = -(I_A/mR_A) \tag{38}$$

$$= 1/T_F' \text{ say} \tag{39}$$

so that

$$M_A = T_F'/(T_0' + T_F') \tag{40}$$

writing

$$T_0' = -(T_{SA} - T_I) \tag{41}$$

and using Eqs. (31) and (16)

$$M_A = \frac{2d_2^{\frac{1}{2}}\{[\lambda(1-\epsilon)+v_k]^{\frac{1}{2}} + [\lambda(1-\epsilon)+d_2]^{\frac{1}{2}}\}}{(d_2 - v_k) + 2d_2^{\frac{1}{2}}\{[\lambda(1-\epsilon)+v_k]^{\frac{1}{2}} + [\lambda(1-\epsilon)+d_2]^{\frac{1}{2}}\}}. \tag{42}$$

Values of $M_k$ and $M_A$ are plotted against $u_k$ in Fig. 7.

## AREA OF SPECIMEN ILLUMINATED IN THE ELECTRON MICROSCOPE

On the basis of the foregoing theory one might expect the radius of the illuminated part of the specimen in an electron microscope $r_0'$ to be given by

$$r_0' = r_e M_k M_A M_c, \tag{43}$$

where $M_c$ is the magnification produced by the condenser lens. Writing

$$M_k M_A = M_G \tag{44}$$

the magnification produced by the electron gun, and taking $M_c = 1$ then

$$r_0' = r_e M_G. \tag{45}$$

Equation (45) applies only to the case in which the virtual image of the cathode due to the anode aperture is focused on to the specimen by the condenser lens.

For values of $u_k$ that make $\tan\beta'$ small, another factor may have a decisive effect on the value of $r_0'$. The condenser aperture may act as a field limiting aperture for the electron gun even though the image produced by the gun is not in the plane of the condenser aperture.

It will be seen from Fig. 8 that electrons leaving a point in the cathode distant $r_e'$ from the axis leave the electron gun in a cone of semi-angle $\beta'$, the axis of the cone making an angle $\gamma$ with the axis of the system. If the radius of the condenser lens diaphragm is $r_c''$, and it is situated a distance $d_1$ from $O_s$, the condition that electrons from $P$ shall pass the condenser lens is then, approximately

$$(\gamma - \beta')(d_1 - v_k) \leqslant r_c'' - |M_G| r_e' \tag{46}$$

with

$$r_e' \leqslant r_c. \tag{47}$$

It is desirable, therefore, to investigate the dependence of $\gamma$ upon $r_e'$. Considering the ray $Pcc'$ and employing the methods of the preceding sections, it can be shown that

$$\gamma = \frac{r_e'}{4}\left\{\left[\frac{\lambda(1-\epsilon)}{d_2}\right]^{\frac{1}{2}}\left[\frac{1}{\lambda(1-\epsilon)} + \frac{1}{u_k}\right] + \frac{1}{d_2}\right\}. \tag{48}$$

Neglecting the term $|M_G| r_e'$ in Eq. (46), and taking

$$r_c''/(d_1 - v_k) = \alpha_c \max, \tag{49}$$

we can calculate the radius $r_e''$ of the area of the cathode from which electrons can pass the condenser aperture. Equation (45) presumes that the electron gun and the specimen are equidistant from the condenser lens. Then from Eqs. (46),

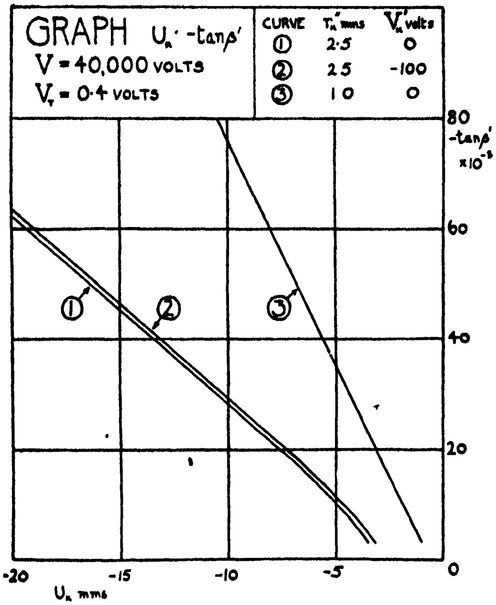

FIG. 6.

(48), and (49)

$$r_e'' = 4(\alpha_c \max + |\beta'|) \Big/ \left\{ \left[\frac{\lambda(1-\epsilon)}{d_2}\right]^{\frac{1}{2}} \times \left[\frac{1}{\lambda(1-\epsilon)} + \frac{1}{u_k}\right] + \frac{1}{d_2} \right\} \quad (50)$$

$$r_0' = r_e'' M_G. \quad (51)$$

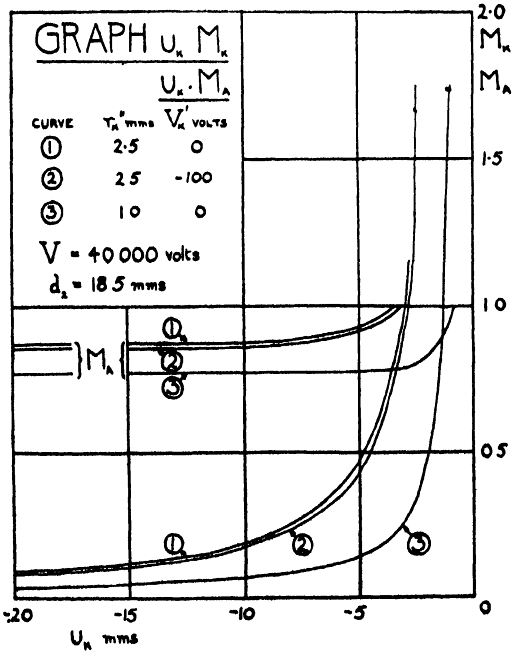

FIG. 7.

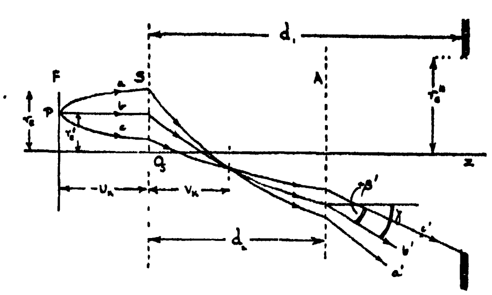

FIG. 8. Trajectories in beam from off-axial point in the filament.

In practice $r_0'$ will be given by the smaller of the values in Eqs. (45) or (51). In Fig. 9 $r_0'$ is plotted against $u_k$ the full line showing the variation from Eq. (45), and the broken line the variation from Eq. (51) for a sufficiently large cathode that relation 47 is maintained at all $u_k$. (The corresponding curves for conditions 1 and 2 lie off the graph with the scale chosen).

It has sometimes been stated that the smallness of the effective source provided by the electron gun is due to the presence of a cross-over of smaller radius than the image of the cathode. From Fig. 10 it can be seen that such a cross-over exists only if $\beta' < \gamma$. This is approximately the condition for Eq. (51) to limit the area of illumination of the specimen.

On the basis of the foregoing calculation one might conclude that the source in an electron microscope operated with a zero-biased, or battery-biased gun and with the filament at a normal height is a reduced image of the filament and not a cross-over. This will be discussed later.

One other point should be mentioned. Only the

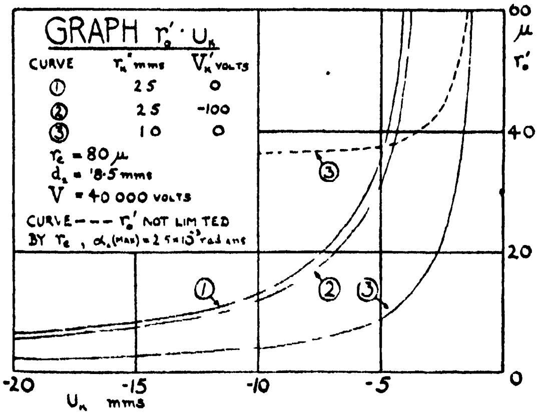

FIG. 9.

trajectories of electrons which leave the filament with zero axial velocity have been considered above. The extension of the theory to cover those electrons which have axial velocities $V_T$ (in electron volts) at the filament would not be difficult but is not attempted here, since the above treatment suffices for the purpose in view. We may note in passing that for the electron gun as commonly employed in the electron microscope $V_T \ll V$, so that the longitudinal chromatic aberration as calculated on the above theory would not be very large.

## THE IDEAL ELECTRON GUN

The heating effect of the beam acting on the specimen is proportional to $\sigma r_0'^2$, where $\sigma$ is the current density at the specimen. The cross-sectional area of film over which this heat can be dissipated is proportional to $r_0'$. There is an obvious advantage in reducing $r_0'$. To a first approximation if $r_0'$ is halved, $\sigma$ may be made four times greater for the same rise in temperature of the specimen. Ideally one would prefer to illuminate only that part of the specimen which is examined on the final screen. If other parts of the specimen are illuminated scattered electrons from these regions may reach the final screen and reduce the contrast.

The illuminating beam, if it does not strike any part of the supporting mesh, will build up a static charge on the film and specimen. Both electron microscopy and electron diffraction require an electron gun giving a small, intense, single source of electrons.

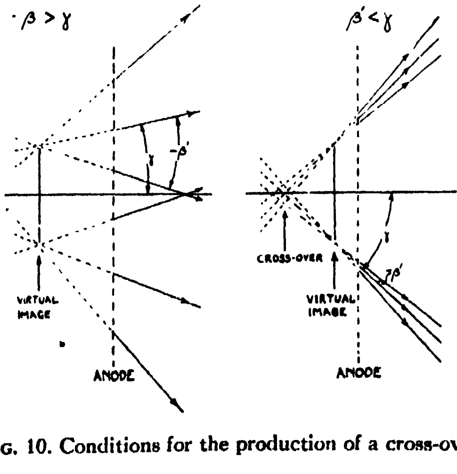

FIG. 10. Conditions for the production of a cross-over.

The angular aperture, $\alpha_c$, of the illumination governs the depth of focus and intensity at constant beam current. When an electron microscope is used for electron diffraction with the specimen below the projector lens the radius of the objective exit pupil which acts as the effective source for the diffraction camera is governed by the aperture of the illumination. The aperture, $\alpha_c$, will influence the resolving power of the microscope, particularly if the objective field lacks symmetry, for in this case when $\alpha_0$ is large the rays leaving the object will move into those parts of the objective field further from the axis with a consequent increase in image assymetries. It has been argued, though convincing experimental proof is lacking, that even with a symmetrical objective field there will be an optimum value for $\alpha_0$ which will be attained for a certain value of $\alpha_c$.

Other factors to be considered in the choice of an electron gun are the ease with which it can be assembled and cleaned. Both the electron gun and condenser lens should form a system which can be readily adjusted to provide an illuminating beam coaxial with the objective lens.

Ideally then one would prefer to have $r_0'$, $\sigma$, and $\alpha_c$ independently variable. In practice, since simplicity of construction is very desirable, this ideal is sacrificed and the chief aim is to provide a small source of adequate intensity.

## PRACTICAL ELECTRON GUNS

The electron guns employed in practice may be divided into two classes according to the conditions under which they are operated. These classes are, the fixed-bias gun operated at emission saturation, and the cathode-biased gun[9]

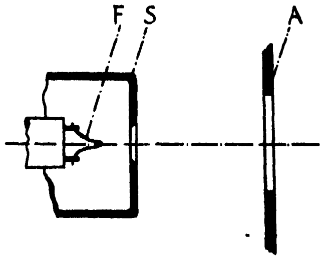

FIG. 11. A three-electrode electron gun as employed in electron microscopy.

---

[9] J. Hillier and R. F. Baker, J. App. Phys. 17, 12 (1946).

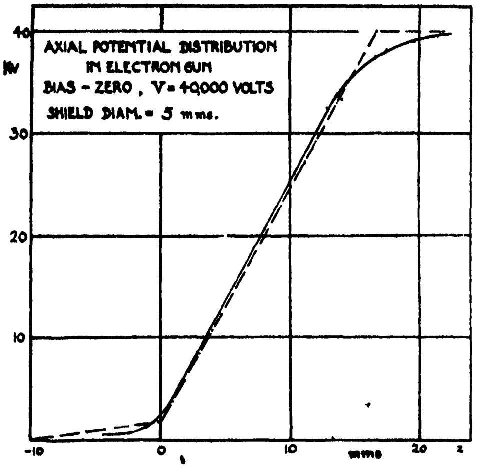

FIG. 12.

operated with space charge limited current.[8] This is not intended to imply that space charge is without effect in the former class of electron gun.

The construction of a fixed-bias gun is shown in Fig. 11. *F* is a hairpin filament of tungsten heated by a d.c. or r-f current. *S* is the shield or grid. It may be maintained at the same potential as the filament or at a negative potential of up to 200 volts with respect to the filament by a battery. *A* is the plate or anode which will be at a voltage of from 30 to 200 kv with respect to the filament in electron microscope practice. Matters of practical interest in the operation of such a gun have been described by Hillier and Baker.[3] Our immediate concern is to see wherein the optical behavior of this type of gun departs from the simple theory outlined above.

The major limitations in the above theory are imposed by the assumption of plane electrodes and linear axial potential variation. With this in mind experiments were undertaken with an electrolytic trough to determine the potential distributions occurring in practice.

Two points may be mentioned in connection with the use of the electrolytic trough. First, since the trough is a relatively large and open structure, it is difficult to shield it from the effect of stray fields which may become troublesome if measurements of high sensitivity are attempted. It is therefore desirable to use for the generator a supply of variable audiofrequency and for the detector a pair of head phones so that the balance can be made to the generator note and stray noises ignored. This is particularly important if an amplifier is used between the probe and the detector, and might well lead to errors if a vacuum-tube voltmeter were employed.

The second point concerns the plotting of the equipotential lines close to the filament. The field distribution near the filament will have a considerable influence on the behavior of the gun since the electrons are moving at slow speeds in this region. It is difficult to determine the equipotentials in this region, however, since the arms of the potential divider have to be made very unequal and the sensitivity of the circuit (which may be considered as a Wheatstone net) becomes very small. Under these conditions the sensitivity was improved by turning a copper plate to the shape of a fairly flat equipotential surface just outside the shield, placing this plate in the tank in the appropriate position, and transfering the lead from the anode to this shaped plate. The low equipotentials could then be studied with less unequal values of the arms of the potential divider.

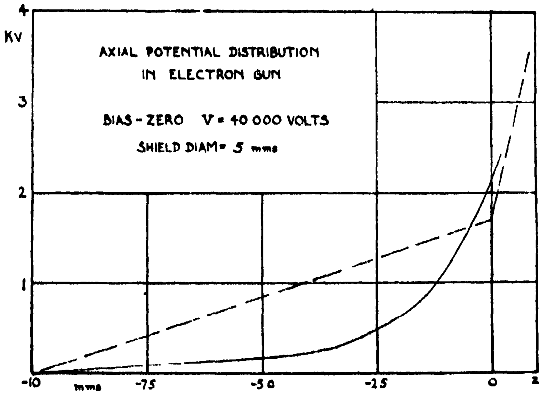

FIG. 13.

Figure 12 shows the axial potential distribution for an electron gun of the form shown in Fig. 11. The full line is from the experimental results; the broken line shows the distribution assumed in the elementary theory above. The origin has been taken at the shield center. In Fig. 13 the distribution of axial potential between the shield and the filament is shown in more detail for $u_k = -10$ mm. Measurements were made with the plane of the filament both in and perpendicular to the surface of the electrolyte. No very significant differences in the axial potential variation were detected in the two cases. It is probable that the magnetic effect of the heating current in the filament would produce effects at least as great as those produced by assymetries in the electric field. For values of $z$ between $-5$ mm and $-10$ mm the measured potentials were of doubtful accuracy, and the curve has been extrapolated linearly to $z=-10$ mm. When $u_k$ was reduced to $-5.0$ mm (Fig. 14) it could be observed that the curve for the axial potential distribution was concave downwards in the vicinity of the filament. In other words, the field strength is relatively high at the filament because of the small radii of curvature of its surface. Under these conditions the optical description of the electron gun is as follows. Leaving the filament the electrons first pass through a thick diverging lens, then a thick converging lens which terminates shortly beyond the shield; at the anode the electron passes through a thick diverging lens. The net effect of these lenses, as compared with the thin lenses treated above will be to further reduce $M_G$, the gun magnification, and to increase the magnitude of $\beta'$, the divergence of the beam from any point of the filament. Under normal conditions of operation, therefore, a cross-over will not be produced in this electron gun.

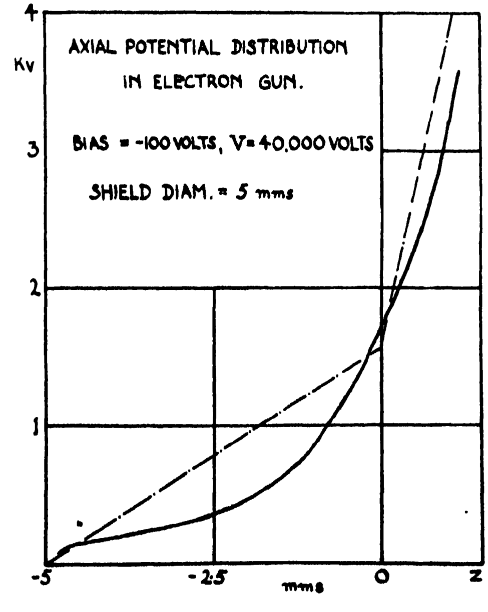

FIG. 14.

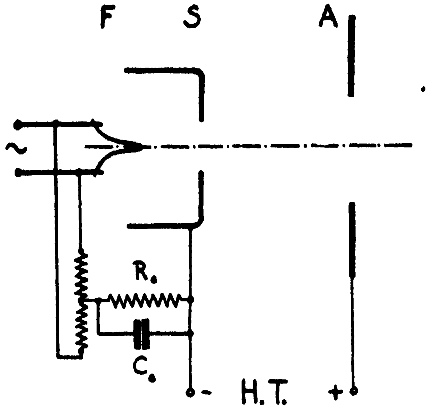

FIG. 15. The cathode-biased electron gun.

Observations with electron microscopes do not discredit this view. In the electron microscope put into operation in 1944 at the University of Toronto[10] the condenser diaphragm can be displaced laterally while the microscope is in operation. If this is done, the region of illumination of the specimen as observed at the intermediate image is seen to move. While this at first sight might seem to indicate the state of affairs shown in Fig. 8, and the existence of a cross-over, it is considered that the effect is due largely to the spherical aberration of the condenser lens.

The major disadvantages of this type of electron gun are the multiple nature of the source, the large source size which must be employed if high intensity is required, and the consequent large beam current. The gun is also inefficient because the large values of $\beta'$ employed mean that most of the electrons hit the condenser diaphragm. The analysis given above indicates a fundamental difficulty in the design of this type of electron gun. The condition for high intensity is $\beta'$ small, which from Eq. 22 indicates

$$\left(\frac{V_T}{V}\right)^{\frac{1}{2}}\cdot\frac{T_0+T_F}{T_F}\quad\text{small.}$$

The condition for a small area of illumination of the specimen is that $M_G$ be small which requires

$$\frac{T_0+T_F}{T_F}\quad\text{to be large.}$$

---

[10] E. F. Burton and W. H. Kohl, *The Electron Microscope* (Reinhold Publishing Corporation, New York, 1946), second edition, Chap. 18.

Unless $V_T/V$ can be reduced or the area of illumination of the specimen independently controlled the final design and operating condition must be a compromise.

### CATHODE-BIASED ELECTRON GUNS

The essential parts of a cathode-biased electron gun are shown in Fig. 15. For small filament and hence small beam currents its optical behavior is similar to that of the fixed-bias gun. As the filament current is increased, however, the beam current reaches a saturation value that is dependent on the geometry of the gun, and the value of the resistor $R_c$. Typical values of the components will be $R_c=0.5$ megohm, $C_c=0.5$ μf, for $r_k''=2.5$ mm. Under these conditions the source is definitely single and intense. Its position is nearly central with respect to the shield and is very little dependent on the centering of the filament with respect to the shield. The image seen at the intermediate screen is no longer the image of the filament but the image of a space charge.

An examination of the image at the intermediate screen of the microscope as the filament current is increased shows the course of events in the electron gun. At low filament current an image of the filament can be seen. It will generally show the die markings on the filament and will be in a position conjugate with the filament. As the filament current is increased this image becomes blurred, larger, and more intense, and moves to a new position, though no movement will be evident if the filament is carefully centered to the axis of the shield and anode holes.

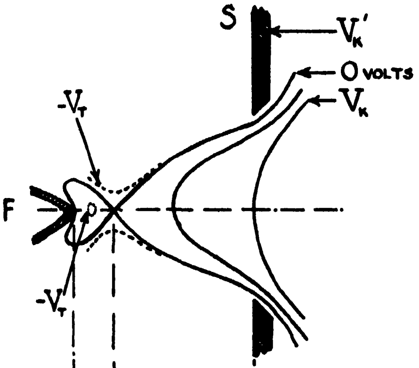

Fig. 16. Assumed potential distribution for a cathode-biased electron gun.

Compared with the zero-biased gun it is possible to obtain a brighter source even when the size of the source and the beam current is smaller. Increasing the shield-to-filament distance reduces the value at which the beam current saturates and also reduces the source size. Over a wide range of filament heights, however, the intensity of illumination is nearly constant, and it is both possible and advantageous to work with the filament raised so that the beam current is of the order 100 to 300 microamperes; the source radius is then of the order 5 to 15 microns and the intensity of the order twenty times that available with the zero-bias gun.

The potential distribution in this type of gun is shown diagrammatically in Fig. 16. Calculations of the potential distribution have been made and an empirical discussion of the behavior of the gun given by Reisner.[11] The space charge enclosed in the zero equipotential surface near the filament acts as a virtual cathode. Since electrons emitted with thermal velocity $V_T$ (in electron volts) cannot cross the $-V_T$ equipotential surface this surface will tend to define the source. Moreover, since electrons cannot reach the shield no secondary sources can be produced by electron reflections there.

The presence of space charge and the ill-defined nature of the virtual cathode do not permit this type of gun to be discussed further in terms of the above theory.

### THE EMISSION MICROSCOPE

Measurements of the performance of an immersion objective have been made by Johannson[12] and Savchenko.[13] In the emission microscope

---

[11] J. H. Reisner, Paper before the Electron Microscope Society of America, December 1946 meeting at Pittsburgh.

[12] H. Johannson, Ann. d. Physik 18, 385 (1933).

[13] F. Savchenko, Zhurnal Tekhnicheskoi Fiziki, Moscow 9, 2211–2219 (1939).

employed by Johannson an image of the emitting cathode was formed on a fluorescent screen 240 mm from the cathode. The constants for the microscope are listed below.

$d_2 = 1.0$ mm
$r_k'' = 0.6$ mm
$v_k = 240$ mm approximately $= L$ a constant for the microscope
$V = 750$ volts.

In operation $u_k$ was set at some value between $-5.0$ mm and zero, and $V_k'$ was adjusted to produce a sharp image on the fluorescent screen. Values of $M_k$, the magnification, and $V_k'$ the screen potential for different values of $u_k$ have been recorded by Johannson.

The foregoing theory must be extended before it can be applied to the above system. Since $v_k \gg d_2$ the electrons travel for the most part at constant speed after leaving the region of the shield. The transit time from the shield to the anode is small and will be ignored compared with the transit time from the anode to the fluorescent screen.

$$T_I = L/\{2d_2^{\frac{1}{2}}(-Ve/2md_2)^{\frac{1}{2}}\}, \qquad (52)$$

and therefore

$$M_k = L[\lambda(1-\epsilon)]^{\frac{1}{2}}/2d_2^{\frac{1}{2}}u_k. \qquad (53)$$

In Fig. 17 the points are calculated from Eq. (53), $\epsilon$ being deduced from the values of $V_k'$ given by Johannson. The agreement between theory and experiment is good for $-u_k > r_k''$. With smaller values of $u_k$ one may expect the assumptions made above as to the potential distribution to become increasingly invalid. In view of the large values of $M_k$, $T_0$ is much smaller than $T_I$, and the condition for focus is therefore approximately

$$T_0 = -T_F. \qquad (54)$$

In calculating the focal time $T_F$ it should be noticed that for this microscope $V_k$ is not always small compared with $V$. Since the electron speed is constant on the image side of the lens, the focal time can be obtained in this case by calculating, first of all, the focal length $F$. If $f_k$, and $f_A$ are the focal lengths of the cathode and anode components, respectively, then:

$$1/F = (1/f_k) + (1/f_A) \qquad (55)$$

$$= \frac{(V-V_k)/d_2 + V_k/u_k}{4V_k} - \frac{(V-V_k)/d_2}{4V}. \qquad (56)$$

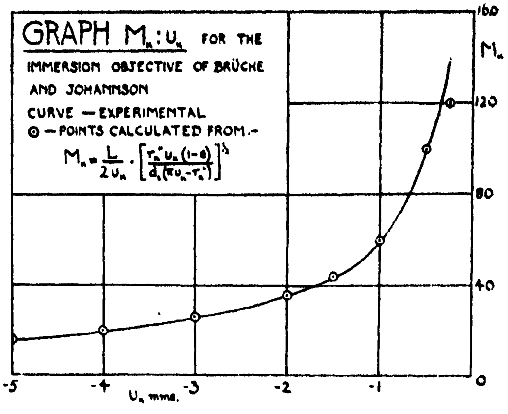

FIG. 17.

Also

$$T_F = F(m/-2eV)^{\frac{1}{2}} \qquad (57)$$

and

$$V_k = r_k'' u_k(1-\epsilon)/[\pi u_k - r_k''(1+u_k/d_2)]. \qquad (58)$$

However Eq. (58) may be replaced by Eq. (13) with sufficient accuracy for the present calculations. With the substitutions previously employed

$$\frac{1}{F} = \frac{[1-\lambda(1-\epsilon)/d_2]^2 u_k + \lambda(1-\epsilon)}{4u_k\lambda(1-\epsilon)}. \qquad (59)$$

Solving for $T_F$ and substituting into Eq. (54)

$$\frac{4\lambda^3(1-\epsilon)^3}{d_2^3} = \left\{\left[1 - \frac{\lambda(1-\epsilon)}{d_2}\right]^2 \frac{u_k}{d_2} + \frac{\lambda(1-\epsilon)}{d_2}\right\}^2. \qquad (60)$$

Working with millimeters as the unit of length we have for the special case of the immersion

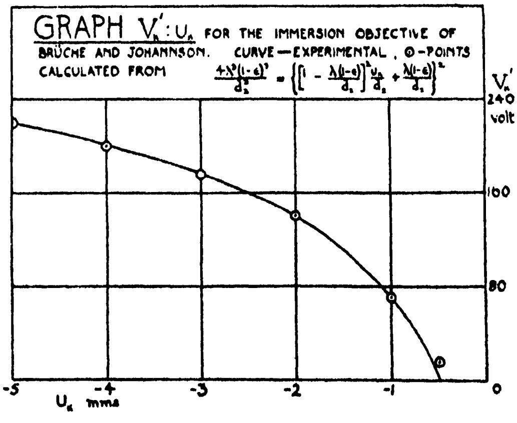

FIG. 18.

*objective used by Johannson $d_2 = 1.0$. Hence writing $x = \lambda(1-\epsilon)$ Eq. (60) becomes*

$$u_k^2x^4 - (4u_k^2 - 2u_k + 4)x^3 + (6u_k^2 - 4u_k + 1)x^2 - (4u_k^2 - 2u_k)x + u_k^2 = 0. \quad (61)$$

Choosing values of $u_k$ Eq. (61) is solved for $x$. From $x$ and the known value of $\lambda$, $\epsilon$ and hence $V_k'$ is deduced. Values of $V_k'$ calculated in this way are plotted as points in Fig. 18—the line represents the values observed by Johannson. The agreement is good for $-u_k > r_k''$.

## CONCLUSIONS

The chief conclusions reached with regard to the zero-bias electron gun used in electron microscopes are that no cross-over is formed in the gun under normal conditions of operation and that the small size of the effective source is due to the demagnification of the gun. The gun is inefficient *since most of the electrons strike the condenser aperture. The dioptrics of such a system is not* Gaussian. The cathode-biased gun is at present the most efficient type of gun for electron microscopy.

A satisfactory first-order theory of the immersion objective has been obtained for the case in which the distance from cathode to shield is greater than the radius of the shield aperture. The dioptrics of this system is also not Gaussian.

## ACKNOWLEDGMENTS

It is a pleasure to record my indebtedness to Professor E. F. Burton, Director of the McLennan Laboratory for his encouragement during the prosecution of this work. Mr. R. S. Sennett, also of the McLennan Laboratory gave valuable help by making the electrolytic trough determinations. Finally I wish to thank Dr. James Hillier of the RCA Laboratories for useful information and informative discussions on the cathode-biased gun.

# On the One-Dimensional Theory of Steady Compressible Fluid Flow in Ducts with Friction and Heat Addition*

BRUCE L. HICKS
*Ballistic Research Laboratories, Aberdeen Proving Ground, Maryland*
DONALD J. MONTGOMERY
*Office of Naval Research (London Branch)*

AND

ROBERT H. WASSERMAN
*University of Chicago, Chicago, Illinois*

(Received April 17, 1947)

Steady, diabatic (non-adiabatic), frictional, variable-area flow of a compressible fluid is treated in differential form on the basis of the one-dimensional approximation. The basic equations are first stated in terms of pressure, temperature, density, and velocity of the fluid. Considerable simplification and unification of the equations is then achieved by choosing the square of the local Mach number as one of the variables to describe the flow.

The transformed system of equations thus obtained is first examined with regard to the existence of a solution. It is shown that, in general, a solution exists whose calculation requires knowledge only of the variation with position of any three of the dependent variables of the system. The direction of change of the flow variables can be obtained directly from the transformed equations without integration. As examples of this application of the equations, the direction of change of the flow variables is determined for two special flows.

In the particular case when the local Mach number $M=1$, a special condition must be satisfied by the flow if a solution is to exist. This condition restricts the joint rate of variation of heating, friction, and area at $M=1$. Further analysis indicates that when a solution exists at this point it is not necessarily unique.

Finally, it is shown that the physical phenomenon of choking, which is known to occur in certain simple flow situations, is related to restrictions imposed on the variables by the form of the transformed equations. The phenomenon of choking is thus given a more general significance in that the transformed equations apply to a more general type of flow than has hitherto been treated.

## INTRODUCTION

THE rational experimental development of jet- and rocket-propulsion power plants requires adequate knowledge of the theoretical mechanics of diabatic (non-adiabatic), frictional, variable-area compressible fluid flow. The differential equations describing this type of flow are well known.[1a, 1b, 2–4] Their solution in the three-dimensional case, however, is so difficult that some simplification is necessary to permit development of the theory in a form immediately useful for technical applications.

In the present paper, such simplification is effected by generalizing the familiar "one-dimensional" or hydraulic treatment of steady fluid flow to include the simultaneous effects of heat addition, friction, and area change upon the flow of a compressible fluid rather than by attempting to show that the one-dimensional approximation follows from a simplification of the hydrodynamic and heat-flow equations in their general three-dimensional form. The generalization leads to one-dimensional equations in differential form, which are identical with equations previously used by other investigators in less general cases.

Generalized conservation equations have been derived in Appendix A in order that a complete and logical basis for the theory may be accessible to the reader. The resulting theory is intended to serve as a foundation in differential form for calculation of all types of mathematically continuous (that is, shockless) flow of perfect gases to which the one-dimensional approximation is applicable. Thus the theory applies directly to

---

compressible flow in combustion chambers and also, with but slight modification, to flow in turbines, compressors,[5] nozzles, and diffusers, whenever the one-dimensional approximation is valid.

In order to obtain convenient and unified equations, the generalized relations are transformed by introducing a new basic variable, the square of the local Mach number $M^2=N$. Pressure and temperature are chosen as the additional basic variables; other relevant flow variables (for example, density, velocity, mass flow) may be expressed in terms of Mach number squared, pressure, and temperature. Values of $M$ from zero to infinity are considered; the treatment is therefore applicable to both subsonic and supersonic flow.

The variable $M$ has been used throughout differential treatments by Gukhman,[6] Bailey,[7] Nielsen,[8] and Chambre and Lin,[9] who investigated various examples of frictional, diabatic compressible flow.** A related variable

$$Z=(\gamma-1)M^2/[2+(\gamma-1)M^2],$$

which can be used alternatively with $M$, will be discussed briefly in Appendix B. Pertinent papers in which $M$ is not used extensively are those by Binder[10] and Keenan and Neumann,[11] which report studies of isothermal and adiabatic frictional flow, respectively. A treatment of frictionless, diabatic compressible flow carried out by Szczeniowski[12] is partly in differential form. The same subject, in $M$ language without differential formulation, is discussed by Hicks[13] and Wood.[14] The variable $M$ has also been employed to advantage by Sorg[5] for the analysis of compressible flow through turbines and compressors, a related field that is not specifically discussed in the present paper. Mach and Crocco vectors, the square of whose magnitudes are $N$ and $Z$, have been found useful for the description of three-dimensional adiabatic and diabatic flows.[15a, 15b]

In the general case, the differential equations obtained in the present treatment do not permit of formal integration; but being of first order, they are particularly amenable to numerical methods. A solution of the system is shown to exist, except possibly at sonic velocity, and the behavior of the solution in this neighborhood is investigated. From the differential equations useful information may easily be obtained about direction of changes in the flow variables. Choking is shown to be a consequence of a certain property of the equations.

## THE ONE-DIMENSIONAL APPROXIMATION

### Basic Equations

The "one-dimensional" steady-flow theory utilizes a model consisting of a perfect gas contained within a duct, across any section of which the flow variables are constant. Only the component of velocity normal to the section is considered; body forces are neglected, and heat, whether supplied by combustion, conversion of frictional work, or conduction from the walls, is assumed to be transferred instantaneously and completely but only transversely throughout the cross section, which may be of variable area. Each flow variable can thus be considered as a function of a single parameter, say the distance along the axis of the tube, whence the term "one-dimensional."

The conventional variables—pressure, temperature, density, and velocity in one-dimensional flow—are connected by four relations derivable from the first law of thermodynamics, the conservation of mass, the second law of motion, and the thermal equation of state for a perfect gas. The four relations are:

Conservation of energy $c_p dT + VdV = dQ$, (1)

Conservation of mass $d(\rho VA) = 0$, (2)

Equation of motion $-dp = \rho VdV + \rho dF$, (3)

Equation of state $d(p/R\rho T) = 0$. (4)

The specific heat at constant pressure $c_p$ and the gas constant $R$ do not vary in the flow. The symbols $\rho$, $V$, $p$, and $T$, respectively, stand for density, velocity, absolute static pressure, and absolute static temperature. The pipe area, which may be variable, is represented by $A$. Heat added per unit mass is indicated by $Q$, and work per unit mass done against friction by $F$. Consistent units are used throughout. In Eqs. (1)–(4) each variable is to be considered as a function of a single parameter, such as the distance $x$ along the tube considered positive in the direction of flow; and, of course, the meaning of each differential $du$ is then given by

$$du = u'(x)dx.$$

Equations (1)–(3) are customarily used without explicit recognition of their true meaning with regard to the one-dimensional approximation. The interpretation of the quantity $dF$ in particular is often obscure. In order to provide a logical, unified basis for the theory, Eqs. (1)–(3) are derived in Appendix A; special care is taken to keep the derivations within the framework of the one-dimensional approximation.

### Applicability

The validity of the one-dimensional approximation depends upon the assumption of the uniformity of flow conditions across a plane normal to the direction of flow. Experience has shown that this assumption constitutes an adequate approximation in many special cases; in particular, with subsonic turbulent flow in long pipes without separation, the reasonably flat velocity profile permits the use of equations derived on this basis. Van Driest[16] has shown how the results of one-dimensional theory for incompressible fluids can be corrected for the effects of turbulence and non-uniformity of velocity distribution in cases where these factors have been evaluated experimentally. The corrections to the energy equation are quite complicated, and their complexity would be increased for compressible flow. In general there is insufficient experimental data available at present to permit formulation of such corrections where compressibility, incomplete growth of the boundary layer, or separation of the flow must be considered. Although compressibility and boundary layer effects are somewhat amenable to calculation, the occurrence of sparation is difficult or impossible to predict, and the question of applicability, in these cases, of the one-dimensional approximation must be determined by experiment or estimated by experience.

The one-dimensional approximation would not be valid if oblique shocks occur in the flow. Nor can normal shocks, if treated as flow discontinuities, be handled in the differential form of the present approximation. If, however, in Eqs. (1) and (3), $dQ$ and $dF$ are considered to depend upon the derivatives of $T$ and $V$ and if heat and momentum transfer in the direction of flow is allowed, then the equations for continuous normal shock[17] can be put in the form of Eqs. (1)–(4).

In the development and use of Eqs. (1)–(4) various approximations are made, such as neglecting the squares of velocity components normal to the direction of flow, replacing the square of the cosine of the half-angle by unity, and assuming the constancy of $R$ and $c_p$. In this paper no attempt is made to state under what circumstances such approximations are suitable.

## TRANSFORMATION OF EQUATIONS

### Change of Variables

A canonical form for Eqs. (1)–(4) is obtained by taking logarithmic derivatives and choosing as a variable the square of the local Mach number,

$$M^2 \equiv N = V^2/\gamma RT, \qquad (5)$$

where $\gamma$ is the ratio of the specific heats. This choice to obtain simplification of the equations is not unique; similar advantages result with other dimensionless combinations of velocity squared and a temperature. For instance, some workers have used the ratio of dynamic tem-

---

[16] E. R. Van Driest, A.S.M.E. Trans. **68A**, 231 (1946).

[17] Reference 1, p. 219.

perature to total temperature; in Appendix B to the present report, the canonical differential equations in terms of this variable are given.

If Eqs. (1)–(4) are divided by $c_pT$, $\rho VA$, $p$, and $p/R\rho T$, respectively, there result

$$(\gamma-1)\frac{V^2}{\gamma RT}\frac{dV}{V}+\frac{dT}{T}=\frac{dQ}{c_pT}, \tag{6}$$

$$\frac{dV}{V}+\frac{d\rho}{\rho}=-\frac{dA}{A}, \tag{7}$$

$$\gamma\frac{V^2}{\gamma RT}\frac{dV}{V}+\frac{dp}{p}=-\frac{\rho dF}{p}, \tag{8}$$

$$-\frac{dp}{p}+\frac{dT}{T}+\frac{d\rho}{\rho}=0. \tag{9}$$

With use of Eq. (5) and the expression for $dV/V$ obtained by logarithmic differentiation of Eq. (5),

$$\frac{dV}{V}=\frac{1}{2}\left(\frac{dN}{N}+\frac{dT}{T}\right) \tag{10}$$

and, upon elimination of $d\rho/\rho$, there are found

$$-\frac{(\gamma-1)N}{2}\frac{dN}{N}+\left[1+\frac{(\gamma-1)N}{2}\right]\frac{dT}{T}=\frac{dQ}{c_pT}\equiv d\theta, \tag{11}$$

$$\frac{1}{2}\frac{dN}{N}+\frac{dp}{p}-\frac{1}{2}\frac{dT}{T}=$$

$$-\frac{dA}{A}\equiv d\alpha, \tag{12}$$

$$-\frac{\gamma N}{2}\frac{dN}{N}-\frac{dp}{p}-\frac{\gamma N}{2}\frac{dT}{T}=\frac{dF}{RT}\equiv d\mu, \tag{13}$$

where the dimensionless quantities $d\theta$, $d\alpha$, and $d\mu$ have been introduced to simplify the following analysis.

### Solution for Logarithmic Differentials

If the determinant formed by the coefficients of $dN/N$, $dp/p$, and $dT/T$ in Eqs. (11), (12), and (13) is not identically zero, the equations may be solved uniquely for these three differentials. As the determinant in question is proportional to $(1-N)$, which vanishes only for $N=1$, the solution is obtained as follows:

$$\begin{aligned}dN/N=(1-N)^{-1}\{(1+\gamma N)d\theta+[2+(\gamma-1)N]d\mu\\+[2+(\gamma-1)N]d\alpha\},\end{aligned} \tag{14}$$

$$\begin{aligned}dp/p=(1-N)^{-1}\{-\gamma Nd\theta\\-[1+(\gamma-1)N]d\mu-\gamma Nd\alpha\},\end{aligned} \tag{15}$$

$$\begin{aligned}dT/T=(1-N)^{-1}[(1-\gamma N)d\theta-(\gamma-1)Nd\mu\\-(\gamma-1)Nd\alpha].\end{aligned} \tag{16}$$

It is also convenient to record the differential expressions for the density $\rho$ and velocity $V$:

$$\begin{aligned}d\rho/\rho=dp/p-dT/T=(1-N)^{-1}\\\times(-d\theta-d\mu-Nd\alpha),\end{aligned} \tag{17}$$

$$\begin{aligned}dV/V=(dN/N+dT/T)/2\\=(1-N)^{-1}(d\theta+d\mu+d\alpha).\end{aligned} \tag{18}$$

### Application of Second Law of Thermodynamics

The first law of thermodynamics was used in the formulation of the basic equations; the second law of thermodynamics may be employed to furnish additional information. The entropy differential $dS$ for a perfect gas is given[18] by

$$\begin{aligned}dS/c_p=dT/T-[(\gamma-1)/\gamma]dp/p\\=d\theta+[(\gamma-1)/\gamma]d\mu.\end{aligned} \tag{19}$$

The second law of thermodynamics then states

$$0\leqslant dS/c_p-dQ/c_pT=[(\gamma-1)/\gamma]d\mu. \tag{20}$$

The relation, according to Eq. (19), that

$$dS/c_p=(d\theta+d\mu+d\alpha)-d\mu/\gamma-d\alpha$$

when used with Eq. (20), results in the inequalities

$$d\theta\leqslant dS/c_p=d\beta-d\mu/\gamma-d\alpha\leqslant d\beta-d\alpha, \tag{21}$$

where $d\beta\equiv d\theta+d\mu+d\alpha$.

## DISCUSSION OF EQUATIONS

### Remarks on Integration of Equations

Equations (14)–(16) can be rewritten as

$$\begin{aligned}N'=\frac{N}{1-N}\frac{1+\gamma N}{c_pT}Q'+\frac{N}{1-N}\frac{2+(\gamma-1)N}{RT}F'\\-\frac{N}{1-N}\frac{2+(\gamma-1)N}{A}A',\end{aligned} \tag{22}$$

---

[18] P. S. Epstein, *Textbook of Thermodynamics* (John Wiley and Sons, Inc., New York, 1937), p. 63.

$$p' = -\frac{p}{1-N}\frac{\gamma N}{c_pT}Q' - \frac{p}{1-N}\frac{1+(\gamma-1)N}{RT}F' + \frac{p}{1-N}\frac{\gamma N}{A}A', \quad (23)$$

$$T' = \frac{T}{1-N}\frac{1-\gamma N}{c_pT}Q' - \frac{T}{1-N}\frac{(\gamma-1)N}{RT}F' + \frac{T}{1-N}\frac{(\gamma-1)N}{A}A', \quad (24)$$

where the primes indicate differentiation with respect to $x$. This system clearly satisfies, except at $N=1$, the conditions of the fundamental existence theorem[19] when $Q$, $F$, and $A$ are differentiable. Hence a solution exists except at sonic velocity and may be obtained formally when possible, and by standard numerical methods otherwise, as soon as the functions $Q$, $F$, and $A$ (or their derivatives) are specified. More generally, the system may be solved in similar fashion for any three of the variables $N$, $p$, $T$, $Q$, $F$, and $A$ as functions of $x$, when the variation with $x$ of the other three is prescribed. Also it may be noted that as all the foregoing variables are functions of one parameter, any two may be considered as functions of each other under suitable circumstances.

### Direction of Change of Flow Variables

In practical as well as in theoretical work it is frequently useful to be able to determine the direction of change of flow quantities with respect to heat addition, friction, or area variation without troubling to get quantitative information from integrated forms. Equations (14)–(18) or (22)–(24) permit the specification of signs of derivatives at any particular point and also throughout certain regions of flow. Thus Eq. (14) shows that in subsonic flow the effect of positive $\theta'$, $\mu'$, or $\alpha'$, is to increase $N$, whereas for supersonic flow the effect is to decrease $N$. When the derivatives have different signs, the net effect will depend upon the algebraic sum of the separate contributions.

As an example of the use of this technique, suppose heat is added to a fluid in a constant-area pipe, with negligible friction; that is, $\theta' \neq 0$, $\mu' = \alpha' \equiv 0$. It is easily seen from Eqs. (14) through (18) that for the entire range of $N$ from zero to infinity

$$(1-N)dN/dQ \geqq 0, \quad (25)$$

$$dp/dN \leqq 0, \quad (26)$$

$$(1-\gamma N)^{-1}dT/dN \geqq 0, \quad (27)$$

$$d\rho/dN \leqq 0, \quad (28)$$

$$dV/dN \geqq 0. \quad (29)$$

These results are given by Hicks.[13] By use of the chain rule for the derivative of a function of a function, the sign of the derivative of any of the flow variables with respect to any of the others may be obtained; thus, from Eqs. (25) and (29) it is clear that

$$(1-N)\frac{dV}{dQ} = (1-N)\frac{dV}{dN}\frac{dN}{dQ} \geqq 0. \quad (30)$$

As another example, consider the flow in circular cylindrical pipes with heat addition and with friction; that is, $\theta' \neq 0$, $\mu' \neq 0$, $\alpha' \equiv 0$. (See also related discussion by Nielsen.)[8] Equation (14) will be used to determine the direction of change of $N$ with respect to $x$. If the heat addition is only through the wall, which is at temperature $T_w$, the heat added per unit mass of fluid in passing a distance $dx$ along the tube is given by

$$\rho V A dQ = h(T_w - T)(\pi D dx), \quad (31)$$

where $D$ is the tube diameter, and $h$ the local surface-to-fluid coefficient of heat transfer in heat units transferred per unit temperature difference, per unit area.[20a] In conjunction with Eq. (11), Eq. (31) leads to

$$d\theta \equiv \frac{dQ}{c_pT} = \frac{h[(T_w/T)-1]\pi D dx}{c_p\rho V\pi D^2/4} = \frac{4h[(T_w/T)-1]dx}{c_p\rho VD}. \quad (32)$$

The expression for frictional work done is

---

[19] L. Bieberbach, *Theorie der Differentialgleichungen* (Julius Springer Verlag, Berlin, 1930), pp. 34–35.

[20] W. H. McAdams, *Heat Transmission* (McGraw-Hill Book Company, Inc., New York, 1942). (a) Eq. 2, p. 135; (b) Eq. 8, p. 119; (c) Eq. 1, p. 162.

assumed to be given[20b] (see also Appendix A) by

$$dF=\frac{fV^2dx}{2(D/4)},\tag{33}$$

where $f$ is the Fanning friction factor. From Eqs. (13) and (33) it follows that

$$d\mu\equiv\frac{dF}{RT}=\frac{2f\gamma Ndx}{D}.\tag{34}$$

If Reynolds' analogy is valid, $h$ may be replaced[20c] by $c_p\rho Vf/2$, whence Eq. (14) becomes

$$dN/dx=[N/(1-N)]\{(1+\gamma N)[(T_w/T)-1] +[2+(\gamma-1)N]\gamma N\}2f/D.\tag{35}$$

This equation may be used to determine the direction of change of $N$ with $x$, and hence of other flow quantities, for various ranges of $N$ and of $T_w/T$. For values of $(T_w/T)\ll 1$, (maximum rate of cooling), $dN/dx$ is positive for values of

$$1>N>[-\gamma+(\gamma(5\gamma-4))^{\frac{1}{2}}]/2\gamma(\gamma-1)=0.58$$

for $\gamma=1.4$; that is, the effects of friction in increasing the Mach number overbalance the effects of the cold walls in lowering it if $1>M=N^{\frac{1}{2}}>0.76$ for $\gamma=1.4$ If $N>1$ then $(dN/dx)<0$, and acceleration of frictional, supersonic flow by convective cooling appears to be impossible. This behavior of compressible gases affects the design of supersonic wind tunnels.[21] Acceleration of frictionless supersonic flow by cooling should, however, be possible[9,13].

## Behavior of Solution at Sonic Velocity

The differential equations (14)–(18) must be examined as to behavior at the singular point $N=1$. In order that the logarithmic differentials may be defined at this point, it is necessary that

$$d\beta\equiv d\theta+d\mu+d\alpha=0 \text{ at } N=1,\tag{36}$$

because each logarithmic differential is proportional to $d\beta/(1-N)$ there. If $d\beta\neq 0$ upstream of the end of the duct, $N$ can equal 1 only at the end of the duct. This situation is illustrated by the "choked" converging nozzle and by the frictional diabatic flow, which is treated in the previous section. Equation (36) is formally satisfied at the end of a duct where $d\theta$, $d\mu$, and $d\alpha$ may be considered to vanish for all values of $N$.

Between the ends of a duct, however, $d\beta$ must always vanish where $N=1$. This condition shows that at $N=1$ arbitrary variations of $d\theta$, $d\mu$, and $d\alpha$ are not possible. A specific illustration is the ideal nozzle in which $d\theta=d\mu=0$; according to Eq. (36), $d\alpha$ is then restricted to the value 0, which means that the area has a stationary value at $N=1$. This is the well-known result that sonic velocity can be attained only in the throat of an ideal nozzle in shockless flow. A quite similar treatment applies for the cases where $d\theta$ and $d\mu$ are the quantities to be investigated (see pertinent material in references 5–14 and 21). Condition (36), which was necessitated by the presence of the determinant $(1-N)/2$ in Eqs. (14)–(18), is thus seen to provide a unification of the treatment of the flow behavior in the neighborhood of sonic velocity.

Combination of the second law of thermodynamics with Eq. (36) also yields limitations on the behavior of the flow at $N=1$. According to Eqs. (21) and (36), at sonic velocity

$$d\theta\leqq dS/c_p\leqq -d\alpha=dA/A.\tag{37}$$

These results may be stated in words to the effect that in converging or constant-area channels at $N=1$, neither the heat term $d\theta=dQ/c_pT$ nor the entropy term $dS/c_p$ can be positive. In diverging channels these two terms may be either positive or negative. If either $d\theta$ or $d\mu$ is everywhere 0, relation (21) yields more detailed results. For example, if $d\theta\equiv 0$, then at $N=1$, by Eqs. (36) and (20)

$$\begin{aligned}d\mu&=-d\alpha\\&=[\gamma/(\gamma-1)]dS/c_p\geqq 0,\quad (d\theta=0,\ N=1).\end{aligned}$$

Continuous flow with friction and without heat addition at sonic velocity cannot, therefore, occur in a converging channel.[7]

A more complete treatment of the behavior of the flow when $N=1$ between the ends of the duct is obtained by considering second-order terms. As $N$ approaches unity, Eq. (14), which may be written

$$N'/N=\{(1+\gamma N)\theta'+[2+(\gamma-1)N]\mu' +[2+(\gamma-1)N]\alpha'\}/(1-N),$$

---

[21] F. Clauser, Phys. Rev. 71, 465A (1947).

takes the form 0/0. For the evaluation of this limit, L'Hopital's rule gives after some calculation

$$N_0'=[\theta_0'N_0'+(1+\gamma)\beta_0'']/(-N_0'),$$

where subscript 0 denotes value of function at $N=1$. The solution for $N_0'$ is

$$N_0'=-\theta_0'/2\pm[(\theta'_0/2)^2-(1+\gamma)\beta_0'']^{\frac{1}{2}}. \quad (38)$$

The double-valuedness of the derivative at $N=1$ will have important consequences in that a unique solution of the equations may not be obtained when $N=1$ along the flow path. In general, it will be possible to continue the solution from $N=1$ along either of two paths, depending on the choice of sign. In certain cases, depending on the signs of $\theta_0'$ and $\beta_0''$, one sign will correspond to continuation into subsonic flow, the other into supersonic; otherwise the two choices will correspond to different continuations into flow of the same character. This result means that specification of initial conditions and of variation of $d\theta$, $d\mu$, and $d\alpha$ alone is not sufficient to insure a unique solution if $N$ becomes unity along the flow. In the event that the radicand is zero, it is possible that only one solution is obtained; or it may happen that some higher derivative is double-valued with resulting ambiguity of solution. The analysis for this case is somewhat involved and will not be continued here.

It is interesting to note that a less general problem of the same nature has been presented by Lorenz[22] and Prandtl and Proell.[23] Some of this work is possibly more accessible in Stodola's book.[24]

## The Phenomenon of Choking

The general equations (11)–(13) impose restrictions on the relations between the flow variables and the heat, friction, and area variation. When these restrictions take the form of upper or lower limits on mass flow, the associated phenomena are termed "choking" processes. As an example, it is well known that the ideal nozzle has for given subsonic entry conditions a maximum mass flow beyond which the discharge cannot be increased no matter how much the exit pressure is lowered. Another case is "thermal choking," wherein the entrance Mach number and hence mass flow in diabatic, frictionless, constant-area flow is limited for given heat addition despite indefinite reductions in outlet pressure.[13]

The nature of choking may be studied with the help of Eq. (22), which was derived simply from the basic equations. It will be shown that unless heat, friction, and area variation are such that $(1-N)$ times the right-hand side of Eq. (22) changes from positive to negative as $x$ increases, the Mach number in the tube cannot become greater than 1 if the entrance velocity is subsonic and cannot become less than 1 if the entrance velocity is supersonic, provided that the flow variables remain continuous.

For convenience, designate by $Y$ the factor $(1-N)$ times the right-hand side of Eq. (22). The quantity $Y$ is seen to consist of a sum of terms in $Q'$, $F'$, and $-A'$ multiplied by functions of $N$ that are always positive. (In the event that only one of the terms $Q'$, $F'$, and $-A'$ is not 0, $Y$ becomes merely the derivative of the heat added, the frictional work, or the area, multiplied by a simple function of the flow variables; then positive $Y$ corresponds to the case of heat addition, friction, or a converging duct.)

Suppose first that $Y$ is always negative. Then if the flow at the entrance section $x_1$ is subsonic, $dN/dx=(1-N)^{-1}Y<0$, and the Mach number decreases; if the entering flow is supersonic, $dN/dx=(1-N)^{-1}Y>0$, and the Mach number increases.

Suppose now that $Y$ is always positive. Then, if the entering flow at $x_1$ is subsonic, $dN/dx=(1-N)^{-1}Y>0$, and the Mach number increases. But $N$ cannot increase past unity as $x$ increases. For suppose $N=1$ at $x=x_0$ and is greater than 1 in the right-hand neighborhood of $x_0$ (exclusive of $x_0$); then $dN/dx$ is negative in this neighborhood, because $(1-N)$ is less than 0 and $Y$ is greater than 0. Now $N$ is equal to unity at $x=x_0$, is continuous, and has a negative derivative in the neighborhood mentioned. Hence $N$ is less than 1 in this neighborhood, which contradicts the assumption. Therefore $N$ cannot be

---

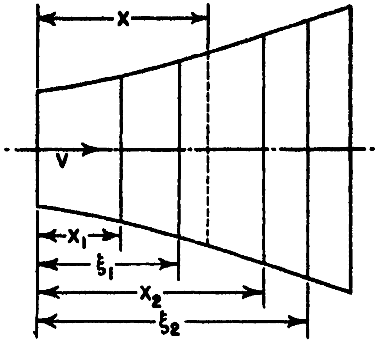

FIG. 1. Fluid elements considered in deriving the equations of energy and mass conservation.

greater than 1 if $Y$ is always positive, $N$ is continuous, and $N(x_1)$ is less than 1. In general, no continuous solution exists for values of $x > x_0$ if $Y$ is always positive. This statement, and the foregoing proof, are valid even if $N'(x_0)$ does not exist. An analogous development may be made for $N(x_1)$ greater than 1 with the conclusion that, with $Y$ positive and $N$ continuous, $N$ cannot be less than 1.

If $Y$ changes from positive to negative at $x = x_0$, however, the value of $N$ may cross unity at that point, but if $Y$ is initially negative, $N$ goes away from unity as previously shown and can only turn toward unity if $Y$ changes from negative to positive; this change must be made at some value of $N$ other than 1. After $Y$ has changed to positive, the situation reduces to the case that $Y$ is always positive, with the $N$ where $Y$ changes sign now taken as the entrance $N$.

It has been shown that up to some fixed point in the tube, which can be either the exit or the point at which $Y$ changes from positive to negative, $N$ and, therefore, the Mach number do not become greater than 1 if the entering velocity is subsonic nor less than 1 if the entering velocity is supersonic. Furthermore, if $Y$ is positive up to the point at which $N$ is limited, the derivative of $N$ before this point is always positive if the entering flow is subsonic and is always negative if the entering flow is supersonic. Thus, for positive $Y$ and subsonic entrance velocity the entrance $N$ cannot exceed some limiting value less than 1 determined by the particular $Q$, $F$, $-A$ variation, for $N$ is always increasing from its initial value and cannot exceed 1; and, by analogous considerations for positive $Y$ and supersonic entrance velocity $N$ cannot be less than some limiting value greater than 1. This limitation is essentially the choking phenomenon.

The specific form this limitation takes is not easily stated in the general case, because the choice of which factors are to be held constant and of which variables are to be considered limited determines the particular form of the restrictions. Numerical results for some particular cases are given in references 7, 13, and 14, among others, to illustrate the nature of possible results. It is felt that additional special cases should be investigated before a thorough study of the general case is attempted.

## APPENDIX A

### Derivations of Three Basic Equations

#### *Conservation of Energy*

The first law of thermodynamics applies to energy changes between two states of a system enclosed within a surface. Let the system (Fig. 1) be the gas of mass $\Delta m$ that is contained in the initial state within the tube walls and the sections at $x_1$ and $x_2$ and in the final state within the tube walls and the sections at $\xi_1$ and $\xi_2$; $x_1$, $x_2$, and $\xi_1$ are arbitrary, and $\xi_2$ is determined by the condition that the mass between $x_1$ and $\xi_1$ equal the mass between $x_2$ and $\xi_2$. When $m(x)$ is defined as the total mass of gas contained within the duct between the sections $x=0$ and $x=x$, the definition of $\Delta m$ becomes

$$\Delta m \equiv m(x_2) - m(x_1) = m(\xi_2) - m(\xi_1). \quad (39)$$

Let $U(x)$ denote the internal (thermal) energy per unit mass of fluid, $p(x)$ the static pressure, $V(x)$ the gas velocity, $A(x)$ the cross-sectional area of the duct, each taken at the section $x$; and $Q(x)$ the heat (in mechanical-energy units) added from walls or by combustion*** to a unit mass of the fluid during its passage from $x=0$ to $x=x$. Then the first law of thermodynamics says for

---

*** Actually, the heat liberated by combustion might be considered as part of the internal energy; or the external surroundings might be considered to include the fuel; or the first law might be generalized to include heat sources. The treatment given here is convenient but must be understood to require some justification on one of the bases mentioned.

steady flow that

$$\int_{m(\xi_1)}^{m(\xi_2)} (U+\tfrac{1}{2}V^2)dm - \int_{m(x_1)}^{m(x_2)} (U+\tfrac{1}{2}V^2)dm$$
$$= \int_{m(\xi_1)}^{m(\xi_2)} Qdm - \int_{m(x_1)}^{m(x_2)} Qdm$$
$$-\left[\int_{x_2}^{\xi_2} pAdx - \int_{x_1}^{\xi_1} pAdx\right]. \quad (40)$$

As $Adx = (1/\rho)dm$, where $\rho(x)$ is the density of the gas, Eq. (40) becomes

$$\int_{m(x_2)}^{m(\xi_2)} (U+\tfrac{1}{2}V^2-Q+p/\rho)dm$$
$$= \int_{m(x_1)}^{m(\xi_1)} (U+\tfrac{1}{2}V^2-Q+p/\rho)dm \quad (41)$$

when the limits of integration are changed.

Provided that the integrand is continuous (which requirement excludes shock), the expression on the right-hand side of Eq. (41) may be written, by the theorem of the mean for integrals:

$$[m(\xi_1)-m(x_1)]f(m_1^*),$$

where $f(m_1^*)$ indicates the value of the integrand at some $m=m_1^*$, $m(x_1)<m_1^*<m(\xi_1)$. The integral on the left-hand side yields a similar result, with subscript 1 replaced by subscript 2, whence, by virtue of Eq. (39)

$$f(m_1^*)=f(m_2^*); \quad m(x_1)<m_1^*<m(\xi_1),$$
$$m(x_2)<m_2^*<m(\xi_2). \quad (42)$$

As $\xi_1 \rightarrow x_1$, $\xi_2 \rightarrow x_2$, this equation becomes

$$f[m(x_1)]=f[m(x_2)]. \quad (43)$$

But $x_1$ and $x_2$ are arbitrary. Hence $f$ is a constant, and

$$\frac{d}{dx}(U+\tfrac{1}{2}V^2-Q+p/\rho)=0$$

or, since $d(U+p/\rho)=dH$, where $H$ is the enthalpy per unit mass,

$$dQ=dH+VdV. \quad (44)$$

For a perfect gas, $dH=c_pdT$, whence the energy equation is finally

$$dQ=c_pdT+VdV. \quad (45)$$

### *Conservation of Mass*

The conservation of mass, in the form useful here, states that in a steady flow the mass entering a closed surface during any time interval $\Delta t$ is equal to the mass leaving during the interval $\Delta t$. Let the closed surface consist of the sections at arbitrary $\xi_1$ and $x_2$ (Fig. 1) and the portions of the duct between these sections, and let $\Delta t$ be the time required for the mass $m(\xi_1)-m(x_1)$ to enter the surface while mass $m(\xi_2)-m(x_2)$ flows out. The value of $x_1$ is arbitrary, whereas $\xi_2$ is fixed by the conditions on the time interval. Upon definition of $t(x)$ as the time required for a fluid particle to travel from origin $x=0$ to $x=x$, $\Delta t$ may be defined by

$$\Delta t \equiv t(\xi_1)-t(x_1)=t(\xi_2)-t(x_2). \quad (46)$$

The law of conservation of mass says that

$$\int_{x_1}^{\xi_1} \rho Adx = \int_{x_2}^{\xi_2} \rho Adx. \quad (47)$$

Upon change of variable, this equation becomes

$$\int_{t(x_1)}^{t(\xi_1)} \rho A\frac{dx}{dt}dt = \int_{t(x_2)}^{t(\xi_2)} \rho A\frac{dx}{dt}dt. \quad (48)$$

As before, by the theorem of the mean for integrals and condition (46), the integrand must be constant, whence

$$d(\rho VA)=0. \quad (49)$$

### *Equation of Motion*

The vector form of the second law of motion for continuous media states that the integral of the density of surface forces over a closed surface

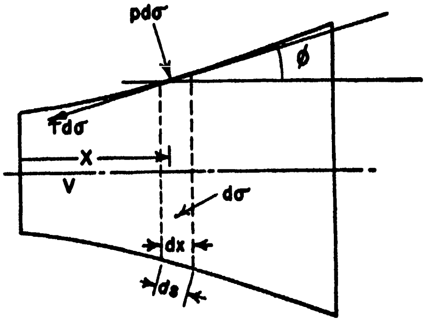

FIG. 2. Forces acting upon a fluid element described in the one-dimensional approximation.

is equal to the integral of the density times the particle derivative of the velocity over the volume enclosed by the surface.[25] For the mass of gas contained within the sections at $x_1$ and $x_2$ (Fig. 1) and the walls of the duct, the horizontal component of the equation of motion becomes

$$p(x_1)A(x_1)-p(x_2)A(x_2)+\int_{x_1}^{x_2} Rdx =\int_{x_1}^{x_2}\rho\frac{dV}{dt}Adx, \qquad (50)$$

where $R(x)dx$ is the horizontal component of the force exerted on the gas by the portion of the duct between $x$ and $x+dx$. For steady flow, the integral on the right-hand side may be transformed as follows:

$$\int_{x_1}^{x_2}\rho\frac{dV}{dt}Adx=\int_{x_1}^{x_2}\rho\frac{dV}{dx}\frac{dx}{dt}Adx=\rho VA\int_{x_1}^{x_2}\frac{dV}{dx}dx=\rho VA[V(x_2)-V(x_1)]. \qquad (51)$$

It follows from Eqs. (50) and (51) that the equation of motion may be written in differential form as

$$pdA+Adp+\rho VAdV=Rdx. \qquad (52)$$

Now $Rdx$ may be resolved into two constituent parts, the horizontal components of the tangential frictional drag and of the normal pressure reaction. If the half-angle of the duct is denoted by $\phi(x)$, the wall surface by $\sigma(x)$, and the tangential frictional drag per unit area by $\tau(x)$, from Fig. 2 it is clear that

$$Rdx=-(\tau d\sigma)\cos\phi+(pd\sigma)\sin\phi,$$

and that

$$d\sigma=dA/\sin\phi,$$

hence

$$Rdx=-(\tau d\sigma)\cos\phi+pdA. \qquad (53)$$

It is possible to use Eq. (53) directly without further analysis if the friction factor is related to $\tau$ by the equation $\tau=f\rho V^2/2$. In many engineering treatments, however, $f$ is defined in terms of the "energy loss due to friction." In order to make this concept of energy loss more precise and to make possible derivation of a rigorous connection between $\tau$ and energy loss, define $F(x)$ as the work done by unit mass of the fluid against friction in moving from the origin to position $x$. The work done in moving the entire mass of fluid between $x_1$ and $\xi_1$ to the region between $x_2$ and $\xi_2$ (see Fig. 3) will be computed in terms of the original variables $\tau$ and $\sigma$ and in terms of the new variables $F$ and $m$. If the two quantities are equated and suitably transformed, a relation will be obtained between $dF$ and $\tau d\sigma$.

Let $x_1$, $\xi_1$, and $x_2$ be chosen arbitrarily, and let $\xi_2$ be determined by the condition that the total mass $\Delta m$ between $x_1$ and $\xi_1$ equal the total mass between $x_2$ and $\xi_2$. Let $x_a$ be an arbitrary point between $x_1$ and $\xi_1$, and let $x_b$ be determined by the condition that $m(x_a)-m(x_1)=m(x_b)-m(x_2)$. In particular, if $x_a=x_1$, then $x_b=x_2$; if $x_a=\xi_1$, then $x_b=\xi_2$. Thus it is seen that, as $x_a$ runs from $x_1$ to $\xi_1$, $x_b$ runs from $x_2$ to $\xi_2$.

In order to determine the work done in terms of the variables $\tau$ and $\sigma$, the procedure is to move thin sections from their original positions, given in each case by $x_a$, to their final positions $x_b$, to find the work done by each of them, and then to add up the work done for all the sections.

First, divide the mass $\Delta m$ between $x_1$ and $\xi_1$ into smaller elements of mass $\Delta_1 m$, $\Delta_2 m$, $\cdots\Delta_n m$. (See Fig. 3.) Let $\Delta_i\sigma$ be the wall surface corresponding to the element of mass $\Delta_i m$, and let the duct wall between the initial and the final position of $\Delta_i m$ be divided into elements of length $\Delta_j s$. For a given $\Delta_i m$ it follows from Fig. 3

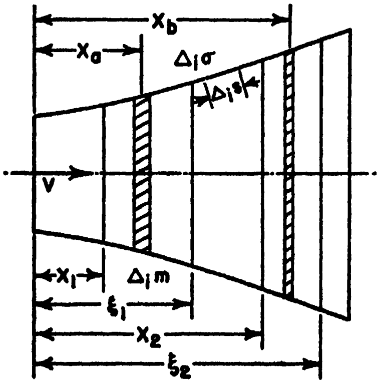

FIG. 3. Fluid elements considered in deriving the equation of momentum conservation.

---

[25] H. V. Craig, *Vector and Tensor Analysis* (McGraw-Hill Book Company, Inc., New York, 1943), pp. 355–356.

that

$$\Delta_i m = \rho_i A_i \Delta_i x,$$
$$\Delta_i\sigma = 2\pi r_i \Delta_i s,$$
$$\Delta_i x = \cos\phi_i \Delta_i s,$$

so that

$$\Delta_i\sigma = g_i \Delta_i m,$$

where $g_i \equiv 2\pi r_i/\rho_i A_i \cos\phi_i$. Each of the quantities $\rho_i$, $r_i$, $\phi_i$, and $g_i$ is to be evaluated at the proper point within $\Delta_i x$.

Finally, from Fig. 3 there exists on $\Delta_i m$ a force $\Delta F_i(s_j)$, to be overcome by the work against friction, equal to

$$\tau(s_j)\Delta_i\sigma(s_j) = \tau(s_j)g_i(s_j)\Delta_i m,$$

where it is convenient to consider $\tau$ and $\sigma$ as functions of $s$, inasmuch as frictional drag and the extension of an element of fixed mass depends on the position of the element in the tubes.

For any element of mass $\Delta_i m$ then, an approximation (the accuracy of which depends on the size of $\Delta_i m$) to the work done by $\Delta_i m$ in going from section $x_a$ to section $x_b$ is

$$\lim_{\Delta_j s\to 0} \sum_{s(x_a)}^{s(x_b)} \Delta F_i(s_j)\Delta_j s = \lim_{\substack{k\to\infty \\ \Delta_j s\to 0}} \sum_{j=1}^{k} \tau(s_j)g_i(s_j)\Delta_i m \Delta_j s$$
$$= \Delta_i m \int_{s[m(x_{a_i})]}^{s[m(x_{b_i})]} \tau(s)g_i(s)ds.$$

It follows that the corresponding approximation to the work done by the entire mass $\Delta m$ is

$$\sum_{i=1}^{n} \left\{ \int_{s[m(x_{a_i})]}^{s[m(x_{b_i})]} \tau(s)g_i(s)ds \right\} \Delta_i m$$

and, as the approximation becomes more and more accurate as the largest $\Delta_i m$ becomes smaller and smaller, the expression for the work done against friction when the entire mass between $x_1$ and $\xi_1$ is transported to the position between $x_2$ and $\xi_2$ becomes

$$\lim_{\substack{n\to\infty \\ \Delta_i m\to 0}} \sum_{i=1}^{n} \left\{ \int_{s[m(x_{a_i})]}^{s[m(x_{b_i})]} \tau(s)g_i(s)ds \right\} \Delta_i m$$
$$= \int_{m(x_1)}^{m(\xi_1)} \int_{s[m(x_a)]}^{s[m(x_b)]} \tau(s)g(s)dsdm. \quad (54)$$

It is clear that the work done against friction when the entire mass is moved as previously described is equal also to

$$\lim_{\substack{\Delta_j F\to 0 \\ \Delta_i m\to 0}} \sum_i \sum_j \Delta_j F \Delta_i m = \int_{m(x_1)}^{m(\xi_1)} \int_{F[m(x_a)]}^{F[m(x_b)]} dFdm$$
$$= \int_{m(x_1)}^{m(\xi_1)} \int_{F[m(x_a)]}^{F[m(x_b)]} (dF/ds)dsdm \quad (55)$$

whence it follows, since the intervals for both integrations are arbitrary, that

$$dF/ds = \tau g \quad (56)$$

and

$$dF = \frac{2\pi r}{\rho A \cos\phi} \frac{\tau d\sigma}{2\pi r}$$

whence

$$(\tau d\sigma)\cos\phi = \cos^2\phi \rho A dF. \quad (57)$$

Because, for the small angles usually under consideration, $\cos^2\phi$ is very nearly unity (for a half-angle of 6°, $\cos^2\phi = 0.989$), the retention of this factor except for particularly precise work would not seem justifiable. Hence Eq. (53) may be written

$$Rdx = -\rho AdF + pdA. \quad (58)$$

The differential equation of motion is finally

$$-dp = \rho VdV + \rho dF. \quad (59)$$

The connection between $dF$ and the differential loss in stagnation pressure $(-dp_t)$ can, with the help of Eqs. (14) and (15), be expressed in the form

$$\frac{-dp_t}{p_t} = \frac{dF}{RT} + \frac{\gamma N d\theta}{[2+(\gamma-1)N]}. \quad (60)$$

Thus except for the limiting case of incompressible flow, $(-dp_t)$ and $dF$ cannot be used interchangeably in defining the friction factor even for the adiabatic case where $d\theta = 0$.

## APPENDIX B

### The *Z* Language

In the place of $N = V^2/\gamma RT$ the equations may be formulated in terms of $Z$, defined through

$$Z = (V^2/2c_p)/(T + V^2/2c_p). \quad (61)$$

The numerator is the so-called dynamic temperature, the denominator is the total temperature. $Z$ and $N$ are related by

$$Z=[(\gamma-1)N]/[2+(\gamma-1)N], \quad (62)$$

$$N=2Z/(\gamma-1)(1-Z). \quad (63)$$

This replacement represents a one-to-one transformation of $N$ into $Z$ in the range 0 to infinity for $N$, 0 to 1 for $Z$.

In order to illustrate the form that some of the earlier equations take under this transformation, Eqs. (14)–(16) are written in terms of $Z$,

$$\frac{dZ}{Z}=\frac{2}{1-[(\gamma+1)/(\gamma-1)]Z}\left\{\frac{1-Z}{2}\left[1+\left(\frac{\gamma+1}{\gamma-1}\right)Z\right]d\theta+(1-Z)d\mu+(1-Z)d\alpha\right\}, \quad (64)$$

$$\frac{dp}{p}=\frac{2}{1-[(\gamma+1)/(\gamma-1)]Z}\left(-\frac{\gamma}{\gamma-1}Zd\theta-\frac{1+Z}{2}d\mu-\frac{\gamma}{\gamma-1}Zd\alpha\right), \quad (65)$$

$$\frac{dT}{T}=\frac{2}{1-[(\gamma+1)/(\gamma-1)]Z}\left[\left(\frac{1-Z}{2}-\frac{\gamma Z}{\gamma-1}\right)d\theta-Zd\mu-Zd\alpha\right]. \quad (66)$$

# Crystalline Aggregation of Cobalt Powder[a]

J. T. McCartney[b] and R. B. Anderson[c]

(Received April 28, 1947)

In electron microscopic studies of Fischer-Tropsch catalysts, an interesting phenomenon was observed in cobalt metal powder reduced from cobaltous oxide. The oxide particles sintered into larger smooth droplets of cobalt that were aggregated into thin hexagonal-shaped platelets. X-ray diffraction analysis showed the presence of the hexagonal crystal phase of cobalt. A possible explanation is that the aggregates are formed by forces similar to those operating in normal crystal formation but of reduced magnitude insufficient to destroy the identity of the component particles.

In the course of examination, with the electron microscope, of various components of cobalt catalysts used in the Fischer-Tropsch synthesis of liquid and solid hydrocarbons from mixtures of carbon monoxide and hydrogen, an interesting phenomenon was observed in cobalt metal powder reduced from the oxide. The cobalt was prepared by precipitation of cobaltous oxide from cobaltous nitrate with aqueous ammonia, reduction of the oxide in hydrogen at 250°C, and stabilization of the metallic cobalt against rapid oxidation by exposure to carbon dioxide at liquid nitrogen temperature. Figures 1 and 2 are electron micrographs showing the relative sizes and shapes of the particles of the oxide and the reduced metal. Surface area measurements by a nitrogen adsorption method[1] gave values of 67 square meters per gram for the oxide and 2 square meters per gram for the reduced cobalt. Thus, during reduction, there was an evident sintering of the irregular particles of the oxide into larger smooth droplets of cobalt metal.

Such droplets have been observed in several other metals prepared and reduced in a similar way. In cobalt, however, these particles are more or less closely aggregated into hexagonal platelets such as shown in Figs. 3 and 4. Varying degrees of dispersion in different specimens are illustrated in Figs. 2–4. The hexagons vary in diameter from 7 to 25 microns, and their thickness is apparently of the order of the diameter of the component particles. The hexagonal shape can be discerned also in the optical microscope. X-ray diffraction analysis shows that the crystal phase present is hexagonal cobalt. The hexagons are quite stable,

their presence being observed in reduced cobalt samples which were at least partly oxidized and in reduced cobalt partially converted to cobalt carbide.

A possibly related phenomenon is that described by Picard and Duffendack[2] in evaporated metals. Their electron micrographs of evaporated zinc and cadmium show hexagonal crystals of the order of 0.1 micron in diameter. These are explained as resulting from migration and combination of the condensed atoms of the metals. In the Bureau of Mines laboratory, cobalt was evaporated onto collodion substrates and observed in the electron microscope. It apparently formed nearly continuous films with no observable migration into large crystals. Such was the case even at elevated temperatures, the cobalt condensing onto evaporated silica films heated probably above 250°C. Since cobalt has a much higher melting point than zinc and cadmium, higher temperatures may be required for migration.

It is suggested that the hexagonal aggregates in cobalt are formed by forces similar to those operating in normal crystal formation. Since, however, the component particles do not lose their identity and the aggregates are easily fractured, they can hardly be classed as true crystals. Possibly the forces acting to combine atoms into crystals are so reduced when the combining units are particles of relatively large size that only a superficial crystal formation occurs. It is not evident why this phenomenon has been observed only in cobalt.

# Surface Studies of Glass.

## Part I. Contact Angles

L. A. Spitze* and D. O. Richards
*Physics Laboratory, Owens-Corning Fiberglas Corporation, Newark, Ohio*

(Received May 5, 1947)

The water-repellent nature of glass surfaces treated with different silicones is examined by means of contact-angle measurements. Results are given showing the effect of various concentrations of silicones, types of glass, temperature of heat treatment, length of time of heat treatment, and surface roughness on the water contact angles. Silicones containing the methyl and phenyl group show good heat stability at temperatures of 500°C for short periods of time.

### INTRODUCTION

In applying glass to many industrial uses, more information is desired concerning its surface properties. This information is increasingly important as the surface area-weight ratio becomes progressively larger. In Fig. 1, the relationship between surface area and diameter of fibers is shown in English and metric units. From this graph it can be seen that fibers of glass are now being made having a surface area more than 50,000 times that of an equal unit weight of bulk glass. These extended surfaces present an opportunity for varied physical and chemical reactions to occur, and emphasize the need for an increasing amount of work on surface studies of glass. Such surface phenomena may possibly alter or mask many of the basic properties of the glass itself with the resultant properties being largely influenced by the type of surface presented. To learn more about some of these properties, different physical characteristics of the surface can be studied. A property of prime consideration is the degree of wetting of glass surfaces by liquids. Investigations of the degree of wetting of glass surfaces by liquids can be done readily by measurements of the contact angles these liquids form on the glass surface. Harkins and others[1] have shown that the contact angle for water, benzene, carbon tetrachloride, chloroform, and ether in contact with clean glass is zero. A solid is completely wetted by a liquid if the contact angle is zero, and incompletely wetted if a measurable contact angle is found. A zero contact angle indicates that the liquid attracts the solid as much as it attracts itself, a 90° contact angle shows that the attraction of the liquid for the solid is half that for itself, and a contact angle of 180° would mean there was absolutely no attraction of the liquid for the solid. Because contact angles of 180° are unrealizable, complete non-wetting is impossible; but solids with liquid contact angles greater than 90° are generally referred to as being non-wetted. In such industrial applications of glass fibers as flotation mats, water-repellent fabrics, and glass-plastic laminates with decreased water sorption, a hydrophobic surface is desired. Such materials as the long-chain fatty acids or their salts, when applied to a glass surface, will make it hydrophobic.. Although these materials will give a hydrophobic surface, they possess poor durability under various conditions, and particularly poor stability at elevated temperatures. Recently a new group of materials has been introduced containing members that also have the ability to give a hydrophobic surface to glass when treated by them. These materials, commonly referred to as the silicones,[2] have the distinct advantage of good heat stability. Materials such as the silcones, when applied to glass surfaces, permit the use of much higher temperatures in the applied product than would be available for glass surfaces treated with the usual organic materials. Thus, more of the inherent heat-resistant properties of the glass will be available for use in products containing glass

treated with these materials. In addition, these silicones, being largely inorganic materials containing silicon, could be expected to be compatible with a clean glass surface and would firmly adhere to such surfaces.

The degree of non-wetting that the silicones impart to a glass surface depends on the individual member, and on the method by which the silicone is applied to the glass surface.

## EXPERIMENTAL

The hydrophobic nature of a glass surface treated with various silicones was studied by determining the water contact angles. Measurements of contact angles may be made by various procedures. Methods most commonly used include direct measurement of the angle by use of photography or projection, tilting plate,[3] sessile drop,[4] or pressure of displacement in capillary tubes. The method selected for this study was the sessile drop. Determinations are made by placing a number of small drops of water on the treated glass surface and then measuring the dimensions of the drops with the aid of a microscope. The size of the contact angle, $\theta$, is then calculated from the relationship[5] $\tan\theta/2 = 2h/d$ where $h$ is the height of the drop, and $d$ is the width of the drop at the place of contact with the solid. The sessile drop method can be used only if the portion of the drop measured is a segment of a sphere. It has been shown that if the size of the drops is kept smaller than 1 mm in diameter, the contact angle attains a constant maximum value that is the advancing contact angle.[4] This method was selected for this study because of the ease of adapting the available equipment, and measurements of a number of drops on a treated surface will give an average value for the drops placed at various positions on the treated surface.

The apparatus used to determine the contact angles of water on the treated glass surfaces consisted of a Bausch and Lomb microscope placed in a horizontal position and containing a 10× objective. The drop was viewed and measured by means of a Bausch and Lomb 12.5× Filar eyepiece. Most of the glass samples used were cut to about 1″×½″ by ¼″ thick. The smooth, uncut, fire-polished upper surface was used in the studies. The treated glass sample was placed on a stage and brought into the line of sight by a mechanical microscope stage. A Spencer microscope illuminator was used to give a sharp outline of the drops placed on the glass surface. Drops of distilled water of fairly constant size, less than 1 mm in diameter, were placed on the treated glass surfaces by means of capillary tubes. For some of the treated surfaces having high contact angles, it became necessary to place the drops on the surface by spraying, as the adhesion tension of the water to the glass capillary was much greater than that for the treated glass surface. No fewer than five separate drops in the desired size range were measured and contact angles calculated. The glass samples were first cleaned with chromic acid cleaning

solution and then by flaming. The cleaned glass was then dipped in a 1 percent solution of the silicone in c.p. benzene, removed and allowed to drain a short while, and then placed in an oven at the desired temperature. After the sample was in the oven the desired time, it was removed and allowed to cool. The treated samples were then placed on the microscope stage and the dimensions of the drops placed on them were measured by use of the Filar eyepiece in the microscope.

## RESULTS

Values of the contact angles of water were obtained for glass surfaces treated with organosilane chlorides and with organosiloxane polymers. The magnitude of the contact angle was found as a function of the variables of temperature, length of time of heat-treatment, type of glass, and concentration of the surface treatment.

### Trichloroorganosilanes

Various members of this particular group of silicones were used to treat the glass surfaces. These materials were diluted with c.p. benzene until a solution was obtained containing 1 percent solids. Contact angles were obtained for these materials, first as a function of the temperature, the other variables being held constant. The samples of glass used here were a borosilicate glass type containing almost no alkali ($Na_2O$ or $K_2O$) and designated as $E$-glass by Owens-Corning Fiberglas Corporation. After being treated with the silicone solutions, the samples were placed in the oven at the desired temperature and left for fifteen minutes. The results of these measurements are shown in Table I. The data of Table I have also been presented graphically in Figs. 2a and 2b. These values represent determinations made at different times on different samples of the same type of glass. At temperatures below 300°C the results were most consistent. At the higher temperatures, the results varied somewhat. This can be expected from the shape of the curves as shown in Figs. 2a and 2b. Because the curves are steep in this region, any small variation in heating temperature or length of time of heating would greatly affect the results.

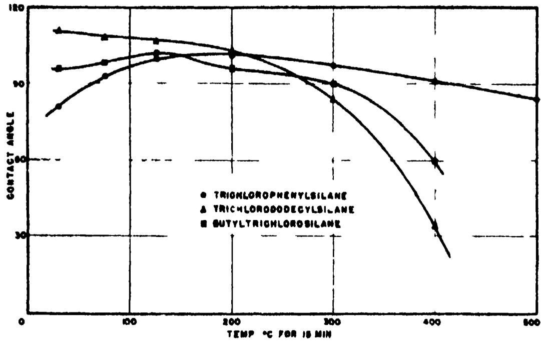

FIG. 2b. Contact angles of water on $E$-glass treated with 1 percent solution of trichloroorganosilanes *vs.* temperature.

TABLE II. Contact angles of water on $E$-glass treated with organosiloxane polymers.

| 15 Min. @ °C | 30° | 75° | 125° | 200° | 300° | 400° | 500° | 550° |
|---|---|---|---|---|---|---|---|---|
| Dimethylsiloxane polymer | 31 | 45 | 67 | 92 | 101 | 99 | 96 | 31 |
| Diethylsiloxane polymer | 40 | 46 | 82 | 102 | 97 | 91 | 44 | 25 |
| Methylphenylsiloxane 0.5 Ph/Si | 31 | 43 | 49 | 90 | 101 | 97 | 97 | 80 |
| Methylphenylsiloxane 0.9 Ph/Si | 25 | 44 | 61 | 91 | 91 | 90 | 91 | 91 |

The effect of the type of glass being treated on the contact angle is shown in Fig. 3. Three different types of glasses were used, treated with trichlorooctadecylsilane (1 percent solids), and heated at the specified temperatures for fifteen minutes. The three glass types used were $E$-glass, Pyrex chemical glass, and window glass. Chemical analysis shows that these glasses contain different amounts of alkali ($Na_2O$ and $K_2O$). The $E$-glass has less than 1 percent, the Pyrex chemical glass about 4½ percent, and the window glass about 12½ percent of these alkali materials.

## Organosiloxane Polymers

In Table II are shown the results of contact-angle measurements of water on *E*-glass treated with 1 percent solutions in benzene of four different organosiloxane polymers. These materials were heated at the desired temperature for fifteen minutes. The data have been plotted in Fig. 4 for visual use of these results.

It was considered advisable to determine the effect of different periods of heating on the contact angles of glass surfaces treated with these polymers. In Table III is shown the effect of various heating periods up to six hours on *E*-glass. Three different temperatures were used for this study: room temperature, 300°C, and 450°C. An upper temperature of 500°C was tried at the beginning, but for periods greater than one-half hour the results varied widely. Consequently, this "burning off" region was avoided and a lower temperature of 450°C selected. The results obtained are also shown graphically in Figs. 5–7.

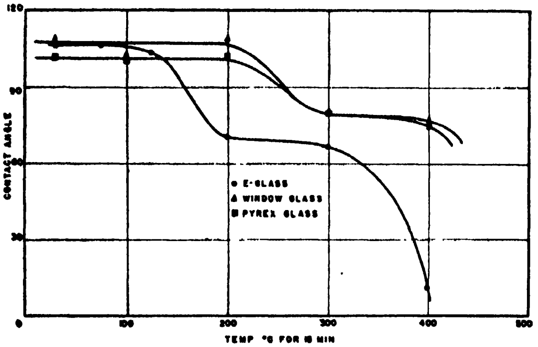

FIG. 3. Contact angles of water on various glasses treated with 1 percent solution of trichlorooctadecylsilane *vs.* temperature.

In addition, the effect of various concentrations of the silicones on *E*-glass was studied by contact-angle measurements. A curve showing the effect of dimethylsiloxane polymer on *E*-glass heated at 200°C and at 500°C for 15 minutes is shown in Fig. 8. A trichloroorganosilane was also used to study its effect at different concentrations. The results obtained for this material are discussed later.

### DISCUSSION

TABLE III. Contact angles of water on *E*-glass treated with organosiloxane polymers.

| Material | Temp. °C | Heating time in minutes 15 | 30 | 60 | 180 | 360 |
|---|---|---|---|---|---|---|
| Dimethylsiloxane polymer | 30 | 31 | 37 | 38 | 40 | 46 |
| | 300 | 101 | 104 | 104 | 100 | — |
| | 450 | 101 | 93 | 93 | 81 | 81 |
| Diethylsiloxane polymer | 30 | 40 | 53 | 54 | 55 | 55 |
| | 300 | 97 | 101 | 93 | 87 | — |
| | 450 | 89 | 79 | 62 | 62 | 20 |
| Methylphenylsiloxane 0.5 Ph/Si | 30 | 38 | 34 | 35 | 36 | 34 |
| | 300 | 101 | 96 | 99 | 96 | — |
| | 450 | 93 | 99 | 90 | 82 | 56 |
| Methylphenylsiloxane 0.9 Ph/Si | 30 | 25 | 45 | 39 | 39 | 36 |
| | 300 | 91 | 90 | 96 | 93 | — |
| | 450 | 96 | 99 | 93 | 79 | 86 |

Before making contact-angle measurements by the sessile drop method on silicone-treated glass, the method was tested by comparing the results obtained on some common materials with the values of the contact angles for these materials as reported in the literature. Measurements made of the contact angle of water on paraffin gave an average value of 105°, which compares favorably with the values reported elsewhere.[6] A photo-micrograph of a drop of water on paraffin is shown in Fig. 9. From this photograph it can be noted that the drop is a segment of a sphere, and the sessile drop method of measurements will give the contact angle for drops this size.

Two additional photo-micrographs of water on *E*-glass treated with dimethylsiloxane polymer are shown in Figs. 10 and 11. Figure 10 shows the appearance of water on *E*-glass treated with the polymer and heated to 125°C for 15 minutes. After the treated glass has been heated to 300°C for 15 minutes, the appearance is shown in Fig.

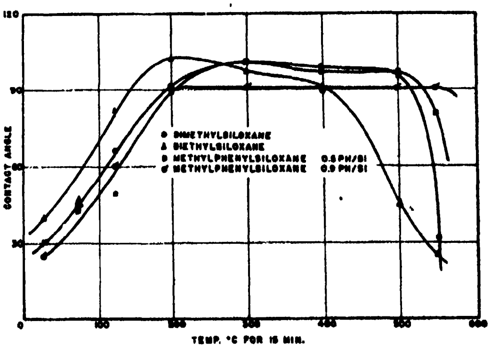

FIG. 4. Contact angles of water on *E*-glass treated with 1 percent solution of organosiloxane poymers *vs.* temperature.

[6] Int. Crit. Tab. 4, p. 434 (1928); N. K. Adams, *The Physics and Chemistry of Surfaces* (Oxford University Press, London, 1941), p. 186.

11. This increase of heat raises the contact angle 34°.

Observation of the data in Table I and the curves of Figs. 2a and 2b bring out the superior heat stability of the trichloroorganosilanes containing the methyl and the phenyl groups. These data show that the heat stability as determined by water repellency of these trichloroorganosilanes is dependent upon the particular organic group attached to the silicon. From these results it appears that the heat stability of the organic groups tested may be arranged in this descending order: methyl, phenyl, ethyl, butyl, octyl, dodecyl, and octadecyl. The maximum water repellency is shown by the materials containing the dodecyl and the octadecyl groups. Although the data in Table I do not show a definite order, it is most likely that the arrangement of the organic groups in the order of decreasing water repellency would be the reverse of the order for heat stability as given above. In particular, the methyl group seems to deviate from this arrangement The maximum contact angles shown by these materials are all within a 10° range; hence any experimental errors may account for the fact that the data are not in the orderly arrangement suggested above. The data for the organosiloxane polymers again show the heat stability of the methyl and the phenyl group. For these materials, the polymer containing the highest ratio of phenyl to silicon shows the best heat stability. Although there is very little difference in the values for the maximum contact angles obtained, the polymer containing the ethyl group appears to have a slightly higher maximum contact angle.

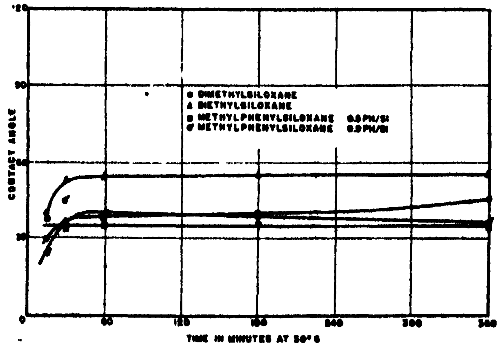

FIG. 5. Contact angles of water on *E*-glass treated with 1 percent solution of organosiloxane polymers *vs*. heating time.

The curves of Fig. 3 show a noticeable difference in the contact angles of various types of glasses treated with trichlorooctadecylsilane. These curves show that the highest contact angles are obtained for the glass containing the most alkali. Thus it is believed that the higher contact angles for window glass and for Pyrex glasses are due to the higher alkali content. It appears that the silicone materials will attach themselves more firmly to the alkali glasses, possibly because of a higher surface activity of these glasses. Results obtained when a dimethylsiloxane polymer was used to treat these various glasses did not show such a difference as exhibited by the trichlorooctadecylsilane-treated glasses. The two treated glasses containing the most alkali did, however, show appreciably higher contact angles at treatment temperatures below 200°C and values a little higher at temperatures above 500°C. It is possible that the polymer is able to orientate itself somewhat faster on these glasses containing alkali and that it is also bound a little stronger to these glasses.

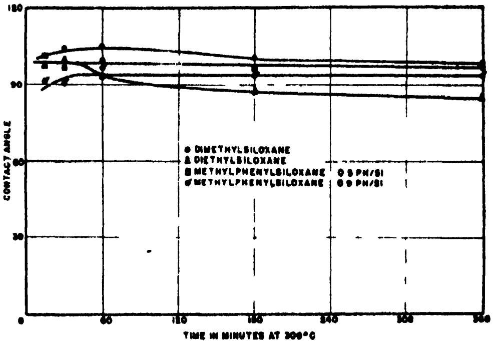

FIG. 6. Contact angles of water on *E*-glass treated with 1 percent solution of organosiloxane polymers *vs*. heating time.

The mechanical condition of the surface of the treated glasses influences the wettability to a large extent. The effect of the roughness of a surface on the contact angles has been recognized[7] as due to a greater net energy change in the wetting process caused by a rough surface. A drop tending to spread on a rough surface will increase the free liquid surface, but the wetted area under the drop will increase to a larger extent because of the rough surface. Increase of

---

[7] R. N. Wenzel, Ind. Eng. Chem. 28, 988 (1936).

the liquid surface involves a consumption of energy, while the increase of wetted area under the drop involves a release of energy. The difference is a net energy change which determines the speed of wetting on the solid. For a rough solid tending to be wet by a liquid, a greater net energy decrease is present than if the surface were smooth and this causes the rough surface to be wetted more thoroughly. For a liquid-repellent rough surface, the same reasoning can be applied. For a change in the shape of a drop on a rough liquid-repellent surface, more actual surface change is involved at the liquid-solid interface. As the dry interface has the lower specific energy, the net energy decrease is greater for the rough surface causing the drop to assume a more spherical form. A roughened surface magnifies the wetting properties of a solid, making it either more liquid-repellent or more easily wetted.

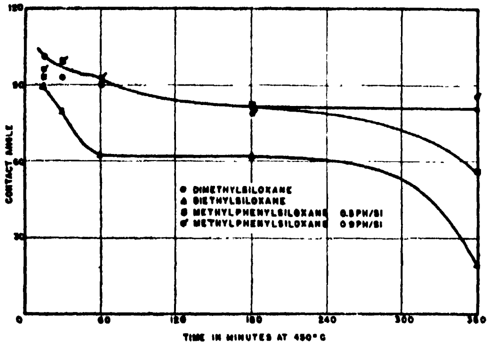

FIG. 7. Contact angles of water on *E*-glass treated with 1 percent solution of organosiloxane polymers *vs.* heating time.

The effect of a roughened glass surface on the contact angles was investigated briefly. A sample of *E*-glass was roughened by grinding with an abrasive and another sample was roughened with an acid etch. These surfaces were cleaned and then treated with a 1 percent solution of dimethylsiloxane polymer and heated for 15 minutes at 300°C. The contact angles obtained on these samples gave values of from 120° to 125°, depending somewhat on the manner by which the surface was roughened. A photo-micrograph of the appearance of a drop of water on a roughened *E*-glass surface treated with dimethylsiloxane polymer at 300°C for 15 minutes is shown in Fig. 12. The contact angle for this sample was found to be 124°, or an increase of 23° over the value of a treated smooth surface. The industrial applications of the surface roughness of materials, as an aid to water-repellency, are being studied and evaluated at the present time.

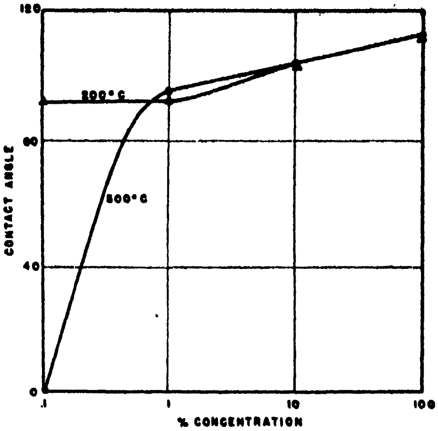

FIG. 8. Contact angles of water on *E*-glass treated with dimethylsiloxane polymer at 200°C and 500°C *vs.* concentration.

The effect of various lengths of time of heating these treated glass surfaces is small at room temperature. The data in Table III and Figs. 5–7 show, also, that at 300°C there is a small effect, if any, because of variation in length of time of heating these treated samples. Two of the samples appear to have a slightly larger contact angle as the time is increased to 30 minutes, but the effect is small. At 450°C, a more noticeable effect begins to appear. At this higher temperature, some of the material is beginning to burn off. This is particularly so for the diethylsiloxane polymer, and to a lesser extent for the methylphenylsiloxane polymer (0.5 Ph/Si). The data for the diethylsiloxane polymer also show a drop in contact angle with time up to 60 minutes, then remain steady until it begins to burn off. This drop may be due to the fact that equilibrium for this material is not reached at the higher temperatures until after 60 minutes. This effect is also somewhat noticeable for the dimethylsiloxane polymer.

The effect of different concentrations of the silicones on glass is significant, particularly at the lower concentrations. The data in Fig. 8 show the effects of varying the concentration of

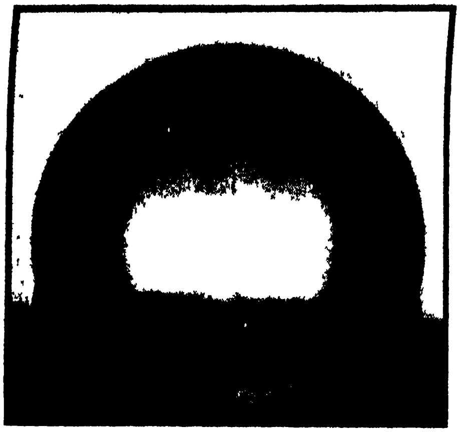

FIG. 9. Appearance of a drop of water on a paraffin surface; contact angle 105°.

dimethylsiloxane on *E*-glass and then heating at 200° and at 500°C for 15 minutes. The data show that an increase in concentration raises the contact angle at a particular temperature. This is most pronounced at the higher temperature and the lower concentration. At 500°C the 0.1 percent solution burns off, but the 1 percent solution gives a high contact angle. The 0.1 percent solution, although heated at 200°C, is not destroyed and gives a high angle. Although experiments were not tried at lower concentrations, it is believed that lower concentrations of dimethylsiloxane polymer would yield lower contact angles for the 200°C curve. Thus if these experiments had been conducted at lower concentrations, the resultant contact angle *vs.* temperature curves would very probably have been lower and burned off at considerably lower temperatures. The increase of the contact angles resulting from increase of concentration may be due in part, at the higher temperatures, to an increased surface roughness. This roughness is probably caused by deposition of some $SiO_2$ on the glass by the high heat, and any undestroyed silicone will give the necessary water-repellency necessary to obtain the higher contact angles. The concentration effect in the case of the trichloroorganosilanes is not as pronounced as that of the organosiloxane polymers. However, at the higher temperatures and lower concentrations, a noticeable drop in the values for the contact angles was apparent. These materials would also be expected to give values of contact angles somewhat lower as the concentration is decreased, but not to such an extent as that shown by the organosiloxane polymers.

Water-repellent glass in the form of fine fibers has proved to be very useful. For example, these treated glass fibers have proved their superiority over other materials as buoyant materials for Navy life preservers.[8] This superiority is due to their fire- and mildew-proofness, superior buoyancy, ability to withstand repeated wetting and drying with little loss in efficiency, and the fact that the treated glass fibers can be produced in

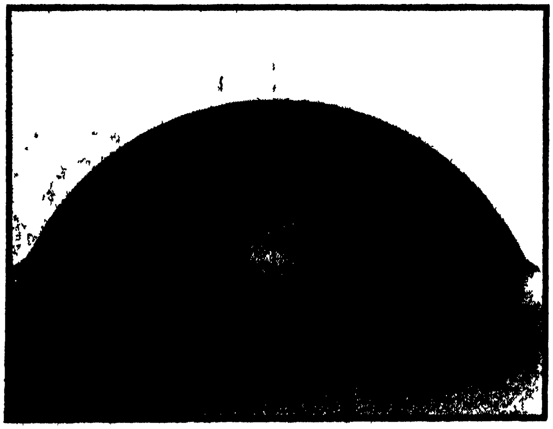

FIG. 10. Appearance of a drop of water on an *E*-glass surface treated with a 1 percent solution of dimethylsiloxane polymer and heated for 15 minutes at 125°C; contact angle 67°.

uniform quality. Such treated glass fibers have been adopted by the Navy as standard material.[8] In addition, these silicone-treated glass fibers have shown their value in reinforced plastics.[9] Their water-repellent properties have been very useful in increasing wet strength of these laminates. The wet strength of cloth laminates, improved by the application of a silicone solution to the glass fibers, has been brought up to a point nearly equal to the dry strength.[10]

This paper shows the results of contact-angle measurements of only a few of the many possible types of silicone materials. More information obtained on the other types of silicone materials available, when applied to glass and other materials, will be of utmost importance. Studies other than contact-angle measurements will also prove their worth in evaluation of surface properties of surfaces treated by the silicones.

## CONCLUSIONS

The values of the contact angles of water on glass surfaces treated with various trichloroorganosilanes and organosiloxane polymers show the good water-repellency properties these materials bestow on a glass surface. In addition, the superior heat stability of these materials is demonstrated. Of the various organic groups in the silicone molecule, the methyl and phenyl impart the best heat-resistant properties, and the dodecyl and octadecyl give the materials their best water-repellency. The value of increased surface roughness in giving better water-repellency also is shown. Finally, the effect of variations in the concentrations of these silicones when applied to the surfaces is given. It is recommended that concentrations no lower than 1 percent solids be used when maximum heat stability and water-repellency is desired.

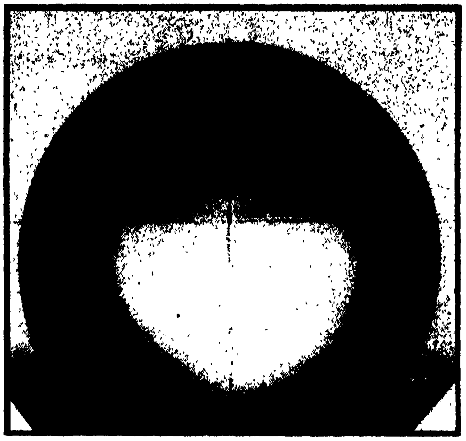

FIG. 12. Appearance of a drop of water on a roughened surface of *E*-glass treated with 1 percent solution of dimethylsiloxane polymer and heated for 15 minutes at 300°C; contact angle 124°.

## ACKNOWLEDGMENT

The silicone materials used in this study were furnished by Dr. M. J. Hunter of Dow-Corning Corporation, Midland, Michigan. The authors also wish to acknowledge the aid given during the course of this study by R. B. Taylor, W. C. Marlow, L. P. Biefeld, Robert Steinman, and G. F. Forman, all of the Research Division of Owens-Corning Fiberglas Corporation.

# An Apparatus for the Observation of the Kerr Effect with Microsecond Electrical Pulses

WILBUR KAYE AND RICHARD DEVANEY
*Tennessee Eastman Corporation, Research Laboratories, Kingsport, Tennessee*

(Received May 9, 1947)

An apparatus for the observation of the Kerr electro-optic effect in liquids and polymers using microsecond electrical pulses, is presented and evaluated. This method offers a convenient way of studying internal motions and molecular configurations of polymeric material with a minimum of heating usually accompanying these observations. Electrical pulses of from 1- to 1000-microsecond width, 60–1000 p.p.s., at amplitudes up to 5000 volts are generated by conventional methods. These pulses are used to orient low molecular weight and polymeric materials placed between the plates of a condenser. The circular polarization induced in the polarized light passing between the plates actuates a photo-multiplier tube in order that the light pulses may be studied with an oscillograph.

Curves of Kerr constant *versus* temperature at temperatures to −80°C are compared with the literature. Oscillograms showing the response of several liquids and polymers are shown. Oscillograms showing an interesting difference between orientation and relaxation time are presented, as are oscillograms showing clearly both orientation and distortion polarization simultaneously.

BRIEFLY the Kerr electro-optic effect is concerned with the elliptical polarization induced in a material subjected to an electrical field.[1] It is the aim of this paper to present the instrumental details and the evaluations necessary to utilize this Kerr effect for the study of internal motions and molecular configurations of organic liquids and polymers.

The instrument described in this report utilizes pulsed electrical fields for the study of the Kerr effect. This method offers the advantage of minimizing heating effects in the material under investigation, and permits one to study the nature of the orienting effect in a more direct manner than has hitherto been accomplished by the use of sinusoidal electrical fields.[2] A circuit similar to that used here was described by Pauthenier[3] using pulsed condenser discharges. However, Pauthenier had no direct method of studying the shape of the response wave as is now practical by use of the oscillograph.

Figure 1 shows a photograph of the exterior of the apparatus, which in conjunction with Fig. 2, a block diagram, will be used to explain the methods by which the Kerr effect may be produced and observed.

Electrical pulses of the order of a few microseconds width are generated every hundredth of a second by the pulse generator. The high voltage amplifier then boosts the voltage of the pulses to several thousand volts amplitude without serious distortion. This electrical pulse on the plates of the Kerr cell causes the plane-polarized light passing through the sample to be circularly polarized; hence, it passes through the analyzing Nicol which is crossed with respect to the polarizing Nicol and oriented 45° with respect to the field in the Kerr cell. The light pulse subsequently produced by the electrical field actuates the photo-tube, wherein it is converted into an electrical signal that can be amplified and studied with the oscillograph.

Ordinary low molecular weight compounds are capable of orienting in an electrical field within $10^{-9}$ second;[4] hence, the wave shape of the optical pulse is very nearly the same as that of the electrical pulse, provided certain restrictions of wave form and amplitude are made. On the other hand, there are materials composed of large molecules in a viscous medium which do not follow the electrical field at such a rapid rate. The optical pulse from such material should be expected to show considerable distortion in relation to the electrical field if one assumes a molecular orientation effect to be responsible for the electro-optic effect.

[1] J. Kerr, Phil. Mag. 50, 337, 446 (1875).
[2] J. W. Beams, Rev. Mod. Phys. 4, 133 (1932).
[3] M. J. Pauthenier, J. de phys. et rad. 2, 183, 384 (1921).
[4] J. W. Beams and Lawrence, J. Frank. Inst. 206, 109 (1928).

The amount of light passing the analyzing Nicol is related to the electrical field intensity, $F$, and the optical path length, $l$, between the Kerr cell plates by the expression[5]

$$I = a^2 \sin^2(\pi K l F^2) = a^2 \sin^2 \delta/2, \tag{1}$$

where $K$ is the Kerr constant and $\delta$ the angular retardation. The general relationship of $K$ with other molecular factors is[6]

$$K = \frac{(n^2-1)(n^2+2)}{4n^2} \frac{(\epsilon+2)^2}{(3)} \frac{\theta_1+\theta_2}{\alpha}, \tag{2}$$

where $n$ is the refractive index, $\epsilon$, the dielectric constant, $\alpha$, the polarizability, and $\theta_1$ and $\theta_2$ are defined as

$$\begin{aligned} \theta_1 = (1/45kT)[&(a_1-a_2)(b_1-b_2) \\ &+(a_2-a_3)(b_2-b_3)+(a_3-a_1)(b_3-b_1)], \\ \theta_2 = (1/45k^2T^2)[&(\mu_1^2-\mu_2^2)(b_1-b_2) \\ &+(\mu_2^2-\mu_3^2)(b_2-b_3)+(\mu_3^2-\mu_1^2)(b_3-b_1)]. \end{aligned}$$

Here, $k$ is Boltzmann's constant; $T$, the absolute temperature; $a_1$, $a_2$, and $a_3$ are proportional to the shape of the induced polarization ellipsoid of the molecule in three mutually perpendicular directions; $b_1$, $b_2$, and $b_3$ are similar coefficients of the optical ellipsoid of the molecule; while $\mu_1$, $\mu_2$, and $\mu_3$ are the components of the permanent dipole moment. The importance of the temperature dependance arising from thermal motion will be discussed later.

From what has been said above, it should appear possible to find a material which would show a definite lag at easily obtainable temperatures in response to the electrical field, and that lag would be markedly dependent on temperature. Such a material would have to be composed of large polar molecules in a viscous medium. These requirements are met by a number of synthetic plasticizers and polymers. The literature records the observation of such lags in rosin,[7] glass,[8] benzopurpurin,[9] and vanadium pentoxide solutions.[10]

## GENERATION OF PULSE

In this section use will be made of Fig. 3, a schematic diagram of the pulse amplifier, to give a brief description of its operation. The pulse generator is a Measurements Corporation model 79-B unit. The output circuit of this generator has been modified somewhat to give control of amplitude and output impedance as well as modified to obtain wide pulses. Normally, the generator is used with full amplitude (approximately 150 v) and 1000-ohm output impedance. Pulses from ½ to 1000 microseconds and repetition rates from 60 to 100,000 p.p.s. are obtainable.

The output coupling condenser has been removed for certain applications to be mentioned later. However, the coupling condenser is in the circuit located on the amplifier chassis to permit control of pulse amplitude through the grid bias. Such a method of amplitude control was used to permit the design of twin amplifiers using a common signal source and plate supply. The amplifier tubes are Eimac 4-125A tubes. Two pairs of load resistors are available, a 10,500-ohm load for narrow pulses and a 75,000-ohm load for wide pulses.

Taps in the load resistors permit a portion of the output signal to be deflected directly to the plates of the cathode-ray tube for observation of

the electrical wave form. This circuit attenuates the output signal but not the a.c. ripple; hence, it greatly enhances this ripple.

Another tap in one of the load resistors permits the use on the Kerr cell of an attenuated pulse, improving the wave form when both channels are operated simultaneously, one with considerably greater amplitude than the other.

The peak pulse voltage is measured by means of a Sensitive Research Instrument Corporation model ESH multi-range electrostatic voltmeter. The pulses are isolated by means of a diode as shown. Care has to be taken in this circuit to place a high resistance to ground to prevent the accumulation of a d.c. charge formation through leakage of the coupling capacitor. The two amplifier channels are carefully shielded for accurate voltage determinations. Switching is accomplished by means of Eimac vacuum switches in the high voltage circuits and antenna relays in the low voltage circuits.

Figure 4 is an oscillogram of the electrical pulse of 10-microseconds width. The wave form has been improved by driving the circuit to saturation in the sense that the pulse voltage approximates the plate supply.

### OPTICAL SYSTEM

The light source mounted on a Cenco optical bench is a Spencer 6-volt lamp operated from a battery to avoid any periodic fluctuations of light intensity. Cenco 10-mm Nicol prisms act as polarizing and analyzing media. The Kerr cells are mounted ridgidly in line. Figure 5 shows the construction of one of these cells and its temperature bath which has operated successfully to keep the temperature constant to within one degree from −80 to +100°C, using a dry ice ether mixture in the side chambers and an immersion heater with De Kotinsky thermo-regulator to maintain the temperature in an alcohol or oil medium. The light enters and leaves through double windows maintained clear at low temperatures by a stream of air. Considerable difficulty was encountered before suitable cell plates were found which could be kept parallel at separations less than a millimeter and still be small and easily cleaned after use with polymeric materials. A solution to this problem was found by coating ordinary glass microscope slides with a layer of gold deposited from duPont Liquid Bright Gold and fired at 1100°F for a short time. Both sides of the slides are coated, as are three of the edges, and electrical contact is made by spring contacts to the outside surface of the slides. The slides are separated by mica spacers averaging 0.016 in. Thicker glass spacers have been used for materials of high Kerr constant.

A Gaertner model L-135 Babinet-Soleil compensator is placed between the Nicols to permit measurement of the retardation, zero out small retardations in the glass windows, and increase the sensitivity of the system as the occasion may require. The compensator requires 4.42 turns per wave of light of 465-mu wave-length.

The analyzing Nicol is crossed with respect to the polarizing Nicol and at an angle of 45° with respect to the plane of the electrical field. A Baird interference filter passing light in the neighborhood of 456 mu was placed directly over the iris diaphragm acting as a window to the photo-tube chamber.

The type 931-A multiplier photo-tube was chosen because of its sensitivity and frequency response.[11] The voltage-divider system for the

multiplier dynodes is mounted in a shielded box directly below the photo-tube. The load resistor of the photo-tube is variable to permit control of the output amplitude and fidelity of the high frequency response. This resistor likewise is mounted close to the photo-tube and connected to the video amplifier by a short shielded lead.

The video amplifier is a United Cinephone model 8240 with a gain of 1000 and a frequency essentially flat from 15 cycles to 4 megacycles. The output of this video amplifier feeds directly to the plates of the cathode-ray tube in a DuMont 208B oscilloscope.

## INSTRUMENTAL RESPONSE

An elaborate discussion of the optics of this type of system will not be given here since it may be found in the literature.[12] However, attention should be given to formula (1), applicable to the above conditions where it may be seen that the light intensity, hence deflection of the oscilloscope tracing, will be primarily a function of the field strength. With a material of sufficiently large Kerr constants it is possible to observe a sinusoidal fluctuation of light intensity on the leading and trailing edges of the pulse. Figure 6 shows an oscillogram of several superimposed optical pulses with nitrobenzene at low voltage. A comparison of this figure with that of the electrical pulse will furnish a measure of the performance of the instrument. Figure 7 is an oscillogram of the response of nitrobenzene to a large voltage pulse. For this photograph the electrical circuit was set to produce sloping edges and high amplitude. With reference to Eq. (1) it is seen that seven waves of retardation are produced. In order to obtain such a pattern, it is necessary to use monochromatic light and an amplifier of high fidelity in addition to accurately parallel cell plates properly aligned.

[12] E. F. Kingsbury, see reference 5.

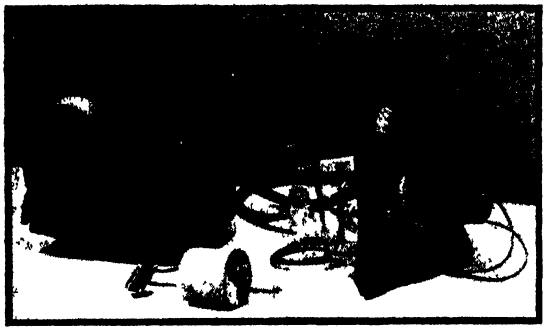

FIG. 5. Kerr cell and temperature bath.

## METHODS OF MEASUREMENT

The simplest method of measuring the Kerr constant would be to measure the amplitude of the signal and compare this amplitude with a material of known Kerr constant. This method, however, is inaccurate though useful for the estimation on materials of very low Kerr constant.

A method of greater accuracy uses the Babinet-Soleil compensator to produce a retardation equal and opposite to that produced in the Kerr cell. The procedure is as follows.

The amplitude of the pulsed retardations produced by the Kerr cell is set to an arbitrary value by varying the gain of the video amplifier. The compensator is introduced and set to a value that will just *invert* the signal an equal and opposite amount. The difference in compensator readings from its null point (previously determined) to the point giving the above retardation is divided by the number of turns per wave to give the waves of angular retardation equal to that produced by the pulse. As noted in Eq. (1), the angular retardation is proportional to the square of the field strength, the constant of proportionality being in turn proportional to the Kerr constant. Hence, a plot of the retardation *versus* the field strength squared will result in a straight line through the origin when everything is properly aligned. If such a graph be obtained for two materials, one of which is $CS_2$ of known Kerr constant and the other the material in question, the desired Kerr constant will be

$$K_x = K_{CS_2}(\delta_x/F^2/\delta_{CS_2}/F^2).$$

This procedure, of course, presumes the use of the same Kerr cell for both materials.

It should be emphasized that in the determination of the retardation by this method the compensator retardation was varied until the signal on the oscilloscope screen inverted an equal and opposite amount. It must be remembered that the photo-tube amplifier circuit does not interpret d.c. signals; hence, the light at the inverted point is striking the photo-tube at all times except during the pulse. This very fact handicaps this method of measurement for the photo-tube fatigues under conditions of constant light as well as increases the noise level. Both of these effects are clearly visible and introduce appreciable errors.

If a second Kerr cell is used in addition to the compensator, the matter of photo-tube fatigue may be minimized. The plates of the Kerr cells must be so oriented as to give retardations of opposite sign (90° rotation if the Kerr constants are of like sign, 180°, if of unlike sign). Using synchronized pulses on the two Kerr cell plates, the voltages on the cells may be adjusted to nullify each other. Figure 8 is an oscillogram of such a null point with $CS_2$ and $CHCl_3$. Only the leading and trailing edges are apparent above the noise level of the photo-tube. The Kerr constant for an unknown relative to $CS_2$ will then be

$$K_{CS_2}{}' = C \cdot K_{CHCl_3}{}'\left(\frac{V_{CHCl_3}}{V_{CS_2}}\right)^2,$$

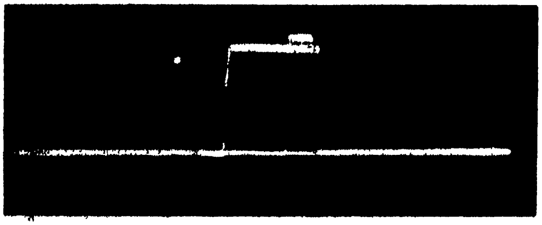

FIG. 6. Oscillogram of optical pulse with nitrobenzene with weak yield at three pulse widths 10, 40, and 150 μsec. 60 p.p.s. 1900 volts, glass separator.

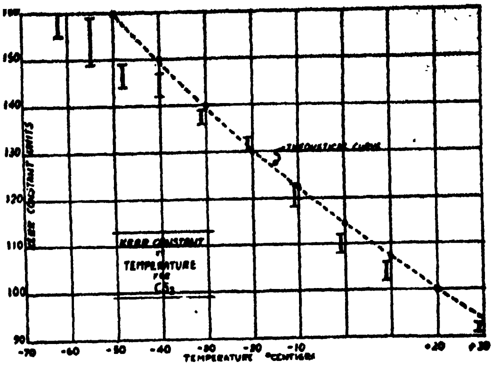

FIG. 9. Kerr constant *vs.* temperature for carbon disulfide.

where $C$ is a constant accounting for differences in cell spacing and length. Figure 9 shows a graph of the Kerr constant *versus* temperature for $CS_2$ determined in this manner, with $CHCl_3$ being used as a standard for null purposes. Changes in temperature ($t'$) of the $CHCl_3$ must be accounted for accurately. The agreement with the literature is good.[13] A small amount of constant retardation was introduced by the compensator. This increases the sensitivity of the system without changing the null voltage ratio. Differentiation of Eq. (1) will show the reason for this.[14] No filter was used in determining the curve in Fig. 9, but the data will apply to the average wave-length of approximately 500 mu.

## APPLICATIONS

An application which was mentioned previously as of importance is the study of relaxation in polymers. The molecular orientation hypothesis for the explanation of the Kerr effect as well as usual dielectric absorption effects has been fairly well established;[15] hence, we may picture the Kerr effect as arising from the orientation of molecules or portions of molecules upon the application of an external electrical field. If the molecule is large, and in a viscous medium, the time of orientation may be large. The apparatus described here should be well suited for the observation of this relaxation phenomenon being, in a sense, more direct than the conventional dielectric methods.

Figure 10 is an oscillogram of this effect in Santolite MS, a highly viscous plasticizer, taken at 56°C. At this temperature the molecules or dipoles completely orient in approximately 40 microseconds. However, the relaxation seems to proceed more rapidly than the orientation—an observation which was not expected. At a slightly higher temperature (65°C) the molecules are capable of orienting in 5–10 microseconds as can be seen in Fig. 11. Upon further increase in temperature the orientation becomes more rapid, but the amplitude of the effect (Kerr constant) decreases as one should expect from Eq. (2). If the temperature is lowered and the pulse width increased, it is possible to observe both the orientation and distortion polarizations simultaneously. Figure 12 shows this effect at room temperature with an 800-microsecond pulse. The increased noise level is a result of high amplifier gain. The optical pulse rises very rapidly to a value considerably less than in Fig. 11, then slowly increases until the end of the pulse when it immediately returns to an intermediate level and tapers off slowly to zero. The distortion polarization, of course, accounts for the sharp rise and decline, while the slow change may be attributed to the orientation effect. By such methods it should be possible to isolate and measure the theta-terms of Eq. (2). The dis-

persion region, measured by conventional dielectric methods, lies in the same range of temperature for the conventional dielectric method as for the electro-optic, giving strong indication to the fact that the same unit (molecule or dipole) is orienting in both cases.

This relaxation effect in polymers can be observed dielectrically with pulsed fields by placing a test condenser of the dielectric directly across the load resistor of the pulse generator cathode-follower circuit and observing the relaxation with a cathode-ray tube. The effect is not as pronounced, because of other instrumental effects, but has been observed to be temperature and time dependent in the same manner as in the Kerr effect.

Further studies are in progress correlating this Kerr effect with conventional dielectric properties and viscosity for a series of primary alcohols.

# On the Localized Afterglows Observed with Long Sparks in Various Gases

J. D. CRAGGS AND W. HOPWOOD
*Research Department, Metropolitan-Vickers Electrical Company, Ltd., Manchester, England*

AND

J. M. MEEK
*Department of Electrical Engineering, Liverpool University, Liverpool, England*

(Received June 2, 1947)

Simultaneous photographs, taken in two perpendicular directions, have been obtained of long sparks in various gases at 1-atmosphere pressure. The experiments were undertaken in order to decide whether the localized afterglows, noticed as long streaks in rotating mirror spark photographs, were caused by some discharge mechanism or by purely geometrical effects resulting from the tortuous nature of the spark channels. The results show that the second explanation is not feasible. Some qualitative interpretations of the effects are given.

## I. INTRODUCTION

THE study of spark discharges in gases has usually been confined to the examination of such discharges in air and to the earlier parts of the process, e.g., the formation of streamers.[1] Recently the later phases of spark formation (spark channels) have been re-examined and some of their properties have been described by Raiskiy (1940),[2] Flowers (1943),[3] and by Craggs and Meek (1946),[4] following the earlier work of several authors such as Lawrence and Dunnington (1930),[5] Ollendorff (1933),[6] and others. Such spark channels may be considered, in brief, to consist of a highly conducting path (i.e., of low voltage gradient) in which the electron temperature may be 10,000–20,000°, and approximating in some aspects to a nascent arc of artificially restricted diameter. Rotating mirror camera records of lightning, taken mainly by Schonland and his collaborators to whom much of the best work is due, and of laboratory sparks (Allibone and Meek (1938), (a) and (b),[7,8] and others) have shown, however, that the last stages of a spark discharge, perhaps even when the current flow has sensibly ceased (Craggs and Meek)[4] are represented by localized afterglows. The significance of the latter has often been overlooked or minimized, and the purpose of the present paper is to present an account of further preliminary experiments made on this effect.

## II. DISCUSSION OF PREVIOUS EXPERIMENTS

Many previous papers, e.g., those of Allibone and Meek[7,8] tend to ignore the afterglow streaks, shown clearly in a typical record such as Fig. 1 (b)(ii) of Allibone and Meek's second paper[8] and concentrate on other aspects of the discharge. Walter (1935),[9] in a discussion on Hoffert's early photograph (1889)[10] of a multiple lightning stroke, noticed the streaks and stated that "they are by no means due to an afterglow of the lightning channel produced by thermal or phosphorescent causes, but they are always associated with a real after-discharge in the channel, i.e., with an electric current following the main discharge along the same track." Walter considered that this conclusion is justified by the fact that the streaks often increase in brightness at an appreciable time after the light from the main channel has greatly decayed. An excellent example of this effect has been published by Allibone and Meek[8] (Fig. 1 (a)(iii)); in such cases there is almost certainly an appreciable oscillatory flow of current, but such currents should be constant at all points along the dis-

charge, a supposition which was apparently overlooked by Walter and which unless other effects are present would demand uniform afterglows along the channel at any particular instant. It is therefore very unlikely that "follow currents" can account for the localized streaks of afterglow, although accentuation of the latter by the former probably occurs.

McEachron and McMorris[11] appear to accept Walter's view in a modified form and suggest that very small (<100 amp.) follow currents may be responsible, but again ignore the peculiar localized nature of the afterglows. It is appropriate to state here that the measurement of small follow currents is difficult, and their existence in many laboratory experiments cannot be denied. Such measurements are now projected in this laboratory, although the arguments to be advanced below tend, it is suggested, to minimize their fundamental importance. The lightning photographs of Malan and Collens,[12] especially their Figs. 13–17 include some excellent records, and those authors agree with the conclusion of McEachron and McMorris.

Flowers[13] subscribes to an alternative theory of the afterglow streaks and states that "portions of the path (of the discharge) which are projected parallel to the direction of motion of the film or the lens provide a greatly increased exposure time and proportionate reduction in resolution. Path components which lie along the photographic axis increase the light intensity. Both effects produce excessive exposures and are associated with the streaks that are observed in nearly all Boys camera photographs." It is clear that, whilst Flowers does not apparently in this communication attribute the streaks directly or wholly to the effects described, which he states "are associated" with them, the effects of bends could contribute to or produce highly localized streaks. This explanation had occurred independently to us some years ago, but was immediately rejected, since the length of the afterglows seem to be of quite a different order of length from the average effective length of a bend in the channel.[14] It appeared necessary to disprove this theory, if possible, before embarking on further experiments since, if true, the bend

theory would entirely remove the physical importance of the effect. It is important to note that Flowers' suggestion refers to bends in the main channel and not in the much dimmer and more transitory leader strokes. (It does in fact appear from many records (e.g., those of Fig. 1) that the streaks arise in the leader strokes or streamers and persist through the later stages of the spark channel's formation and extinction.)

In the discussion following a paper by Allibone (1938),[15] O'Dea made the suggestion that the streaks may be due to the persistence of "ionized or ozonized pockets." Allibone, in reply, referred to the theoretical work of Neugebauer[16] on ball lightning. The present authors favor O'Dea's proposition, with the important correction that the presence of free electrons and ions, demanded by Neugebauer's theory, may not be necessary since the afterglows may be explained on other grounds. (Craggs and Meek,[4] with references to earlier work from 1943 by the same authors.)

As mentioned above, it appeared necessary first to investigate the possibility of a geometrical explanation of the afterglow streaks, i.e., the effect of sustained illumination of the photographic film caused by the increased exposures at channel bends, either in or perpendicular to the plane of the film. This paper describes such experiments.

## III. THE EXPERIMENTAL METHOD

The most obvious method for assessing the importance of the geometrical bend theory, outlined above, is to photograph the sparks with a rotating film or mirror camera in two different, preferably perpendicular, directions at once. If the results should, for example, show that the luminous afterglow streaks are noticed at points where no channel bending is perceptible, then it would appear reasonable to discount the bend theory and to suppose that some effect in the ionized or excited gas in the spark channel is operative. Further investigations to elucidate the nature of the effect would then be warranted.

Strigel[17] is apparently the only author to have photographed sparks previously in this way, but his object was not to investigate the afterglow streaks, which are indeed not mentioned in his paper, and it is not possible to use Strigel's reproductions of spark photographs in deciding the point at issue in the present paper.

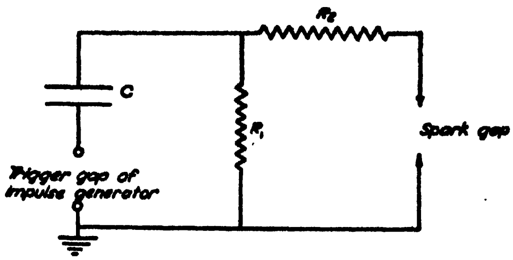

FIG. 3. Impulse generator; $C=6$ series stages of 0.22 uf per stage. Total discharge capacity$=0.037$ uf; $R_2=210$ ohms; $R_1=35{,}000$ ohms; charging voltage$=70$ kv.

The optical system is shown in Fig. 2, in which the rotating drum (3000 r.p.m.) carries the photographic film. The drum diameter was approximately 12″. The records (see Fig. 5) were therefore composed of pairs of photographs arranged one above the other on the film, each pair corresponding to one spark.

The spark was produced with a 2-million volt impulse generator (0.11 mfd/stage) rearranged to give effectively the circuit of Fig. 3, in which a peak current of 2000 amp. was used. The point/point gap of 20 cm needed some 280 kv for breakdown in air. Other experiments were made at 1000 and 500 amp., with suitable alterations to the circuit of Fig. 3. A current oscillogram for 2000-amp. peak current is given in Fig. 4.

For gases other than air, a glass vacuum chamber (30-cm diameter, 60 cm long) was used, pumped down before gas admission to a pressure of about 1 mm Hg. The gases from cylinders were then introduced to a pressure of 80 cm Hg, in order to prevent contamination by air leakage. It was found to be necessary to attach a black cloth inside the glass cylinder to prevent reflections. The thickness of the glass chamber was about 1 cm so that ultraviolet radiations from the sparks were prevented from reaching the film.

About 30 films, each with 10–20 pairs of records, were taken.

## IV. RESULTS OF THE EXPERIMENTS

Figure 5 shows some results (full-size reproductions of original negatives), obtained with 2000-amp. discharges in oxygen (3 sparks), hydro-

gen (2 sparks), and nitrogen (2 sparks) which are typical of the many other photographs taken (1 cm on the time axis ≡ 240 microseconds). The value of the method for assessing the importance of channel bends is at once apparent. Oxygen and nitrogen show pronounced afterglow streaks which are highly localized, particularly in nitrogen. The formation of branched channels was found with oxygen and nitrogen but not with hydrogen, and the latter gas showed very short afterglows, in agreement with previous experiments. The spark channels in hydrogen have a pronounced tendency to form bends which are particularly sudden and well defined. The very short afterglows in hydrogen are fairly localized, as shown by the tufted appearance of the channels on their afterglow side.

It is clear, especially from the oxygen records of Fig. 5 (a) that the streaks are formed in both records at the same points in the channel, not necessarily where bends or inflections are noticed, and are generally of the same length. These findings are in general disagreement with the geometrical theory. Where channel division occurs (Fig. 5 (a)) the different views of the spark may be different largely because of the geometrical (not time) separation of the channel branches with subsequent overlapping and confusion of the afterglows. The exceptionally tortuous bends in hydrogens do not give enhanced streaks, as would be expected from the geometrical theory which does not invoke any difference in channel structure from gas to gas.

When the argon results, typical specimens of which are given in Fig. 6, are examined it seems even clearer that the afterglow streaks are associated with localized discharge conditions in the channel. Figure 6 (b) particularly demonstrates the evidence; argon spark channels show only a tendency to form bends which are, even then, very gradual and yet the streaks are particularly long and well defined, and situated clearly at the same points and for the same times, in both records for each spark. Figure 6 (a) shows an exceptionally straight spark. Figure 6 (b) demonstrates another effect noticed in argon, i.e., the formation, at approximately the same point in the channel even for different sparks, of a single well-defined streak. This phenomenon is probably, it is thought, connected with the earlier parts of the discharge process and if substantiated this conclusion would constitute irrefutable evidence against the supposed importance of channel bends. It is, however, considered that the data given in Figs. 5 and 6 and described above constitute sufficient proof of the genuine physical basis of the afterglow streaks which, while not being explained finally in this paper (see below), assume a greater physical interest than they would have possessed if explained in the manner suggested by Flowers and others.

The use of pairs of photographs, such as those of Figs. 5–7, enable the true length, in three dimensions, of the spark channels to be found. This may be useful in experiments on the voltage drop in spark discharges, where the true channel length if it differs appreciably from the two dimensional value, should be known. This effect would probably be noticeable only with hydrogen channels; further experiments on these lines are in progress.

Before describing further analyses of records similar to those of Figs. 5 and 6, it is necessary to mention the very frequent and often complex division of channels noticed in argon and demonstrated in Figs. 6 (c), (d), and (e). The other gases so far examined show relatively infrequent branching which generally extends (Figs. 5 (a) and (d)) only for a fraction of the gap length. Argon, on the other hand, often shows (Figs. 6 (c) and (d)) complete branching of the gap by divided channels and also multiple division, a complex case of which is shown in Fig. 6 (e). The value of bi-directional photography in the elucidation of such phenomena is obvious. Yet another interesting effect is seen in Fig. 6 (c) (and many other records) where the afterglow streaks are seen to change their positions in space, as time advances. It seems probable in Fig. 6 (c) that the right-hand channel of the upper photo-

TABLE I.

| Gas | Total No. of sparks examined | No. of sparks with two channels | No. of sparks with three or more channels |
|---|---|---|---|
| Hydrogen | 27 | 0 | 0 |
| Oxygen | 43 | 27 | 5 |
| Nitrogen | 39 | 22 | 1 |
| Argon | 85 | 35 | 6 |
| Air | 71 | 10 | 0 |
| Methane | 20 | 1 | 0 |

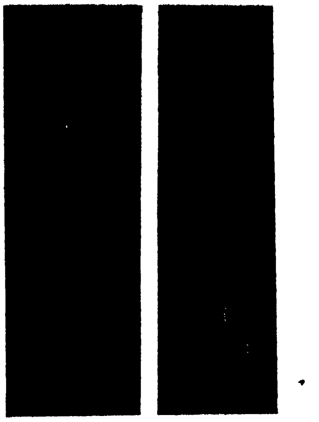

FIG. 7. Photographs of spark discharges in methane

graph is the left-hand channel of the lower photograph, since this branch shows, in both photographs, relatively little afterglow. These effects are being investigated further.

Table I gives some statistical data on channel division, which are discussed below.

The methane photographs (Fig. 7) were taken in the hope that the known high absorption of photo-ionizing radiations in such a complex molecular gas[18] would lead to the demonstration of unusual properties of the spark channel. The peculiar rippling structure of the methane channels are indeed noticeable, particularly on the leading edge of the channels where the afterglows, being absent, do not cause confusion. Such tortuous channels are to be expected, on general grounds, if the photo-ionization process at the streamer tip is inefficient.[1]

Microphotometer tracings of typical records in several gases were taken at right angles to the mean channel direction along afterglow streaks and across parts of the channel where such streaks were absent Figures 8 (a)–(c) show, respectively, tracings for argon, oxygen, and nitrogen. The right-hand tracings for each gas were taken along an afterglow. Figures 9 (a) and (b) show hydrogen records, the former taken in the afterglow. 1 cm on the time axis (right to

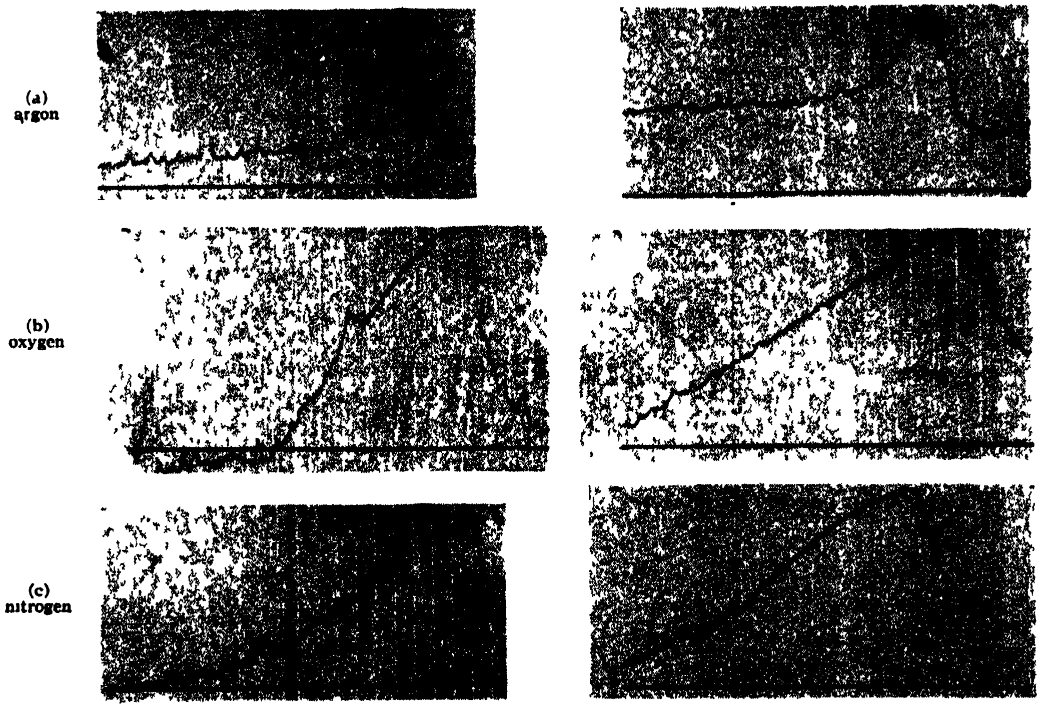

FIG. 8. Microphotometer tracings of spark photographs, such as those of Figs. 5–7. Time scale is from right to left. The left-hand records are for normal parts of the channels, and the right-hand records are for points in the channels which show the localized afterglows.

left) of the figures represents 21 microseconds. It is possible to deduce from these records the light emission/time relation for any part of the channel if the response curve of the film is known. The latter quantity was determined by exposing samples of the film to 2000-amp. sparks, of the type studied in this paper, through an Ilford stepped filter (neutral) which was in turn calibrated with the usual photo-cell arrangement. Exposures were also made to steady light. A typical calibration record, using spark light, is shown in Fig. 10. Figures 11 and 12 show the results of the analysis, i.e., the gamma-curves for the film using spark and steady light, respectively.

Since the light from the spark channels is relatively very intense, with respect to the afterglows, the calibration records, such as Fig. 10, show the film's response to the channel and not the afterglow light. However, since Fig. 11 shows that the difference in the responses to channel and steady light is negligible and the response to the afterglow light must lie between the limits set by Fig. 11, it is reasonable to take the spark-light data of Fig. 11 as referring to the afterglow light.

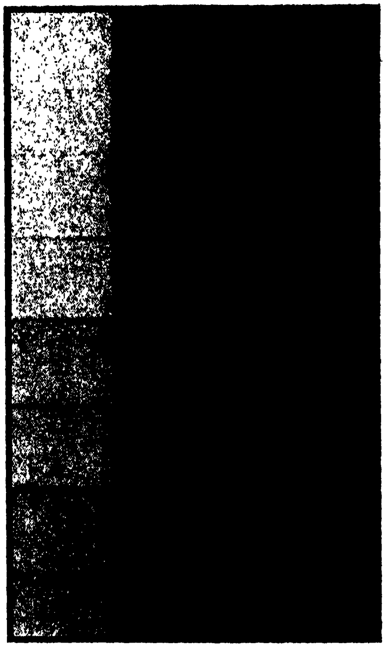

FIG. 10. Step wedge photograph with argon spark light, for film calibration purposes.

Figure 12 shows the final light intensity/time curve for an argon afterglow, with traces taken along an afterglow streak and across the channel at a point where no appreciable streak was observed.

## V. DISCUSSION OF THE RESULTS

It seems clear from the data given in Section IV that the suggestion of the bends being responsible, in a geometrical sense, for the afterglow streaks is untenable. The influence of the magnetic field of the discharge channel on the afterglow should be considered. This effect was suggested originally by Anderson and Smith[19] to account for similar localized afterglows, described as being due to vapor jets, with exploded wires, and it was pointed out that the magnetic field tended to prevent charged particles from leaving the conducting channel especially at the points of strongest fields. The field is weakest, however, at the outside of a sharp bend where afterglow

---

[19] J. A. Anderson and S. Smith, Astrophys. J. 64, 295 (1926).

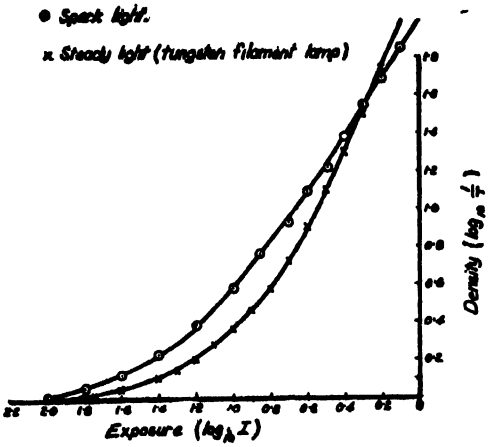

FIG. 11. Calibration of the photographic films with the step wedge.

streaks are often, but not always, encountered; and it is clear that no definite conclusion as to the relevance of this effect which could, at least, explain the localization of the afterglow can be made in the absence of further data.

The following mechanisms could account for general, i.e., non-localized afterglows. The influence of the low current still passing through the discharge channel after say 100 microseconds is not so easily dismissed. Figure 4, which is a reproduction of a current oscillogram for argon (no apparent systematic difference in residual currents for the different gases was noticed, but the accuracy of estimation of these low currents by the present method is not great) shows that the current at 100 microseconds from the beginning of current flow is about 20 amp. The records showed currents varying from this order of magnitude to almost zero. However, the passage of a small residual current cannot by itself account for the localized nature of the afterglows, since the current must also flow through the relatively dark regions of the discharge. It has been shown[4] that the afterglows persist even when square-wave pulses of current are used, and it therefore seems reasonable to postulate the existence of afterglows more or less independent of even a small current flow in the gap.

Afterglows in low pressure discharges are well known, by the pioneer work of Rayleigh, and later, many others on active nitrogen. Kenty[20] has observed an afterglow in argon, following a low pressure arc discharge, and has attributed this to electron/ion recombination. Afterglows in luminous clouds, following arc discharges at atmospheric pressure, have been noticed by O'Doherty[21] and others.

The afterglows in hydrogen have been discussed elsewhere, and it is sufficient here to state that they are probably due to electron/ion recombination. The afterglows in argon (and certain other gases, e.g., oxygen and nitrogen) could presumably be due either to recombination of various kinds (electron/ion mechanism in argon, where attachment is small) or to the persistence of metastable atoms. It is hoped that further experiments by the authors will clarify the matter.

It seems unlikely that persistence of metastable atoms in argon is the sole cause of the afterglows, since addition of oxygen or hydrogen to argon in reasonable quantities has only a minor effect on them,[4] although both diluents in very small amounts have a great effect on the dielectric recovery of argon spark gaps. If, therefore, electron/ion recombination is the main cause of the visible afterglow streaks it is of interest to consider why the afterglows in hydrogen and argon should be widely different in duration. The recombination coefficients themselves are not likely to be widely different, and the problem would then resolve into a study of the energy losses (by elastic collisions) of the electrons in the afterglow, since the recombination cross sections increase with decreasing electron energy. It is apparent at once from the known data on the Ramsauer effect etc., that for equal electron energy, the elastic collision cross sections are much greater in hydrogen than in argon for low electron energies, so that the electrons would attain thermal energies more quickly in the former gas and would therefore be removed by recombination more quickly. Unfortunately, Ramsauer data are not available for electron temperatures of ∼500–1000° (mean energy ∼0.1 volt or less), which probably obtain in the afterglow conditions.[22] Cravath[23] has worked out the average energy loss ($f$) per encounter, in elastic

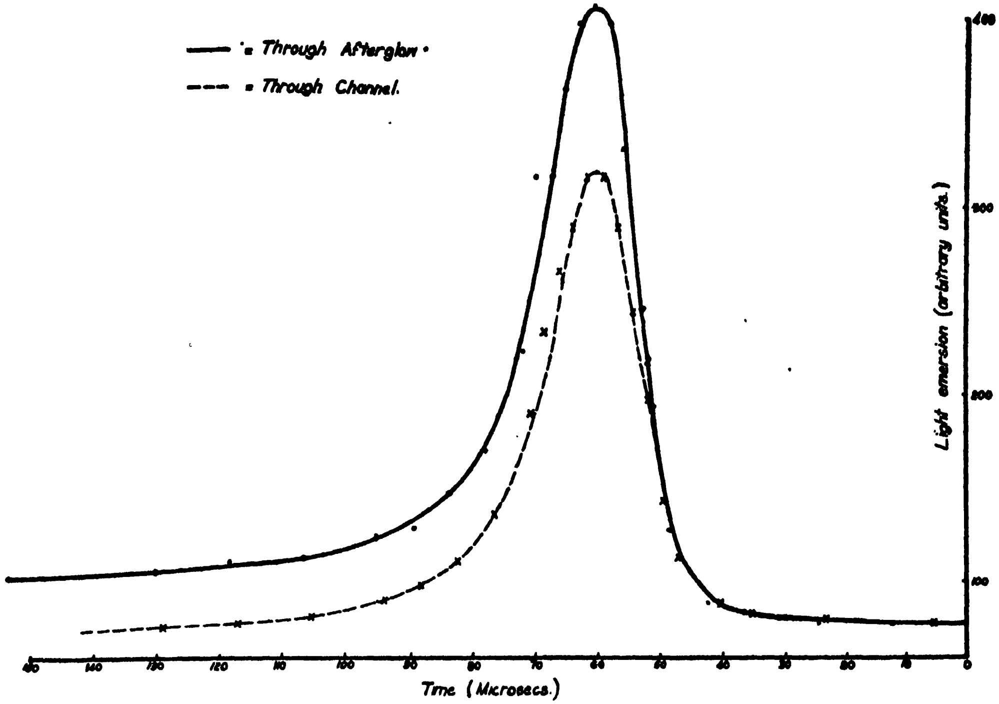

FIG. 12.

collision, expressed as a fraction of the average energy of the electron:

$$f=\frac{8}{3}\frac{mM}{(m+M)^2}\left(1-\frac{T_M}{T_e}\right),$$

where $T_M$ is the equivalent temperature of the molecules present and $T_e$ is the equivalent temperature of the electrons. Generally, $T_M \ll T_e$ so that

$$f \simeq \frac{8}{3}\frac{mM}{(m+M)^2}$$

($m+M$ are the electronic and molecular masses, respectively). It can be shown that $f$ is very great until $T_e \sim T_M$. Using elastic cross sections ($P_e$) given by Normand[24] and Brode,[25] the data of Table II are easily calculable. In some cases (at the lowest temperatures) extrapolation of the elastic cross-section/electron energy curves has been necessary; this is clearly a most unsatisfactory procedure, but it is the only possible one in the circumstances and leads only to approximate results. $T_M$ has been taken at 300°K. If a higher value for $T_M$ is permissible, then $f$ will be lower than the respective values in Table II, particularly at $T_e \sim 500$°K. The procedure for determining the total $f$ is (i) calculate the mean electronic energy and velocity ($v$) from $T_e$, which is assumed to correspond to a Maxwellian distribution; (ii) determine the mean free path $\lambda$ for elastic collisions, i.e., $1/P_e$, for the known electronic energy; (iii) from $\lambda$ and $v$ the total number of collisions in a given time, for each one of which a fractional energy loss $f$ is suffered, can be found, and so (iv) the total $f$ for that time can be computed.

TABLE II.

| Gas | Electron temp. °K | Total $f$ for time of $10^{-8}$ sec. |
|---|---|---|
| Hydrogen | 10,000 | 32 |
| Hydrogen | 1,000 | 39 |
| Hydrogen | 500 | 20 |
| Argon | 10,000 | 0.093 |
| | 5,000 | 0.066 |
| | 1,000 | 0.062 |

It must be emphasized again that the results are only approximate, but they show that the energy loss for electrons in hydrogen in our par-

---

[25] R. B. Brode, Rev. Mod. Phys. 5, 257 (1933).

ticular conditions is far higher than for argon, and so a recombination spectrum would persist for a longer time (other things being equal) in argon than in hydrogen. The important influence of $T_M$ at values of $T_e \sim T_M$, and our ignorance of its magnitude, render further speculation unprofitable. Experiments now being made will, it is hoped, provide more accurate data on the values of $T_M$ and $T_e$ obtaining in the decaying channels of spark discharges.

## VI. CONCLUSIONS

1. Photographs have been taken with a rotating film camera, and simultaneously in two perpendicular directions of spark discharges.

2. The photographs show, we believe conclusively, that the localized afterglow streaks seen in records of this kind are not due to bends, in the spark channels, causing artificially long exposures by virtue of the enhanced depth of glowing gas, etc.

3. The causes of the afterglows are not known with certainty in all cases.

4. We believe that further experiments, now in hand, will give further information on localized afterglows in spark channels and probably, therefore, on ball or bead lightning[26] which we consider to be probably due to the same causes.

## VII. ACKNOWLEDGMENTS

The authors are grateful to Mr. F. R. Perry for the interest he has shown in, and the support he has given to, the work. They also wish to thank Mr. G. C. Williams and Mr. W. Dale for assistance with the camera and high speed oscillograph, respectively. Finally thanks are expressed to Sir Arthur P. M. Fleming, C.B.E., D.Eng., Director of Research and Education, and to Mr. B. G. Churcher, M.Sc., M.I.E.E., Manager of Research Department, Metropolitan-Vickers Electrical Company, Ltd., for permission to publish this paper.

## Quantitative Analysis of Mixed Powders with the Geiger-Counter X-Ray Spectrometer

ZIGMOND W. WILCHINSKY
*Esso Laboratories, Standard Oil Company of New Jersey, Baton Rouge, Louisiana*

July 23, 1947

A USEFUL characteristic of a Geiger-counter spectrometer is its ability to measure diffracted x-ray intensities for several samples in succession, on the same intensity scale. This property greatly facilitates the quantitative determination of crystalline components in a sample of mixed powders. In particular, it becomes quite easy to determine the amount of a crystalline component in the presence of other components which may be crystalline or amorphous, identified or unidentified. A simple expression relating the weight fraction of a crystalline component to experimental quantities is developed below.

For a flat sample used in a North American Philips x-ray spectrometer,[1] the relationship between the sample and the incident and diffracted x-ray beams is indicated in Fig. 1. Let us assume that simple x-ray diffraction theory is applicable. Then, for a chosen diffraction line of the *i*th crystalline component, the contribution to the integrated intensity from the elemental layer $dx$ is

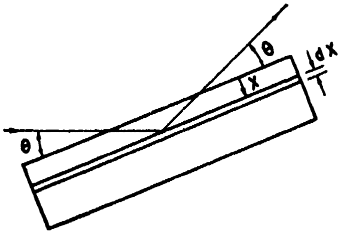

FIG. 1. Diffraction of x-rays from a flat sample in a Geiger-counter x-ray spectrometer.

$$dP_i=\frac{AJ_i}{\sin\theta}W_i\rho\exp(-2\mu_l x/\sin\theta)dx, \tag{1}$$

where $A$ = effective cross-section area of the beam at the sample, $J_i$ = contribution to the integrated intensity per unit weight of sample on the basis of no absorption, $W_i$ = weight fraction of the *i*th component in the sample, $\rho$ = mean density of the sample, $\mu_l$ = linear absorption coefficient for the sample. For a sample of sufficient thickness to be considered opaque, $P_i$ is obtained by integrating the right-hand side of (1) from $x=0$ to $x=\infty$, the result being

$$P_i=\tfrac{1}{2}AJ_iW_i\rho/\mu_l=\tfrac{1}{2}AJ_iW_i/\mu, \tag{2}$$

(2) where $\mu=\mu_l/\rho$ is the mass absorption coefficient for the sample. The factor $AJ_i$ can be evaluated by considering a sample consisting only of the *i*th component; the integrated intensity, $P_{0i}$, for this case, by Eq. (2) is

$$P_{0i}=\tfrac{1}{2}AJ_i/\mu_i, \tag{3}$$

where $\mu_i$ is the mass absorption coefficient for the *i*th component. Eliminating $AJ_i$ from (2), one obtains the useful and very simple expression:

$$W_i=\frac{P_i}{P_{0i}}\frac{\mu}{\mu_i}. \tag{4}$$

The value of $\mu_i$ can be readily computed from the chemical formula of the *i*th component and a table of mass absorption coefficients for the elements. Similarly, the value of $\mu$ can be computed from an elemental analysis for the sample.

## The Conversion Factor for *kX* Units to Angström Units

ELIZABETH ARMSTRONG WOOD
*Bell Telephone Laboratories, Murray Hill, New Jersey*

July 21, 1947

X-RAY wave-lengths have been expressed in *X* units. The *X* unit is defined in terms of the calcite spacing and is nearly $10^{-11}$ cm, but is now known to differ from $10^{-11}$ cm by about 0.2 percent. During the last twenty-five years x-ray diffraction workers have expressed x-ray wave-lengths and crystal dimensions in terms of a unit which was 1000 *X* units, but instead of calling it 1000 *X* units have erroneously called it an Angström unit. In recent years, the x-ray diffraction groups have agreed to use the term kilo *X* unit (abbreviated *kX*) in place of the incorrectly used Angström unit, until agreement was reached on the best conversion factor to use for converting from *kX* to Angström units. Agreement on the factor has now been reached.

As Secretary of the American Society for X-Ray and Electron Diffraction, I have been instructed to call the attention of American x-ray workers to the following announcement which appeared in the January 1947, issue of the Journal of Scientific Instruments. Because of its importance it is here reproduced in its entirety.

At the annual conference of the X-ray Analysis Group of the Institute of Physics in July 1946 it was announced that agreement had been reached concerning the factor for converting measurements in *kX* units to Angström units. The factor agreed upon, after consultation with the American Society for X-ray and Electron Diffraction and Prof. Siegbahn was 1.00202. This factor is probably correct to 0.003 percent. Since wave-lengths in X-units have been measured to an accuracy of 0.001 percent, the wave-lengths in Angström units can be taken as accurate to 0.004 percent in general.

The following is a list of values of wave-lengths in Angström units of certain emission lines and absorption edges in common use. The column headed $K\alpha$ gives the mean value of $K\alpha_1$ and $K\alpha_2$, $K\alpha_1$ being allowed twice the weight of $K\alpha_2$.

Current values of the physical constants, such as those quoted by Birge in the 1941 volume of the Physical Society's *Reports on Progress in Physics*, should be used in conjunction with these wave-lengths. In particular density $\rho$ is given by the equation

$$\rho = 1.66020 \Sigma A / V$$

where $\Sigma A$ is the sum of the atomic weights of the atoms in the unit cell, and $V$ is the volume of the unit cell in $A^3$.

# New Books

## Astronomy

By JOHN C. DUNCAN. Fourth Edition. Pp. 500. Harper and Brothers, New York, 1946.

Professor Duncan's book now in its fourth edition offers an excellent text for the beginning college student of astronomy. This book may be read with profit by anyone who wishes to obtain a knowledge of modern astronomy.

The introductory chapter includes an exceptionally fine set of star charts showing the naked eye stars, though a more detailed description of how to use them would have helped the student. Following the chapter on the celestial sphere and coordinate systems is one on telescopes. Though the Schmidt telescope is described, the reader is not given the simple explanation of the function of the correcting plate. A new and very excellent chapter on Celestial Navigation has been added following the chapter on the Earth and Sky. Chapters on the Orbital Motion of the Earth, the Moon, and Eclipses are followed by a chapter on Spectroscopy which is introduced early in order to make use of the principals involved in the chapter on the Sun which follows. The Paths of the Planets and the Law of Gravitation are next taken in order; the latter seems rather detailed in parts for a book designed for beginning students. Chapters on the Planets, Meteors, and Comets precede a discussion of the evolution of the solar system, a chapter which dwells unduly long on the older theories at the expense of the more modern theories of Spitzer, Littleton, and Russell. However, since even modern theories on this subject are still far from giving us a complete answer to this riddle, perhaps Dr. Duncan is justified in these omissions.

The stars and their motions are next discussed and then follows a completely up-to-the-minute (1945) chapter on Physics of the Stars. Here the student may find "the going a little tough," and will undoubtedly want to review the earlier chapter on Spectroscopy before wrestling with even elementary astrophysics. After a chapter on Variable Stars is one on Star Clusters and Nebulae in which the careful student may be somewhat confused to find that the Magellanic Clouds are discussed as star clouds in our own galaxy rather than as external galaxies which are satelites of our system. The concluding chapters on the Galactic System and Beyond the Milky Way are excellently treated. One might desire a more detailed discussion of the age of the universe which indicates that we are relatively young ($10^9$ or $10^{10}$ years old) and not a decrepit $10^{12}$ years as Professor Duncan states.

The appendix to the book includes many useful tables which in the earlier editions had been scattered through the book. A table for obtaining the Julian Day for any date from 1940–1990 is an especially welcome addition.

Teachers will wish that the paragraphs were numbered for ease in making assignments, but this is more than compensated for by a large selection of excellent problems involving simple mathematical manipulation.

The book is excellently written, is thoroughly up to date, and includes a nice balance of historical background. It is by far the most attractive general book on astronomy ever written, and the illustrations, many of which were made by Dr. Duncan, are magnificent. The book will undoubtedly be even more popular than the widely used earlier editions, and rightly so.

# New Booklets

The following recent publications of the National Bureau of Standards are of interest to physicists: RP 1790, *Infrared Emission Spectra of Krypton and Argon*, Curtis J. Humphreys and Earle K. Plyler, 10 cents; RP 1793, *Changes Caused in the Refractivity and Density of Glass by Annealing*, Arthur Q. Tool, Leroy W. Tilton, and James B. Saunders, 10 cents.

Beginning with the October issue, the quarterly journal *Mathematical Tables and Other Aids to Computation* will publish a new feature section, "Automatic Computing Machinery," designed to disseminate information and news on research and development in the field of high speed automatic calculating machinery. Contributions to this section are invited and should be addressed to Dr. E. W. Cannon, Head of the Mathematics Group, Machine Development Laboratory, National Bureau of Standards, Washington, D. C. Calendar year subscription to the journal is $4; single numbers cost $1.25. Payments should be made to the National Academy of Sciences.

*Tracerlog* for August 1947, published by Tracerlab, Inc., 55 Oliver Street, Boston 10, Massachusetts, describes the film badge service offered by Tracerlab for health monitoring purposes where employees are exposed to radiation. 16 pages.

Sound Apparatus Company, 233 Broadway, New York 7, New York, recently brought out two bulletins of interest to physicists: *Impedance Vectorgraph* (4 pages) and *Portable Reverberation Analyzer* (12 pages). Because of the highly specialized nature of the latter brochure, the Company is interested in sending it only to people actually engaged in acoustical measuring work.

North American Philips Company, 100 East 42 Street, New York 17, New York, has announced two publications that are available without charge: an 8-page booklet on quality control, and a 4-page folder (R1050) entitled *Geiger-Mueller Counters Applied to Mining.*

*The Frontier* for June 1947, published by Armour Research Foundation of Illinois Institute of Technology, contains the following featured articles: "The Application of Industrial Research," "Noise and Vibration Reduction," "The Mechanism of Cavitation Erosion," "Crystal Structure of Nicotinamide," and "Contact Angle Measurements in Lithographic Research."

# Here and There

### Personnel

The University of Wisconsin has announced the retirement in June of Florence E. Allen, Assistant Professor of Mathematics, and John R. Roebuck, Professor of Physics.

Two promotions in the Department of Physics at New York University were announced recently. Morton Hamermesh was elevated to an Associate Professorship and Serge A. Korff to a full Professorship.

Donald A. Quarles, Director of Apparatus Development of Bell Telephone Laboratories, was elected a Vice President at a meeting of the board of directors in July.

Kinichi Watanabe, formerly of the University of Hawaii, has been appointed Assistant Professor in the Department of Physics at Wabash College.

### College of Horology and Instrument Technology

A National College of Horology and Instrument Technology is being set up in the Northampton Polytechnic, London, England, to open in October of this year. Full information may be obtained by addressing Mr. R. A. Fell, Northampton Polytechnic, St. John Street, London, E.C. 1.

### Institute of Numerical Analysis Established

Plans have been completed for the establishment of one of the newest units of the National Bureau of Standards—the Institute of Numerical Analysis—at the University of California. One of the giant high speed electronic computing machines now under development by the Bureau of Standards will be installed at the Institute when completed. The Institute has two primary functions. The first is research in applied mathematics aimed at developing methods of analysis which will extend the use of the high speed electronic computers. The second is to act as a service group for western industries, research institutions, and government agencies. The service function will include not only the use of the machines for problem solving but also assistance in the formulation of problems in applied mathematics of the more complex and novel types.

### Induction Heating Corporation

The Induction Heating Corporation, manufacturer of induction and dielectric heating equipment, has moved to new quarters at 181 Wythe Avenue, Brooklyn 11, New York.

### Fellowship on Waterproofed Paper

A comprehensive investigation of waterproofed papers, used for such purposes as packaging, curing of concrete, and moisture barriers in buildings, is being undertaken at the National Bureau of Standards through a fellowship of the Waterproof Paper Manufacturers Association. A long-range research program, extending over at least three years, has been jointly agreed upon. The services of Robert C. Reichel as Research Associate are being provided by the Association, with laboratory facilities and technical assistance furnished by the Bureau.

### Applied Mathematics Symposium

The first annual symposium in applied mathematics of the American Mathematical Society was held at Brown University August 2–4. The subject of the symposium was "Non-Linear Problems in Mechanics of Continua." The American Institute of Physics, the American Society of Mechanical Engineers, and the Institute of the Aeronautical Sciences were co-sponsors.

### Contractor for Brookhaven Atomic Pile

The H. K. Ferguson Company will build the atomic pile and associated facilities at Brookhaven National Laboratory for atomic research on Long Island, New York. Construction has begun and will be completed in 1948.

### Honorary Degrees

The following scientists received honorary degrees recently: John H. Van Vleck, Harvard University, the D.Sc. from the University of Wisconsin; Roger Adams, University of Illinois, the D.Sc. from the University of Pennsylvania; Vannevar Bush, Carnegie Institution of Washington, the D.Sc. from Columbia University.

### New Course at Yale

Yale University has announced the inauguration of a new course to be offered this year on the Development of the Sciences. It is designed to aid in "the closer integration of the sciences and the humanities in the college curriculum and to emphasize the contribution of the sciences to liberal education." The course will cover two terms. Representing the science of physics is Henry Margenau.

### Pittsburgh Spectroscopy Conference

The Eighth Pittsburgh Conference on Applied Spectroscopy, sponsored by the Spectroscopy Society and the University of Pittsburgh, will be held Thursday to Saturday, November 13 to 15, 1947, inclusive, at the Mellon Institute Auditorium. As in the past, sessions on both emission and absorption spectroscopy are planned. Address inquiries to Mary E. Warga, University of Pittsburgh, Pittsburgh 13, Pennsylvania.

### Ionosphere Studies Truck Station

A major problem in the study of long distance radiowave propagation is the role of the ionosphere in returning radio waves of suitable frequency back to the earth's surface. This study may best be accomplished by pulse techniques as used in radar. In fact, the radar techniques developed during the war were based, in great part, on work of this nature previously developed in connection with ionosphere problems.

Up to the present time most ionosphere studies have been confined to the vertical incidence case for reasons of simplified instrumentation and theoretical analysis. The oblique incidence and practical case has been studied by remote station field intensity recording and by theoretical analysis. But little oblique incidence pulse work has been done up to the present time because of the relatively complex instrumentation required. This is the purpose of the equipment set up in the truck station illustrated on the front cover.

The truck contains complete facilities for recording manually or photographically the pulse emissions from a high power ionosphere transmitter located at the Pennsylvania State College. Moderately high power communications equipment is also included for communication with the college station over distances of several hundred miles. A power unit for supplying the equipment is contained in the trailer at the rear of the truck. The pulse equipment receiving antenna is supported by two sectionalized masts.

For operation, the truck is driven to the place where observations are to be made, the two antennas are erected and, by pushing a button, the power unit is turned on. The equipment is then ready for operation. Experience has shown that this may all be done in about five minutes. Hence, if desired, observations may be conducted at many distances or locations with respect to the transmitting position in a single day.

Several studies utilizing this equipment are currently in progress. This work is being done by Professor A. H. Waynick of the Electrical Engineering Department under contract between the Pennsylvania State College and the Watson Laboratories, U. S. Army Air Forces.

### Calendar of Meetings

**October**

# Initial Oscillation on a Rotational Viscometer

RUTH N. WELTMANN
*Interchemical Corporation, New York, New York*

(Received May 7, 1947)

The oscillatory system of a rotational viscometer has been investigated. The oscillation equations were checked with experimental bob deflection-time curves obtained for Newtonian liquids.

To be able to rapidly obtain correct values when taking flow curves the oscillatory system should be critically damped. Since this condition cannot be easily obtained in practice, the system should be slightly overdamped, meaning that the inertia ($I$) should be equal or smaller than $\pi\mu^2/720KS^2$. It is shown that due to the higher viscosity of thixotropic materials at lower rates of shear, the flow curves at these rates of shear give an indication of rather too low than too high shearing stresses.

THE flow characteristics of thixotropic substances are known to change as a function of time, when these materials are subjected to shearing forces. However, there is little information available about the change in structure of the material during the initial period of agitation, since no instantaneous readings can be made with most systems of measurement. For studying the structural changes in the initial period, the use of recording equipment is most desirable since it provides a continuous graph of the position of the indicating means of the viscometer, thus seemingly allowing an interpretation of the flow behavior of the material from the start of motion.

This paper deals with the problems encountered with a rotational viscometer when changing the cup speed from one to another angular velocity. Details of the viscometer have been described by Green.[1] The recorder which has been used in conjunction with this viscometer has also been previously discussed.[2]

However, even the recorded values are not always true representations of the flow characteristics of the investigated material, since the indicating means which control the recording mechanism do not instantaneously adjust themselves to the proper position but require time to perform the necessary motion.

In a rotational viscometer the shearing force at any rate of shear is obtained from the angular deflection of a bob, but only after the bob has come to an equilibrium position. In Green's design of a viscometer the bob is suspended on a helical spring. The stiffness of the spring and the inertia of the bob structure form an oscillatory system in which damping is provided by the viscosity of the test material which is located between the cup and the bob. When the cup of the rotational viscometer is set into motion for the purpose of performing a viscometric measurement the bob starts to move from its zero position until it reaches its final deflection. The time which is required to complete the bob motion depends upon the three elements of the oscilla-

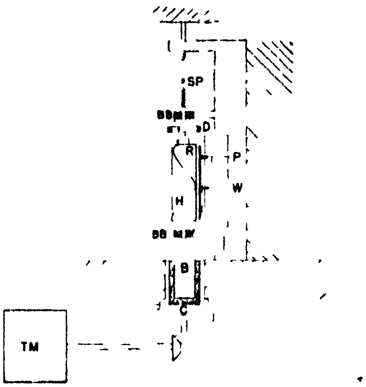

FIG. 1. Schematic viscometer and recorder assembly.

tory system, the stiffness of the spring, the inertia of the bob parts and the viscosity of the material. Though reference has been made to a condition which exists only when starting a viscometric measurement, the same reasoning also applies when the cup speed is changed step by step from one speed to another to obtain a rate of shear—shearing stress diagram.

It is of greatest importance to design properly the spring-bob combination so that the bob will come to its equilibrium condition in the shortest period of time. An analysis is being made of the most suitable physical dimensions of the elements of the oscillatory system for various test materials.

## INSTRUMENTATION

Figure 1 is a schematic sketch of the measuring and recording means of a rotational viscometer. The test material is contained between cup (*C*) and bob (*B*). The cup which is placed in a 30°C constant temperature bath is driven at various speeds to obtain different shearing forces in the material. The bob, supported between two ball nearings (*BB*), deflects until the torsional force of the spring (*SP*) equals the resistance force in the test material. This deflection is a measure of the applied shearing stress. The bob carries the deflection indicating disk (*D*) for visual measurements and the movable registering elements of the recorder (*R*). The recorder consists of two electrodes between which a high frequency spark is generated. The one electrode is a straight wedge (*W*), while the other electrode is a helical wire (*H*) wound around a cylinder concentric to the bob shaft, so that each position of the wire with respect to the straight wedge coincides with a unique deflection reading. The recording paper (*P*) travels between these electrodes at a constant speed, being moved by a slow constant speed motor (2.9 cm/sec.), and holes are pierced in the paper whenever a spark jumps over the gap. Thus the continuation of pierced points on the paper represents a bob deflection-time curve. On recording a flow curve the paper is coupled to the drive mechanism, the transmission motor combination (*TM*), in such a manner that the paper position becomes a function of the cup speed.

## CUP INERTIA

The cup as part of the drive mechanism is expected to obtain a constant angular rotation which is being impressed on it by the synchronous motor and transmission combination as soon as the initial acceleration period is over. This has been checked experimentally by rigidly connecting the cup with the bob from which temporarily the spring was removed. Wax was poured in the clearance between cup and bob and left to solidify before the test. The deflection of the bob as a function of time was recorded. Small curvatures are obtained at the beginning of the straight lines characteristic for each applied speed, as shown in Fig. 2. This is evidence that the cup needs a certain time before it attains its given speed. This time lag of the cup was determined by extending the straight line to zero deflection. From numerous experiments performed at various speeds this time intercept was found to average about 0.14 second. For further reference it will be designated as $t_c$.

## OSCILLATORY SYSTEM

The force equilibrium of the oscillatory system in such a rotational viscometer is given by the basic differential equation,

$$I\frac{d\alpha^2}{dt^2}+\frac{\mu}{S}\frac{d\alpha}{dt}+K\frac{360}{2\pi}\alpha=\frac{\mu}{S}\omega, \qquad (1)$$

$I$—the inertia of the bob, bob shaft, and deflection indicating dial in gram $\text{cm}^2$,
$\alpha$—the deflection in radians,
$\mu$—the viscosity in poises,

$t$—the time of motion in seconds,
$S$—an end effect corrected instrumental constant $S=[(1/R_b^2-1/R_c^2)/4\pi(h+h_e)]$,
$R_c$—radius of cup in cm,
$R_b$—radius of bob in cm,
$h$—immersed height of bob in cm,
$h_e$—hypothetical height added to bob to correct for end effect,
$K$—torsion constant of spring in dynes cm determined per degree deflection,
$\omega$—applied angular velocity in radians per second.

The end effect is the shear produced between the bottom of the cup and the bob. It can be experimentally obtained by measuring shearing stresses for various bob heights under otherwise constant conditions. Upon extrapolation of the shearing stress—bob height curve, which is a straight line, it is found that for zero shearing stress a negative bob height is required. This is the hypothetical bob height $h_e$—contributing a shear equal to the shear effect between the bottom of the cup and bob—which has to be added to the immersed bob height in the equation for the end effect corrected instrumental constant $S$. In the cup and bob assembly employed, the end effect amounts to about 2 percent and the corrected $S$ equals $2.24\times10^{-3}$.

Equation (1) is only strictly correct for materials whose viscosity is independent of time and rate of shear. It has three solutions:

(1) The overdamped or aperiodic oscillation, where the bob deflection increases slowly until the bob reaches its final position. If the bob creeps very slowly towards its maximum deflection there is some danger that the cup speed is increased to the next step before the bob has reached its final position and thus incorrect results will be obtained. Case 1 is realized when:

$$\frac{\mu^2}{4I^2S^2}>\frac{360K}{2\pi I} \quad \text{or} \quad I<\frac{\pi\mu^2}{720KS^2}. \tag{2}$$

Then the solution of Eq. (1), if $D$, the deflection in degrees, is substituted for $(360/2\pi)\alpha$, is:

$$D=\frac{\mu\omega}{2KS\Gamma}e^{-(\mu/2IS)t}[(-\mu/2IS-\Gamma)e^{\Gamma+} \\ -(-\mu/2IS+\Gamma)e^{-\Gamma t}]+\frac{\mu\omega}{KS},$$

where

$$\Gamma=(\mu^2/4I^2S^2-360K/2\pi I)^{\frac{1}{2}}. \tag{3}$$

(2) The underdamped or periodic oscillation, where the bob deflection increases rather fast but exceeds its final position and oscillates around this position before it ultimately reaches it. In this case the most erroneous values can be obtained giving either too low or too high readings depending on the time after which they are taken. Case 2 is realized when:

$$\frac{\mu^2}{4I^2S^2}<\frac{360K}{2\pi I} \quad \text{or} \quad I>\frac{\pi\mu^2}{720KS^2}. \tag{4}$$

With this condition and again substituting $D$ for $(360/2\pi)\alpha$, Eqs. (1) and (2) become:

$$D=-\frac{\mu\omega}{KS}e^{-(\mu/2IS)t}\left[\cos\Gamma t+\frac{\mu}{2IS\Gamma}\sin\Gamma t\right]+\frac{\mu\omega}{KS}$$

where

$$\Gamma=(360K/2\pi I-\mu^2/4I^2S^2)^{\frac{1}{2}}. \tag{5}$$

(3) The oscillation with critical damping where the bob reaches its final position fastest. This most desired case 3 is realized when:

$$\frac{\mu^2}{4I^2S^2}=\frac{360K}{2\pi I} \quad \text{or} \quad I=\frac{\pi\mu^2}{720KS^2}. \tag{6}$$

Then

$$D=-\frac{\mu\omega}{KS}e^{-(\mu/2IS)t}\left(1+\frac{\mu t}{2IS}\right)+\frac{\mu\omega}{KS}. \tag{7}$$

It is also interesting to investigate the case in which the inertia is negligibly small. Under these conditions when $I=0$, the first term of Eq. (1) is omitted and then the equation becomes:

$$\frac{\mu}{S}\frac{d\alpha}{dt}+K\frac{360}{2\pi}\alpha=\frac{\mu}{S}\omega. \tag{8}$$

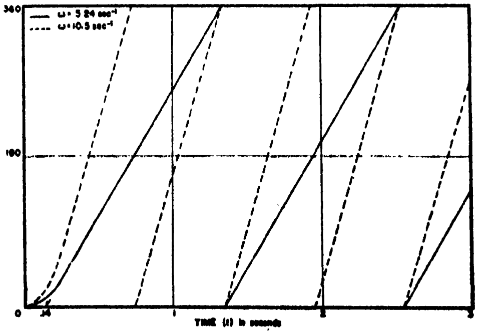

FIG. 2. Recorded cup deflections versus time of rotation for two different cup speeds to indicate cup inertia.

The solution of Eq. (8), if $D$ is again substituted for $(360/2\pi)\alpha$ is:

$$D=-\frac{\mu\omega}{KS}e^{-(360KS/2\pi\mu)t}+\frac{\mu\omega}{KS}. \tag{9}$$

Equation (7) represents the case in which the inertia in the oscillatory system has the highest permissible value without allowing the system to fall into a periodic oscillatory motion. Equation (9) on the other hand represents due to the removal of inertia the extreme case of aperiodic damping provided that everything else is maintained equal (same stiffness and same damping).

Equations (3), (5), (7), and (9) give the deflection ($D$) at any instant only if the angular velocity prevailing in the system before a change took place was zero. Otherwise $D$ is the deflection which has to be added to the prevailing deflection to obtain the new deflection value. The prevailing deflection is equal to $\mu\Omega/KS$, where $\Omega$ is the prevailing angular velocity.

## EXPERIMENTS

Experimental bob deflection-time curves for various rates of shear, test oils and bob inertias, were obtained with the recorder. As mentioned before, Eq. (1) is only correct when dealing with materials whose viscosity is independent of rate of shear and time of application at a constant rate of shear. Therefore, only true Newtonian materials can be used to check experimentally the solutions of Eq. (1). Oils, as shown in the literature,[3] are only true liquids up to their limiting rates of shear. Hence for these experiments they were tested at various rates of shear but only below the limiting rate of shear, where they are definitely known to behave like true liquids.

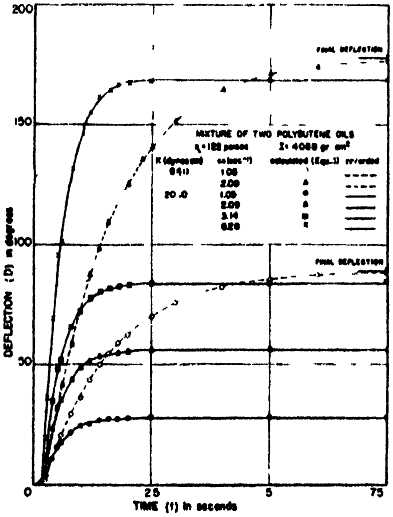

Fig. 3. Aperiodic oscillation curves for an oil in the Newtonian region, showing calculated points superimposed on experimentally recorded curves.

By using materials which varied in viscosity the damping of the oscillatory system was changed. In most cases for materials of different viscosity a change in the stiffness of the spring was required, since otherwise the deflection readings would have become either too small, thus lacking in accuracy, or too large so that the spring would have been overstrained.

In Fig. 3, bob deflection-time curves following Eq. (3), representing the case of over damped or aperiodic oscillation, are shown, for different applied rates of shear. Two bob springs of different stiffness were used. The same is shown in Fig. 4, but for an oil which gives underdamped bob deflection-time curves representing the case of periodic oscillation. In each case the cup started motion at zero time. Thus the prevailing angular velocity ($\Omega$) in both cases was zero. It was found that the equations check the experimental curves only when the time lag ($t_c$) of the cup is taken into consideration. This was done by deducting $t_c$ in each case from the measured time $t$. In Figs. 3 and 4 points obtained from Eqs. (3) and (5), have been super-imposed on the respective experimental curves with very good agreement.

In all cases so far described the inertia of the bob system was kept constant, ($I=4088$ g cm$^2$). In Fig. 5 curves are shown, representing conditions in which the inertia of the bob parts was varied in order to demonstrate that an increase in inertia can change the oscillatory system in such a manner that aperiodic oscillations will become periodic ones even though the same material and the same spring are used. Experimentally the inertia of the bob system was changed by operating without and with the deflection-indicating dial and by substituting the

---

[3] Weltmann, R. N., Ind. Eng. Chem. Anal. Ed. 15, 424 (July, 1943).

deflection-indicating dial with various lead disks. The weight of the lead disks was limited only by the carrying capacity of the spring. Thus the inertia was changed in various steps from 452 to 29308 grams cm². The bob deflection-time curves in Fig. 5 have been taken with one oil and at one applied rate of shear but with bob systems of different inertia. As can be seen two of these curves follow Eq. (3), while the other three follow Eq. (5). Again experimentally obtained and calculated bob deflection values are plotted.

### INERTIA OF THE TEST MATERIAL

Since the test material has to be accelerated when changing the cup speed, it was thought that the inertia of the test material in the viscometer might have to be taken into consideration in deciding whether under critical conditions periodic or aperiodic oscillation will result. To obtain experimental evidence about the inertia effect of the material the time-deflection curves of two substances of almost the same viscosity but of quite different specific gravity were recorded at various rates of shear. To exclude the stiffness element from the measurement the bob was decoupled from the spring. The time-deflection curves which were thus obtained were identical for the two test materials used which had a viscosity of about 5.5 poises. One of the two substances was a mineral oil with a specific gravity of 0.93 and the other one was a mercury potassium iodide solution in glycerine with a specific gravity of 2.84. The results are not surprising since the inertia of the test material even with the high specific gravity does not exceed 15 percent of that of the lightest bob system. The specific gravity of the mercury salt solution has been chosen to be high enough so that it will hardly be exceeded by any other material to be tested in the viscometer.

### PRACTICAL CONSIDERATIONS FOR NEWTONIAN LIQUIDS

In the measurement of flow curves of materials of which the flow characteristics had not been previously determined, it is important that the rate of shear can be increased and decreased at a very fast pace. On the other hand precautions must be taken that the rate of increase and decrease is not so high that the bob is prevented from attaining its final deflection value for each rate of shear step. The fastest adjustment of the the bob takes place when the oscillatory system is critically damped and it is thus this condition which is most desirable to maintain while performing a flow curve measurement. If the system is underdamped, a condition which will produce periodic oscillations whenever the rate of shear is changed, flow curves could be recorded which would provide shearing stress values for the different rates of shear which are either lower or higher than the correct values. For this reason an overdamped oscillatory system should be used in preference to an underdamped one. In order to accomplish this for materials of low viscosity an extremely low bob inertia is required.

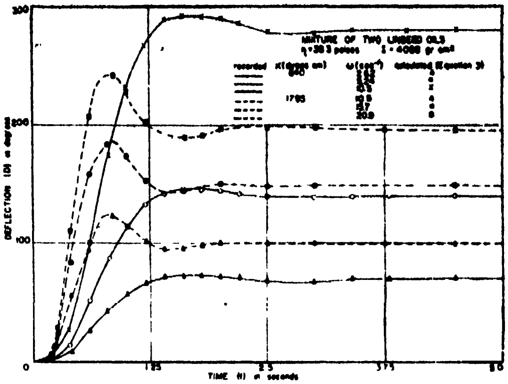

FIG. 4. Periodic oscillation curves for an oil in the Newtonian region, showing calculated points superimposed on experimentally recorded curves.

The bob reaches its final position after an infinite time has elapsed. This end value of the deflection is realized in all cases when,

$$D=\frac{\mu\omega}{KS} \quad \text{for} \quad \Omega=0 \qquad (10)$$

and

$$D=\frac{\mu(\Omega+\omega)}{KS} \quad \text{for} \quad \Omega\neq 0. \qquad (11)$$

Equation (10) represents not only the final deflection when the prevailing angular velocity was zero, but also equals the final deflection value which has to be added to any previously prevailing deflection.

Both Eqs. (10) and (11) will be recognized as the general viscosity equations for a rotational viscometer,[4] and are obtained from Eqs. (3),

---

[4] M. Reine and R. Riwlin, Kolloid Zeits. 43, 1 (1927).

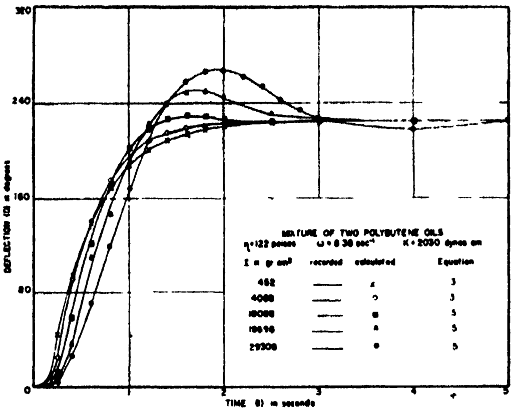

FIG. 5. Oscillation curves of an oil in the Newtonian region obtained with different bob inertias under otherwise constant conditions, showing calculated points superimposed on experimentally recorded curves.

(5), (7), and (9) for an infinite time. When $t$ is infinite the whole first term of all four equations becomes zero. However, for all practical purposes the end position can be assumed to have been reached when the deflection is about 1 percent less than the ultimate value. To obtain a value of 1 percent less than the deflection value $D$ of Eq. (10), the whole first term of Eqs. (3), (5), (7), and (9) has to be equal to the one percent which in turn means that the multiplicant of $\mu\omega/KS$ in the first term has to equal 0.01.

Since periodic oscillations are undesirable because of the possibility of obtaining not only too low, but also too high deflection readings and since the case of critical damping is difficult to achieve in practical tests, the damped oscillation curves will occur most frequently and therefore have been investigated further. It might be recalled that the two limiting conditions for the damped oscillation curves are the critical damping with the highest inertia before periodicity is obtained and the case where no inertia is present.

For the case of critical damping, which gives the fastest deflection movement, the equation which contains the time $t_F$ necessary to reach the final deflection value within 1 percent is,

$$e^{-(\mu/2IS)t_F}\left(1+\frac{\mu}{2IS}t_F\right)=0.01. \qquad (12)$$

By employing the graphical method,

$$t_F(\text{critical})\cong\frac{2IS\,6.64}{\mu} \qquad (13)$$

and since in this case Eq. (6) is valid,

$$t_t(\text{critical})\cong\frac{6.64\pi\mu}{360KS}. \qquad (14)$$

In the case that there is no inertia present the time for a deflection which is 1 percent short of its final position becomes from Eq. (9)

$$t_F(\text{inertialess})=-\frac{2\pi\mu\ln 0.01}{360KS}. \qquad (15)$$

Thus Eqs. (14) and (15) differ by a factor of about 1.4 That means, that everything else being equal, the fastest swing of the bob takes a little less than $\frac{3}{4}$ of the time which would be required for a swing with an inertialess system. Equation (15) can be written:

$$t_F=0.08\mu/KS=0.08D/\omega. \qquad (16)$$

In prior experimental work the author has taken most flow curves in one of the following manners. In the majority of cases the speed of the cup was raised in about 10 distinct steps during a period of about 26 seconds to cover a change of angular cup velocity of about 10 reciprocal seconds. For special runs the change of angular cup velocity of about 10 reciprocal seconds was attained in 13 seconds by taking only 5 steps. Under both these measuring conditions the time available for adjustment of the bob to its final position was 2.6 seconds. Thus $t_F$ in Eq. (16) should not exceed 2.6 seconds. Therefore in the case of flow curve measurements with an inertialess bob system $\mu/KS$ or $D/\omega$ should not exceed 32.5. It is relatively easy to review the validity of previous flow curve measurements by considering the ratio $D/\omega$. In most cases the viscometer constants were so adjusted that for a top angular velocity of about 42 reciprocal seconds (400 r.p.m. of the cup) the bob would rotate for a maximum of 360 degrees. Under these conditions $D/\omega=8.6$, which corresponds to a value of 0.69 second for $t_F$. This certainly means that flow curve measurements have been made with a substantial margin of safety as far as final adjustment time of the bob was concerned. This, of course, is only correct under the assumption that the oscillatory system was overdamped. Therefore, prior to a flow curve measurement it has to be determined whether the inertia of the oscillatory system is of the correct order (Eq. (2)) to assure overdamped conditions. For low viscosity materials the inertia of the bob and its associated parts were found of the correct order for the overdamped condition only after removing the deflection indicating dial.

### PRACTICAL CONSIDERATIONS FOR NON-NEWTONIAN MATERIALS

Though Eq. (1) as mentioned before is only correct for Newtonian materials, its interpretation can be used to determine whether the decrease in deflection obtained with a thixotropic material is derived from the thixotropic breakdown of that substance or from an undesirable overshooting effect of an underdamped system. The following reasoning might be applied. If the thixotropic material has a sufficiently high viscosity at the top rate of shear at which the shearing stress is measured to overdamp the oscillatory system then it must be assumed from the nature of the thixotropic substance that it would have even a higher damping effect at lower rates of shear since its viscosity must be higher. However, because of the relatively high viscosity at the low rates of shear the time $t_F$ which is required to get the bob within 1 percent of the final position could conceivably be longer than the time interval which is used in performing the step by step flow curve measurement, even if $D/\omega$ is adjusted to be less than 32.5. When that happens the measured shearing stress for a given shearing force is lower than it should be. To illustrate the condition which might exist when measuring a flow curve of a thixotropic material the assumption can be made that the ratio $D/\omega$ for the top rate of shear is again equal to 8.6 which means that the time $t_F$ equals 0.69 second. If a further assumption is made that the viscosity for the first measuring step of the flow curve is four or five times higher than for the top rate of shear, then at this point 2.76 and 3.45 seconds, respectively, would have been required to make the bob come up to within 1 percent of its final deflection. From Eq. (15) it can be calculated that if only 2.6 seconds are allowed to perform a measurement the bob was about 1.4 and 3.2 percent, respectively, off its final value at the instant of recording. In such a case the hysteresis loop of the flow curve would be recorded smaller than the material warrants, especially at the low rate of shear.

It is unfortunate that two contradictory conditions have to be met, when running flow and time-deflection curves of thixotropic materials. Because of the thixotropic nature of the material the measurement should be made speedily to obtain the flow characteristics of the materials before breakdown takes place. On the other hand due to the high viscosity in the beginning of motion the damping is so great that breakdown will start before the final deflection is reached. From Eq. (16) it can be seen that the swing in time ($t_F$) is proportional to the viscosity ($\mu$) and inversely proportional to the torsion constant ($K$). Therefore, to determine the viscosity values of thixotropic materials at low rates of shear with a higher degree of accuracy it is suggested to use a stiffer bob spring than would be otherwise employed. Though the bob deflection when using a stiffer spring will be smaller, the indicated shearing stress allowing the same limited time for taking the measurement will be greater, since the final deflection will be approached faster with the stiffer spring. Unfortunately one is restricted in increasing the spring constant since finally the motion of the bob becomes too small for accurate reacings even when a recorder is used.

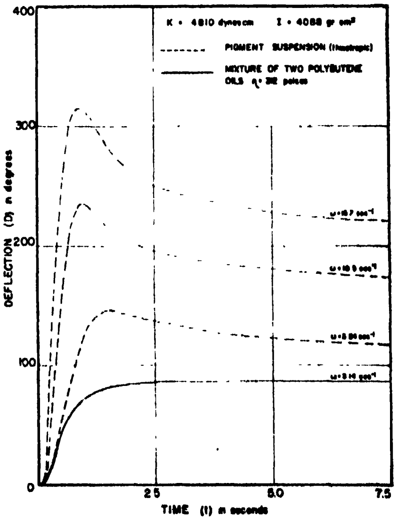

FIG. 6 Aperiodic oscillation curves of a thixotropic pigment suspension compared to that of an oil in the Newtonian region.

For the study of the initial conditions of thixotropic materials a special recorder might have to be designed which could provide some means of amplification of the purposely low deflection readings obtained with a too stiff spring. Such a recorder, for example, might make use of a long light beam which is thrown on a photographic recording paper. Another possibility might be to use a bob arrangement in which the bob is essentially motionless and the shearing force is measured with a strain gage. A high speed electrical recorder should be used to draw the flow curve from the indication of the strain gage.

### COMPARISON BETWEEN NEWTONIAN AND NON-NEWTONIAN BOB DEFLECTION-TIME CURVES

Since bob deflection-time curves can be calculated for true liquids, a deviation from the expected curve will show up any material which is non-Newtonian. Pryce Jones[5] used a method which was based on this consideration. In accordance with this procedure the bob was in a deflected position before the measurement was started and the bob deflection-time curve was recorded while the bob returned to its zero position. Recently Clark and Hodsman[6] employed a method similar to the one of Pryce-Jones for measuring viscosities.

In distinction to Pryce-Jones and Clark and Hodsman the author is presently engaged in studying at different rates of shear bob deflection-time curves which result from changes of the cup speed for Newtonian and non-Newtonian materials.

In Fig. 6 overdamped bob deflection-time curves are shown at three rates of shear for a thixotropic pigment suspension. In each case the curves were measured starting from a zero rate of shear. The breakdown in thixotropic structure is apparent from the decrease in bob deflection with time. As can be calculated by substituting the maximum deflection in Eq. (16), thixotropic breakdown occurred long before the bob would have reached its final deflection. For comparison one overdamped oil curve was added, which was taken at a rate of shear below its limiting rate of shear and which has a Newtonian viscosity of 312 poises. Attempts are being made to find some means of correlating the bob deflection values for Newtonian and non-Newtonian materials at any instant and rate of shear. No definite data are as yet available. But there are indications that this approach might make it possible to evaluate the consistency of thixotropic materials at very low rates of shear.

### ACKNOWLEDGMENT

The author is grateful to the Interchemical Corporation for permission to publish this paper and expresses thanks to Evelyn Berezin, Marjorie McElligott and Vera Osman for assistance in preparing it.

# Stability and High Frequency

Aurel Wintner
*The Johns Hopkins University, Baltimore 18, Maryland*

(Received April 21, 1947)

In a linear oscillator which is not conservative, let the frequency vary so as to tend to infinity when time increases indefinitely. It seems to be evident that the oscillations must then be of stable type. Actually, this is not true. The paradox results from the circumstance that the relevant criterion of stability depends on the monotone decrease, rather than on the indefinite decrease, of the instantaneous period.

## I

If a continuous $\omega=\omega(t)$, given for large positive $t$, varies so as to satisfy

$$\omega(t)\rightarrow\infty \quad \text{as} \quad t\rightarrow\infty, \tag{1}$$

it is usually assumed to be quite evident that the corresponding non-conservative oscillator

$$x''+\omega^2x=0 \tag{2}$$

must be of stable type (in the sense that

$$|x(t)|<\text{const. as } t\rightarrow\infty, \tag{3}$$

if $x=x(t)$ is any solution). A closer reflection on the energy balance shows, however, that the stipulation of (1) in (2) as a sufficient criterion for (3) is just a superstition. In fact, it turns out that the variability of $\omega(t)$ can be subject to (1) and be still so much in phase with the loss and gain in energy, that the local amplitudes of a solution of (2) fail to remain under any preassigned bound.

What *is* always true is that (2) must be of stable type if

$$d\omega(t)\geqq 0 \quad \text{when} \quad t_0<t<\infty. \tag{4}$$

But (1) does not imply that (4) is satisfied (nor is, of course, the converse inference true). In fact, if $\omega(t)$ is asymptotically proportional to $t$, say $\omega(t)=t+\theta(t)$, where $\theta(t)$ is of a lower order than $t$ as $t\rightarrow\infty$, then (1) is satisfied but (4) need not hold. For, even if the remainder term, $\omega(t)-t$, is of so small an order as to satisfy an inequality $|\theta(t)|<C$ (for some $C=$const.), possible fluctuations of $\theta(t)$ can lead to a situation violating (4). The construction of a $\omega(t)$, by means of which the actual insufficiency of the alleged stability criterion will now be proved, turns out to be precisely of this fluctuating type.

## II

The proof will consist in calculating a pair of functions, $\omega=\omega(t)$ and $r=r(t)$, which satisfy (1) and

$$r(t)\rightarrow\infty \quad \text{as} \quad t\rightarrow\infty, \tag{5}$$

respectively, and are such that

$$x(t)=r(t)\cos(t^2) \tag{6}$$

becomes a solution of (1). Clearly, (5) and (6) will imply the failure of (3); they will imply even more. In fact, (5) and (6) show that the local maxima (that is, the successive amplitudes) of the elongation $|x(t)|$, instead of being just unbounded, *tend* to $\infty$ as $t\rightarrow\infty$.

Substitution of (6) into (2) gives

$$\tfrac{1}{2}\omega^2=\{(2tr'+r)\tan(t^2)+2t^2r-\tfrac{1}{2}r''\}/r. \tag{7}$$

Hence, it is sufficient to show that it is possible to choose some function $r=r(t)$ in such a way that, on the one hand, (5) is fulfilled and, on the other hand, (7) defines, in terms of this $r=r(t)$, a *continuous* function $\omega=\omega(t)$ satisfying (1).

It is understood that $r(t)$ should have continuous derivatives. But this of itself does not take care of the proviso just italicized, since the $\tan(t^2)$, occurring in the definition of $\omega(t)$, has a sequence of infinities. These infinities can, however, be eliminated from (7), by choosing $r=r(t)$ so as to satisfy, for instance, the relation

$$(2tr'+r)r=t\cos^2(t^2). \tag{8}$$

In fact, (7) is reduced by (8) to

$$\tfrac{1}{2}\omega^2=\{t\sin(t^2)\cos(t^2)\}/r^2+2t^2-\tfrac{1}{2}r''/r; \tag{9}$$

so that the infinities of the tangent are compensated by the choice (8) of $r=r(t)$.

## III

Since the product on the left of (8) is identical with the derivative of $tr^2$, the differential equation (8) for $r=r(t)$ is satisfied by

$$r=\left\{\int_0^t s\cos^2(s^2)ds\right\}^{\frac{1}{2}}/t^{\frac{1}{2}}. \tag{10}$$

Clearly, the function (10) is asymptotically proportional to $\{t^2\}^{\frac{1}{2}}/t^{\frac{1}{2}}=t^{\frac{1}{2}}$, that is, there exists a numerical constant, say $c$, satisfying

$$r\sim ct^{\frac{1}{2}} \quad \text{as} \quad t\rightarrow\infty, \quad \text{where} \quad c>0. \tag{11}$$

But (11) implies (5). Consequently, the proof will be complete if it is verified that, when $r$ is given by (10), the (positive) function $\omega$ which is then defined by (9) is such as to satisfy (1).

According to (11), the first of the three terms on the right of (9) is asymptotically proportional to $\sin(2t^2)$ and remains, therefore, in absolute value less than a constant, as $t\rightarrow\infty$. Since the second term on the right of (9) is $t^2$, it follows that the sum of the three terms, which is $\frac{1}{2}\omega^2$, will be asymptotically equal to $t^2$ if the third term is of a lower order than $t^2$. Finally, the third term is the function $r''/r$ which, in view of (11), is of the order of $r''/t^{\frac{1}{2}}$.

Consequently, (1) will be assured if it is ascertained that $r''/t^{\frac{1}{2}}$ is of a lower order than $t^2$. This (and more) will be proved by showing that

$$r''=O(t^{\frac{1}{2}}). \tag{12}$$

In (12), use is made of the familiar notation, $f=O(t^\alpha)$, for any function $f=f(t)$ which is of the order of $t^\alpha$, *at most*. In other words, $f(t)=O(t^\alpha)$ means that the quotient $f(t)/t^\alpha$ stays between finite bounds, as $t\rightarrow\infty$. In particular, $f(t)=O(1)$, where $\alpha=0$ means that $|f|<$const. as $t\rightarrow\infty$. In the following proof of (12), the obvious rules

$$O(t^\alpha)O(t^\beta)=O(t^{\alpha+\beta}), \quad O(1)+O(1)=O(1) \tag{13}$$

will repeatedly be applied.

According to (8),

$$2tr'+r=O(t)/r=O(t^{\frac{1}{2}})$$

by (11). Since this means that $r'=O(t^{\frac{1}{2}})/t-rO(t^{-1})$, it follows that

$$r'=O(t^{-\frac{1}{2}}), \tag{14}$$

again by (11). On the other hand, differentiation of (8) gives

$$(2tr''+3r')r+(2tr'+r)r'=O(t^2).$$

Hence, from (14),

$$tr''r+O(t^{-\frac{1}{2}})r+tO(t^{-\frac{1}{2}})^2+rO(t^{-\frac{1}{2}})=O(t^2).$$

In view of (11), this can be simplified to

$$tr''r+O(1)=O(t^2).$$

Consequently, $rr''=O(t)$, and so (12) follows from (11).

## IV

This proves that condition (1), without (4), does not insure the stability of (2). On the other hand, condition (4), without (1), does insure stability (if $\omega=\omega(t)$ is positive), even though (4) is not a *necessary* condition. That it is ***sufficient*** for stability, is known to follow by an argument familiar from the theory of Bessel's functions. It proceeds as follows:

Whether (4) is satisfied or not, it is seen (by differentiation) that

$$d(x^2+x'^2/\omega^2)=x'^2d(\omega^{-2}) \tag{15}$$

is an identity in $t$ along any solution $x=x(t)$ of (2), where $\omega=\omega(t)$. If (4) is assumed, then, since $\omega(t)$ is supposed to be positive, the increment on the right of (15) cannot be positive. Hence, the same is true of the increment on the left of (15). This means that the function

$$x^2(t)+x'^2(t)/\omega^2(t) \tag{16}$$

does not increase when $t$ increases. In particular, if $t_1<t_2<\cdots$ is a sequence of $t$-values at which $x'(t)$ vanishes, then, since (16) reduces to $x^2(t)$ when $t=t_1,\ t_2,\ \cdots$,

$$|x(t_1)|\geqq|x(t_2)|\geqq\cdots.$$

In other words, the successive amplitudes $|x(t_1)|$, $|x(t_2)|$, $\cdots$, representing the relative maxima of $|x(t)|$, do not increase. This proves more than what is claimed by (3), that is, by mere stability.

# Mechanism of Fracture of Glass and Similar Brittle Solids*

Nelson W. Taylor
*Research Department, Minnesota Mining and Manufacturing Company, St. Paul, Minnesota*

(Received May 15, 1947)

A theory is proposed which connects the stress, $f$, required to break a brittle material in simple tension, with its duration of application, $t$. The slow process preceding fracture is shown to be the orientation of the atomic network contained in an elementary prism of length $r=\lambda_0E/f$, where $E$ is Young's modulus and $\lambda_0$ is the critical elongation required for fracture. The rate-controlling factor is the activation energy, $E\alpha/f$, for the orientation or rearrangement of the atomic network under the stress, $f$. Moisture on glass, and moisture plus oxygen on certain metals; are important catalytic or fatigue-promoting factors because they reduce the unit activation energy, $\alpha$. The theory leads to the equations

$$t=(1/k_0)e^{E\alpha/fkT}$$

and

$$\log t=-\log k_0+(E\alpha/2.3kT)/f,$$

where $t$ is the time for fracture (duration of the stress), $k$ is the Boltzmann constant, $T$ the absolute temperature, and $\alpha$ and $k_0$ are experimentally determined constants. The logarithmic expression has the same form as the Glathart-Preston [J. App. Phys. 17, 189 (1946)] empirical relation $\log t=-a/m+1/fm$, which, in the case of glass, appears to be valid over a time factor of $10^7$.

The theory shows why a solid object does not have a single characteristic breaking strength, and how it adjusts its fracture mechanism to whatever stress is applied. Quantitative tests of the theory are made, using fracture data on various glasses and on one glass at various temperatures. Applicability of the theory to certain aspects of fatigue of metals under stress-corrosion conditions, as well as to failure by fracture of the more rigid organic plastics, is indicated.

An equation, $E\lambda_0=2\gamma$, is proposed which connects Young's modulus and the critical fracture distance with the surface tension, $\gamma$, of the solid. Some examples are given.

## INTRODUCTION

In a discussion of the strength of "brittle" materials, it is desirable to define such terms as brittle, ductile, elastic, etc. We speak of glass as a brittle material "par excellence," and yet glass when hot is quite ductile or plastic. Under some conditions, for example under impact, tar is a brittle material, whereas if a more gentle pressure is applied over a period of time the tar will undergo some deformation, part of which is permanent and part slowly recoverable. Rubber, quite typically elastic at room temperature, is brittle at liquid-air temperatures. Thus, we see that time and temperature are important factors.

Webster's new International Dictionary, Second Edition, defines *brittle* as "breaking with very slight deformation;" *ductile* as "capable of being permanently drawn out or hammered thin; capable of being molded or worked;" *elastic* as "capable of recovering size and shape after deformation."

In view of the fact that a substance like glass is quite fluid at very high temperatures, ductile in the temperature range where it is worked into useful shapes, simultaneously ductile and elastic in the annealing range of temperature, brittle at ordinary temperatures and below, and that a substance like tar is brittle or ductile depending on the time element, it is to be seen that there is no sharp dividing line where a substance can pass exclusively from one property to another. It is not surprising, therefore, to find that a brittle material shows elastic properties including not only the instantaneous response but also lesser known reactions called elastic after-working, delayed elastic effect, primary creep, etc. Likewise, normally ductile materials, under impact or brief intense stresses show essentially brittle properties.

As soon as we recognize that "time is a necessary dimension of strength," that it is vital to any consideration of the mechanical properties, we look for the reason. The problem takes on some of the aspects of a chemical reaction running at a characteristic rate, and the concepts and methods of physical chemistry should be applicable.

The strength of brittle materials depends on many factors, not only on the time, but also on the chemical environment, on pre-stressing or residual stresses resulting from the preparation of the test piece, on the method of testing, and on

---

* Presented at the Annual Meeting, Society of Rheology, New York, New York, November 2, 1946, as part of the Bingham Memorial Symposium.

size and shape. This latter factor is very significant in thin fibers, wires, and foils. Surface cracks may also act as centers of dangerous local stresses. The common belief that every material has a characteristic breaking strength is very far from the truth.

Probably most materials are brittle at the time of actual rupture or fracture. The various molecular or atomic mechanisms which can adjust to the applied stress are exhausted just prior to the instant of fracture. "Primary creep," "slip," "delayed elastic adjustment" appear to be a necessary prelude, determining by their slowness how long the stress can be sustained.

The theory developed in this paper emphasizes this atomic rearrangement as the essential factor determining the time for fracture, and advocates a method of plotting which has both practical and theoretical value.

## I. THE EMPIRICAL LINEAR RELATION: RECIPROCAL STRESS *VS.* LOG TIME

J. L. Glathart and F. W. Preston[1] have presented a linear equation showing the strength of glass as a function of time under constant load. This equation is $1/f=a+m\log t$, where $f$ is the breaking stress, $t$ the time, and $a$ and $m$ are constants. Each line is thus defined by its slope $m=d(1/f)/d(\log t)$ and by the point $(t_0)$, where the line intersects the time axis. This equation is based on the experiments by T. C. Baker[2] in Preston's laboratory, covering the exceptionally large time range of $10^7$.

The above equation may be written

$$\log t=-a/m+1/fm.$$

The numerical values of the slope $m$ range from $0.72\times 10^{-5}$ to $2.93\times 10^{-5}$ in.²/lb. for disannealed Pyrex, dry, and for plate glass, dry, respectively. However, much smaller values of the slope are indicated in the case of glass which had been especially dried by baking at 350°C in high vacuum. From the data on experiment VII of the Baker and Preston paper the value of $m$ for soda-lime glass is calculated to be only $0.04\times 10^{-5}$. In fact, some data are shown in which there appears, within the limits of experimental error, to be no decline of strength in glass which had been very thoroughly vacuum-dried by baking at 0.1-micron mercury pressure for 10 minutes at 350°C. The value of $m$ in this case would be smaller than $0.04\times 10^{-5}$. This shows that moisture plays a very important role in bringing about fatigue or decline in strength of glass under load, with the passage of time. Removal of moisture also raises the absolute strength in experiments conducted at constant time. As stated by Baker and Preston, in certain tests the ratio of the vacuum strength to the wet strength is 2.5 for Pyrex, 2.0 for soda-lime glass, 1.7 for silica glass, and 1.5 for porcelain.

If we regard the empirical relation of Glathart and Preston as measuring the speed of a molecular process, we can consider that this speed is controlled by an activation energy, just as we find the speed of an ordinary chemical reaction controlled by such an energy. This activation energy is a minimum energy which a molecular complex must acquire before it is in a position to undergo reaction. Certain bonds must be broken or weakened before new bonds can form. It would appear that moisture has the effect of greatly lowering the activation energy for fracture of glass. In other words, the presence of moisture somehow provides a mechanism of molecular rearrangement which requires lower energy than if moisture is absent. This seems reasonable since $H_2O$ can convert the strong Si−O−Si bond into weak Si−OH bonds. A theoretical derivation of an equation taking account of this activation energy will now be set forth.

## II. THEORY OF THE FRACTURE PROCESS

We shall imagine that the elementary process in fracture consists in the slow elongation of the strongest bonds in an elementary or unit rectangular prism having length, $r$, cross-sectional area, $A$, and volume $V=rA$. Under tension $f$ parallel to the length, there will be, according to Hooke's law, an extension of the prism in the amount $\lambda_0$ where $\lambda_0/r=f/E$, $E$ being Young's modulus. This establishes the length $r$ in terms of a characteristic unit of length, $\lambda_0$. The prism may be regarded as made up of $E/f$ layers, each $\lambda_0$ in

---

[1] J. L. Glathart and F. W. Preston, "The fatigue modulus of Glass," J. App. Phys. 17, 189 (1946). See also F. W. Preston, "Strength of glass and duration of stressing," Nature 156, 55 (July 14, 1945).

[2] T. C. Baker and F. W. Preston, "Fatigue of glass under static loads; effect of water on the strength of glass," J. App. Phys. 17, 170 (1946).

thickness and $A$ in area. Let the extension $\lambda_0$ of the prism be just sufficient for fracture. The activation energy for fracture is then equal to $\alpha E/f$, where $\alpha$ is the activation energy required for orientation and associated stretching of each layer of thickness $\lambda_0$ and area $A$. (See Fig. 1.) The product $\alpha E/f$ represents the whole activation energy for orientation and consequent stretching of all of the network of atoms contained in the volume $V$. Since $\lambda_0/r=f/E$ and since $\lambda_0$ is a characteristic constant length, $r$ becomes less as $f$ increases, so that for constant cross-sectional area the volume $V$ diminishes as $f$ increases. It thus appears that the activation energy for orientation and stretching of the material contained in volume $V$ will diminish as $f$ increases. The rate of the fracture process is, therefore, the rate at which the material in $V$ acquires its critical activation energy $\alpha E/f$, and this can be written:

$$\text{rate of fracture}^{**}=k_0e^{-E\alpha/fkT}.$$

The corresponding time for fracture then becomes:

$$t=(1/k_0)e^{E\alpha/fkT}$$

and

$$\log t=-\log k_0+(E\alpha/2.3kT)/f.$$

This equation is of exactly the same form as that of the empirical Glathart-Preston relation: $\log t=-a/m+1/fm$. We see that $m=2.3kT/E\alpha$. It is to be emphasized that the assumption of a characteristic or critical energy which must be supplied per unit of length $\lambda_0$ (or more exactly, per unit of volume $\lambda_0 A$) leads to a theoretical equation exactly identical in form with the empirical linear relation, namely that the logarithm of time for fracture is inversely proportional to the stress.

The equation $m=2.3kT/E\alpha$ is dimensionally correct because $m$ has the dimensions of reciprocal stress, $E$ has the dimensions of stress, and $\alpha$ and $kT$ have the dimensions of energy. It is probably impossible to predict the value of $\alpha$ from fundamental considerations, since it is the experience in chemical kinetics that the activation energy can be calculated from fundamental constants only in the case of very simple gas reactions. However, $\alpha$ can be derived from the experimental data by the use of the equation given here.

The basic assumptions may be re-stated as follows: The strongest atomic bond in the system must be stretched a distance $\lambda_0$ in order to effect fracture. This elongation $\lambda_0$ is constant, regardless of the stress. The length of the chain of atoms which cooperates to produce this elongation $\lambda_0$ is $r=\lambda_0 E/f$ and, therefore, is inversely proportional to $f$. The elongation of this chain, or more properly speaking, the elongation of a prism of length $r$ and area $A$, is a slow process because of the many bond angles which must be changed and the many atoms which have to be squeezed and rearranged in order to permit elongation of the strongest bond in the amount $\lambda_0$. When this elongation has occurred, it can be imagined as being distributed in a statistical way among all the bonds whose total length is $r$, but because of extremely rapid thermal vibration, the whole $\lambda_0$ soon concentrates on some one bond and then fracture occurs. This redistribution is a very rapid process. The rate-controlling process is a relatively slow orientation of the whole network of atoms whose total length is $r$. The activation energy necessary for the orientation process has a characteristic value per unit of length, so that if for convenience $\lambda_0$ be regarded as that unit, we define $\alpha$ as the activation energy required per unit of length $\lambda_0$, with cross-sectional area $A$. The whole activation energy, then, for the elementary process of fracture, is $\alpha E/f$. One can see that when the stress is small, the time for fracture is

** For details as to the connection between rate of elongation and rate of fracture, see the next section.

very long because the elementary cell or prism which has to acquire the critical activation energy $\alpha E/f$ is large. When the breaking stress is high, the elementary cell is smaller, $\alpha E/f$ is smaller, and fracture occurs sooner. The solid responds automatically to any tension which is imposed, and will break under that stress if it is applied for the right length of time. *Thus we cannot speak of a definite characteristic breaking stress of the specimen.* However, for practical purposes the times for fracture under mild stresses may be so extremely long that they can be regarded as unlimited. This is why the concept of an "endurance limit" has been found useful in the fatigue testing of metals.

### A. Phenomena Preceding Fracture

A series of researches by Taylor[3] and coworkers have shown that in the annealing range of temperature the elastic deformation of a glass fiber or rod under tension may be represented by one or more terms, each of which follows the law $dl/dt=-kl$, where $l$ is the unstretched length or the distance from equilibrium. The elongation is rapid at first but falls off with time because the fraction of the molecular network available for orientation is rapidly decreased. In this respect the phenomenon is much like radioactive decay.

The same law is found to hold at room temperature, for example, in the change of readings of a fixed point such as the ice-point of a thermometer. (See Taylor and Noyes.[4]) In one case, measured at room temperature, the "half-life" for the process was 6.75 months.

In fracture phenomena, our tests are usually of much shorter duration, and we find that the rate of elongation appears to follow the law $dl/dt = -k_0'e^{-E\alpha/fkT}$, which is to say, that for a given value of the stress, $f$, the rate $dl/dt$ is constant. Such a result would follow if the magnitude of the elongation $\lambda_0$ which is necessary for fracture is quite small compared with the original length, so that $l$ on the right side of the expression $dl/dt = -kl$ (or the apparent value of $r$ in the expression $dr/dt=-kr$) changed very little. Now the ratio $f/E$ in the glass fracture studies of Baker and Preston never exceeded 1/300, so this represents the maximum ratio of $\lambda_0/r$ for these experiments. This ratio is also small in most fatigue tests on metals, since $E$ is about $10^7$ p.s.i., and $f$ rarely exceeds $5\times10^4$, yielding a maximum $f/E$ of 1/200. Hence, we appear to be justified in converting the differential rate, $dl/dt$, to the integral form $\Delta l/\Delta t=\lambda_0/t$, where $\lambda_0$ is the characteristic critical elongation required for fracture, and $t$ is the duration of the stress.

Hence if the rate of elongation of the unit cell or prism of length, $r$, under stress, $f$, is $dr/dt = -frk_0''e^{-E\alpha/fkT}$, then $\lambda_0/t=-frk_0''e^{-E\alpha/fkT}$. But the apparent value of $r$ does not change appreciably, and $fr=E\lambda_0$, so that

$$\lambda_0/t=-E\lambda_0k_0''e^{-E\alpha/fkT},$$

$$1/t=-Ek_0''e^{-E\alpha/fkT},$$

$$t=-\frac{e^{E\alpha/fkT}}{k_0},\quad\text{where}\quad Ek_0''=k_0,$$

and

$$\log t=-\log k_0+(E\alpha/2.3kT)/f,$$

(in converting to logarithms we discard the negative sign in the preceding equation since this came originally from the equation $dr/dt=-kr$, and has no effect on the *numerical* value of $t$ or $\log t$). Negative values of $t$, the duration of stress, are meaningless.

The proper value of $E$ to use in the calculation is the mean value of the modulus over the whole range of strain from $dr/r=0$ to $dr/r=\lambda_0/r$. Since $\lambda_0/r$ is 1/200 or less we are justified in using the ordinarily measured value of $E$ which is obtained for lower values of $dr/r$ (or of $dl/l$).

If fracture tests are conducted at relatively high ratios of $f/E$, e.g., as high as 10 percent, the ratio $\lambda_0/r$ would be as high as 10 percent when fracture occurs. Some very strong short glass fibers, having a diameter $5\times10^{-4}$ inch, which were studied by F. O. Anderegg[5] showed 6 percent elongation at fracture. The percentage elongation was less for longer fibers, following a systematic trend. Anderegg estimated that a fiber of zero length would elongate 14.5 percent before fracturing. For these relatively large elongations

we must express the rate of elongation

$$dr/dt = -frk_0''e^{-E\alpha/fkT},$$

in the form

$$d\ \ln r/dt = -fk_0''e^{-E\alpha/fkT},$$

$$[-\ln r/(r+\lambda_0)]/t = fk_0''e^{-E\alpha/fkT}.$$

Again we discard the negative sign, so that

$$t = \frac{\ln r/(r+\lambda_0)}{fk_0''}\cdot e^{E\alpha/fkT}.$$

Actually these very strong fibers broke immediately, as soon as the full stress was reached, and it is practically impossible to determine the time effect. The reason for the extremely rapid fracture is that the ratio $E/f$ in Anderegg's case is only about 10 instead of about 300–1000 of Preston *et al*, so that the activation energy, $E\alpha/f$ is reduced by the factor 10/300 or 10/1000. This change occurs in the exponent so that it (profoundly) reduces the time for fracture, $t$, to a time which is inaccessible by our ordinary methods of measurement. The following excerpts are from Anderegg: "It seems unlikely that variation in the rate of loading is of any importance in these results. The stress-strain curves were all perfectly straight, as far as the methods would indicate." This latter statement indicates that the ordinary modulus $E$ is applicable right up to fracture.

We are therefore justified in writing our theoretical equation connecting breaking stress, $f$, with its duration, $t$ as follows:

$$\log t = -\log k_0 + (E\alpha/2.3kT)/f.$$

Some very careful experiments have been made which have failed to reveal evidence of creep. For example, F. W. Preston[6] quotes some experiments by J. T. Littleton on strong rods of borosilicate glass where very high stresses were used and where delicate optical tests failed to show creep. Preston also mentions experiments by a French worker, Grenet, in 1899, which had been carried to the point of fracture, but no displacement of optical interference fringes were observed during the last two or three minutes before fracture took place.

One possible interpretation of the negative results of Littleton and of Grenet would be that there is an internal molecular rearrangement taking place in the glass at constant total strain. In other words, the effect of the load is to produce deformation of a certain magnitude, and then with the passage of time molecular rearrangement occurs, resulting in fracture. There is direct evidence for such molecular rearrangement in glass at room temperature. Some of the early work by F. Kohlrausch[7] in 1863 demonstrated this. Kohlrausch twisted a glass filament through a given angle and measured the torque necessary to hold the filament at that constant angle of twist over a period of 24 hours. The torque gradually fell approximately proportionally to the logarithm of the time. There is much subsequent work demonstrating this relaxation phenomenon under constant deformation, and it has been shown that this is an elastic phenomenon rather than a viscous flow or permanent set, because the phenomenon is reversible. It therefore appears that we are justified in our belief that slow internal molecular rearrangements do, in fact, precede the actual fracture. Not very much detail can be given as to the actual molecular process, but it seems likely that the weaker parts of the network take up the initial strain and that this strain is transferred slowly to the stronger bonds, so as to effect a more equitable distribution of the strain energy between all the kinds of bonds in the system. However, when these stronger bonds become stretched sufficiently, fracture results.

Similar ideas regarding the transfer of strain energy by molecular rearrangement have been expressed by S. A. Shorter.[8] The following is quoted from Shorter: "If a given force be applied rapidly and maintained for a lengthy period of time, we get a rapid extension followed by a slow one. The process of extension proceeds for a very lengthy period—days or even weeks. The explanation of this is not as might be supposed that the elastic elements are showing a plastic yield, but

that the fiber contains elastic elements with very different degrees of damping so that on the first application of an external force, the more lightly damped elements extend, and as time goes on, the extension of the more highly damped elements begins to show itself, We get a similar effect on removing the external force, and it is undoubtedly the extreme slowness of the recovery of the more highly damped elements that has given rise to the erroneous ideas of plasticity and permanent strains. Similar considerations apply to the case where a fiber is held stretched to a definite length. We get an apparent elastic relaxation which, however, is very different from the effect contemplated in Maxwell's theory of viscosity."

A familiar example of decrease in tension in a fiber held at constant length is the decline in pitch of a violin string.

"It is not the disappearance of a state of strain owing to molecular readjustment, it is merely a transference of a state of strain from lightly damped to highly damped elements."

### B. Role of the Chemical Environment

One can only guess at the details of the atomic rearrangements which occur during the instantaneous and the delayed elastic elongation. The instantaneous part probably corresponds to elongation of the network as a whole, that is, each atom or ion is displaced or deformed slightly without disrupting the framework. This establishes a higher potential energy for the system, and *sets the stage* for the slow rearrangement which follows. This slow step is of a much more profound nature than the first since it calls for the expenditure of a substantial activation energy, which may be as high as 100,000 to 200,000 calories.[9] On the other hand, it may be quite small if "catalytic" agents such as moisture or other chemically active gases are present. In soda-lime glass which has been vacuum-baked to remove moisture, the atomic rearrangement probably involves first breaking of Na$-$O bonds, these being the weakest bonds in the structure. The stress is then transferred to stronger bonds such as Ca$-$O, and ultimately to Si$-$O which is the strongest of all. Finally, when the Si$-$O bonds are stretched to a sufficient extent, fracture occurs. In silicate crystals cleavage usually takes place in such a way as to avoid breaking the strong Si$-$O bonds, but in quartz and in glasses this cannot be avoided. All of this rearrangement (prior to fracture) could take place without any elongation beyond the original instantaneous stretch, since the stretch due to bond breaking might be compensated by a contraction due to the deformed atoms returning in part to their normal shape. We have a good deal of experimental evidence of such compensation in the behavior of electric condensers made of glass,[8] and also in the elastic response of glass, rubber, etc. as a result of a complex history.

Corrosive or chemically active gases or liquids definitely accelerate the rearrangement of the atoms of the solid and shorten the time for fracture. They do this by providing a mechanism of low activation energy, as shown by the steep $E/f$ *vs.* $\log t$ curves, the slope being $2.3kT/\alpha$. There are various possible mechanisms for this acceleration. One is that strong primary bonds such as Si$-$O$-$Ca or Si$-$O$-$Si are disrupted by reaction (e.g., with $H_2O$) and that the heat of this reaction supplies part of the requirements of the activation energy for the delayed elastic process. Likewise in metals, the heat of oxidation would supply energy to aid in the dissociation of the bonds which join the metal atoms.

The linear relation, $\log t = -a/m + 1/fm$ implies constancy of the slope $m$ over the whole duration of the test. This means that the "catalyst" has a constant influence over the whole period, and that the activation energy for molecular rearrangement is constant over this period. One would expect this to happen in glass if the moisture content remained constant. However, the situation might arise in long time tests where the sample gradually dried out. In this case, the activation energy would gradually rise and the later points of the curve would fall below the projected straight line which represented the results of the early part of the experiment. Likewise, an increase in moisture content, due to a higher humidity in the atmosphere, might cause an upward trend in the $1/f$ values. This sensitivity to the environment must be a general phenomenon in the fatigue testing of materials of

TABLE I. Percentage elongation at rupture (or fracture).

| $f$ (p.s.i.) | $E$ (p.s.i.) | calculated $(f/E)100$ | observed $(dl/l)100$ |
|---|---|---|---|
| $0.204\times 10^6$ | $2.8\times 10^6$ | 7.3 | $6.1\pm 1.7$ |
| 0.219 | 4.9 | 4.5 | $4.5\pm 0.8$ |
| 0.182 | 5.2 | 3.5 | $4.1\pm 0.2$ |
| 0.160 | 6.3 | 2.5 | $2.6\pm 0.5$ |
| 0.112 | 4.7 | 2.4 | $2.3\pm 0.4$ |
| 0.107 | 6.3 | 1.7 | $1.7\pm 0.2$ |

all kinds. The test piece should be seasoned before the fatigue tests are begun in order that it may come into "equilibrium" with the environment.

Solids under tension are at a higher potential energy and are therefore more susceptible to chemical attack than when stress-free, so that even the mildest agents may shorten the time for fracture. For this reason, investigations pointing toward more chemically-resistant materials, toward stable protective coatings, and toward reduction of tension by pre-stressing, are very much worth while. In high temperature service, corrosion may be very rapid and the danger of fracture very greatly enhanced. The problem is a critical one for the development of gas turbines, jet engines, etc.

In view of the intimate relation which appears to exist between the slow atomic rearrangement and the time required for fracture, it would be of great interest to determine quantitatively the rate constants for the delayed elastic effects in solids as affected by different chemical environments, comparing these with corresponding data from fatigue tests under stress-corrosion conditions. These studies could take the form of measurement of the decrease in Young's Modulus as a function of the time, for example by measuring the force needed to maintain a given displacement. Another procedure would be to measure the residual displacement (and its rate of relaxation) after holding a sample under a given tension for various lengths of time. Recent developments in strain gauges should make these latter measurements quite easy.

## C. Percentage Elongation at Fracture as a Test of the Theory

The present theory assumes that $\lambda_0$ is constant. The percentage elongation at fracture, $(\lambda_0/r)100$, should therefore not be constant for different stresses, but should be equal to the corresponding percentage of the breaking stress in terms of the modulus of elasticity, $(f/E)100$. Now $\lambda_0/r$ cannot be measured directly but $\lambda_0/r=dl/l$, if the tension is the same along the whole length, $l$, of the specimen. Fortunately, all the necessary data are available from the work of Anderegg,[5] who broke his very strong glass fibers by straight pulling. Table I shows Anderegg's directly observed percentage elongations and also those calculated as the ratio of his observed $f$'s and $E$'s. The data are from Table II of Anderegg's paper.

It is to be noted that the agreement is quite good. The lack of constancy in the percentage elongation forces us to discard the old idea that fracture occurs when a certain percentage elongation of the specimen is reached. On the other hand, the results are consistent with the concept that the elongation $\lambda_0$, necessary for fracture, is constant. Unfortunately, we are not in a position as yet to calculate $\lambda_0$ with certainty. Anderegg estimated by extrapolation that a fiber of zero length should elongate 14.5 percent before fracture. We might regard this as 14.5 percent of the normal length of the strongest bond in a glass, which is the silicon-oxygen bond, known from x-ray data to be 1.62 Ångstrom units. In this case, $\lambda_0$ would be $1.62\times 0.145=0.23$A. Hence, for example, when $E/f=r/\lambda_0=1000$, we find $r=230$A.

## D. Possibility of Viscous Flow?

The term "primary creep" is used in this paper in the sense of a reversible delayed elastic process. The question arises as to whether true viscous flow accompanies the elastic deformation preceding fracture of brittle materials, as it does, for example, in glasses in their annealing range of temperature. Anderegg's observations that the percentage elongation at fracture of his glass fibers were equal to the calculated elastic distortion $f/E$, would seem to eliminate the presence of viscous flow, or at least make it negligible. Under "weaker" stresses, where $f/E$ is 1/200 or less, it seems even less probable. Viscous flow is not the essential process in fracture, although it is barely possible that it goes on in parallel with the elastic deformation that does lead to fracture. Possibly one reason why a material is brittle is that it may have lost that capacity for viscous flow which it possessed at higher temperatures.

### E. Surface Tension of the Solid

The product $E\lambda_0$ measures the energy per unit area which is released when fracture occurs. If this all goes into new surface we may write $E\lambda_0=2\gamma$, where $\gamma$ is the surface tension, or specific surface energy. Taking $E=5.0\times 10^6$ p.s.i., which is the mean value of Anderegg's moduli in his Table II, and using $\lambda_0=0.23\times 10^{-8}$ cm, gives $\gamma=400$ ergs/cm². Since this result depends very much on the values assigned to $E$ and to $\lambda_0$, it must be taken with caution. It is, however, of the right order of magnitude. Parmelee, Lyon, and Harmon[10] give $\gamma=336-0.0671t$, where $t=$ °C, for a glass containing 10 percent $Na_2O$, 20 percent $B_2O_3$, 70 percent $SiO_2$, the measurements being made at 1150–1350°C. Extrapolation to 24°C yields $\gamma=335$ ergs/cm².

In cases where $E$ and $\gamma$ are known, $\lambda_0$ can be calculated, $\lambda_0=2\gamma/E$. Let us assume that the ratio $\gamma/E$ for ice is the same as that for water. From the velocity of sound in water, $v=1.45\times 10^5$ cm/sec., we calculate $E$ from the relation $v=(E/\rho)^{\frac{1}{2}}$ where $\rho$ is the density. Thus $E=2.10\times 10^{10}$ dynes/cm². Taking $\gamma=73$ dynes/cm we find $\lambda_0=0.7$A. This is about one-half the length of the H−O bond in water or ice, 1.275A. We shall make similar calculations for lead and zinc in order to get some idea of the critical bond elongation in these metals. The calculations are only approximate, since the pertinent data are not all available for one and the same temperature. For *lead*, $\gamma_{\text{liq}}=445$ dynes/cm, $E$ (calc. from the velocity of sound and density of the solid Pb)$=1.60\times 10^{11}$ dynes/cm². Then $\lambda_0=0.56$A. The Pb-Pb distance from x-ray data is 3.5A, so that $\lambda_0$ is 16 percent of this bond length. For *zinc*, $\gamma_{\text{liq}}=750$ dynes/cm, $E_{\text{solid}}=9.8\times 10^{11}$ dynes/cm². Therefore, $\lambda_0=0.15$A. The Zn-Zn distance is 2.65A, so that $\lambda_0$ is 6 percent of this bond length. The percentages are substantially less than that for $H_2O$, and more like that for the glass. Probably each substance has its characteristic percentage determined by its valences, type of binding, etc.

TABLE II. (Temperature 75°F, 297°A). Unit activation energies, $\alpha$.

| Material | $m$(in.²/lb.) | $E$(lb./in.²) | $\alpha$ |
|---|---|---|---|
| Disannealed Pyrex, dry | $0.72\times 10^{-5}$ | $8.86\times 10^6$ | $10.7k$ |
| Scratched Pyrex, wet | 1.74 | $8.86\times 10^6$ | $4.44k$ |

| Plate glass, dry | 2.93 | $1.00\times 10^7$ | $2.33k$ |

### F. Testing Procedure

Some tests on breaking strength or on fatigue are conducted with a steadily increasing load. Such tests are difficult to interpret because of the difficulty of integrating the effects of the load over a period of time. Some tests, for example, on organic plastics, are conducted under such a condition that the cross section of the sample decreases markedly during the test. These tests are also difficult, if not impossible, to interpret. Some tests apply a periodic or cyclic stress, the mean value of which may or may not be calculable. The simplest method of testing which will give results useful from a theoretical point of view are those conducted at constant stress.

The condition of the surface of the material, of course, plays an important role in determining its strength characteristics. Presence of scratches or notches act as stress concentrators and, therefore, make it difficult to calculate the actual stress existing prior to failure. Probably one of the main factors in causing scatter of test results is just this inability to be able to determine actually the stress which exists at the point where fracture starts. Precompression of the surface by special heat treatments or, in the case of metals, by peening, tends to raise the strength. However, if the amount of pre-stressing is not accurately known, the net tensional stress existing will not be truly known.

In view of the well-known influence on strength of the size and shape of the specimen, it is necessary that this be recognized in any series of tests. James Bailey[11] has given a statistical treatment

---

[10] C. W. Parmelee, K. C. Lyon, and C. G. Harmon, "The surface tensions of molten glasses," Univ. of Ill. Eng. Exp. Sta. Bull. Ser. No. 311 (1939).

[11] J. Bailey, "An attempt to correlate some tensile strength measurements on glass," Glass Ind. **20**, 21, 59, 95, 143 (1939).

which shows that if surface defects (flaws) are distributed randomly, the probability of obtaining a flaw in the highly stressed region of the specimen becomes a function of the stressed area. His idea explains the fact that the mean strength of a number of rods or laths is higher when tested in cross-bending by the single knife-edge method than by the double knife-edge method. In some A.S.T.M. experiments made at Corning, these mean values were 15,000 and 10,000 p.s.i., respectively. The latter method establishes a high uniform stress over a large area, whereas the single knife edge produces a high stress gradient.

Bailey saw that his theory was not sufficient to account for the very high strength of glass fibers, and he postulated that possibly there was a very good orientation of the "flaws" in these fibers, parallel to the fiber axis. Later, Powell and Preston[12] showed that equally high strengths could be obtained on large pieces of glass under certain conditions of loading. These authors concluded that the assumption of oriented flaws was of no help in explaining the high strengths. The writer makes an alternate proposal in this regard: exceptionally high strengths always appear to be associated with tests which place some part of the specimen in compression. Thus, for example, fine wires or fibers are compressed radially while being stretched axially, and the strength goes up as the diameter diminishes. Likewise, in the Hertz ball method[12] the area directly beneath the ball is under compression, surrounded by a cone in radial tension. The smaller the ball the higher is the measured breaking strength of the glass. Careful analysis of the stress distribution in these two cases should lead to a relation between strength and area which should be valid if the duration of the stress to produce fracture, i.e., the breaking time, is kept constant.

Bailey recognized that time is a factor in determining the breaking strength of glass, and in fact he conducted a series of tests "wherein strips of window glass were loaded by bending to a stress corresponding to approximately 12,000 p.s.i. in about 0.2 sec., then released and reloaded at a rate of about 1 cycle per sec. The samples were eventually broken by this repeated loading. The usual spread of results was found but the evidence was definite that the effect of repeated loading was, at least to some degree, cumulative. Fatigue effects could, no doubt, be entirely removed by annealing or heating the glass to a sufficient temperature to permit molecular rearrangements."

TABLE III. Molal activation energies, $Q$, for fracture.

| Material | Time ($t$) (sec.) | $f$ (p.s.i.) | $E/f$ | $Q$ (cal.) |
|---|---|---|---|---|
| Disannealed Pyrex, dry | 0.01 | 24,600 | 360 | 7,704 |
| | 1.00 | 17,100 | 518 | 11,085 |

| Soda-lime glass, wet | 10.00 | 10,500 | 952 | 8,625 |

## G. Importance of the $E/f$ *vs.* log$t$ Relation

The present theory indicates the desirability of plotting $1/f$ or $E/f$ *versus* log$t$. Objection may be raised to the use of reciprocal stress, $1/f$, on the ground that it is a difficult concept to understand. On the other hand, $E$ can usually be determined, and it is preferable to use $E/f$, which is the ratio of Young's modulus to the stress, and is a pure number. A plot of $E/f$ as ordinate *vs.* log$t$ as abscissa, should yield a straight line having the slope $2.3kT/\alpha$. A steep slope thus denotes a small value of $\alpha$, while a nearly horizontal line denotes that $\alpha$, the unit activation energy, is quite large. Increase of $T$ will increase the slope, if $\alpha$ remains constant.

When the object has been pre-stressed to a surface compression, $x$, parallel to the applied tension, the net tension is $f-x$. In this case a plot of $E/(f-x)$ *vs.* log$t$ should be linear, and a plot of $E/f$ *vs.* log$t$ should be concave downward. The magnitude of the original compression, $x$, can be determined by trial, until the plot of $E/(f-x)$ *vs.* log$t$ becomes linear. It may also be determined analytically by simultaneous solution of three equations, since the only unknowns are log$k_0$, $\alpha$, and $x$. In order to insure constancy of $\alpha$, the sample should be allowed to come to equilibrium with the chemical environment, before stress is applied. The existence of a substantial precom-

---

[12] H. E. Powell and F. W. Preston, "Microstrength of glass," J. Am. Ceram. Soc. 28, 145 (1945).

pression, $x$, may be responsible for the extremely long life of specimens when tested under low tensions, $f$, since $f-x$ may actually be quite small.

If a systematic study is made of the variation of $\alpha$ resulting from different chemical environments, e.g., moisture, oxygen, moisture plus oxygen, vacuum, etc. a pattern will undoubtedly develop which will lead to a more detailed understanding of the chemistry of the stress-corrosion process in any particular case, and of the means of protection. Some examples will now be presented.

## III. CALCULATION OF $\alpha$ FOR SEVERAL GLASSES

Data summarized by Glathart and Preston in their Table I "Average breaking stress in pounds per square inch (and its reciprocal) for various durations of load" permit calculation of the slopes $m$. These are shown in Table II. Additional columns show $E$ (from the International Critical Tables) and $\alpha$ calculated from the equation $m=2.3kT/E\alpha$. The value of the Boltzmann constant $k=1.38\times10^{-16}$ ergs per degree, but for convenience $\alpha$ will be expressed as a certain number of $k$'s, rather than in absolute units.

The molal activation energies, $Q$ (Table III), may be calculated for each value of the breaking stress at corresponding durations of load, by the equation $Q=N\alpha E/f$, where $N=$ Avogadro's number and where $Nk=R=2$ cal./mole. Typical calculations will be made for breaking times of 0.01 sec., 1 sec., and 1000 sec. We shall also calculate the results for a vacuum-baked (350°C) soda-lime glass where $m=0.04\times10^{-5}$ in.$^2$/lb., assuming $E$ to be $1.0\times10^7$ p.s.i. In this case $\alpha=171k$. (See Fig. 2.)

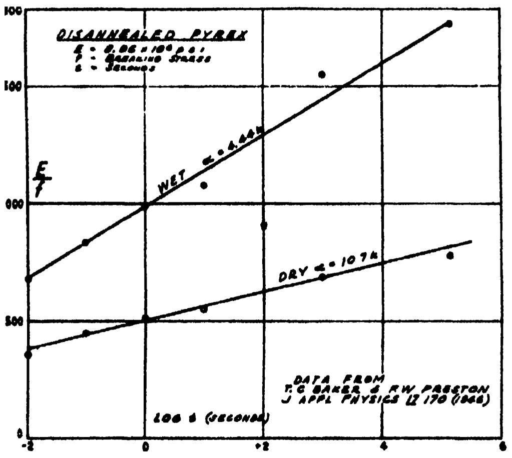

FIG. 2. $E/f$ *vs.* log$t$ for wet and dry Pyrex under static load.

It is to be noted that the molal activation energies are not large under wet conditions or "ordinary" conditions of dryness. They are of the order of 8000–16,000 cal. This can be compared with the activation energy for electrolytic or ionic conduction in soda-silica glasses (25,000 to 30,000 calories per mole.), as found by Seddon, Tippett, and Turner.[13] On the other hand, when special pains are taken to produce very dry glass, as by baking in vacuo, the molal activation energy for fracture is 135,000 cal., roughly 15 times as large as that for glass in its "ordinary" condition. The "catalytic" role of water is obvious. It provides a mechanism of low activation energy. The 135,000-calorie value is very nearly identical with 140,000 cal. for the delayed elastic process in soda-lime glass in the annealing range of temperature as found by Taylor, McNamara, and Sherman.[9] The close agreement indicates that the rate controlling process for fracture is in reality a delayed elastic phenomenon.

### A. Constancy of Young's Modulus, $E$

In the preceding calculations, it was necessary to assume that $E$ is constant for a given glass regardless of its water content. This assumption is of doubtful validity because it would seem that the replacement of strong bonds by weaker ones should lower the modulus. The writer has been unable to find the report of any scientific study of the role of water on the elastic modulus of glass. However, there is a small variation in moduli of various samples which could be attributed to varying water content. Some erratic data on vitreous silica, shown by Sosman,[14] show about twofold variation in modulus.

A reduction of $E$ would result in a corresponding increase of the calculated $\alpha$, since $\alpha=2.3kT/Em$, but, on the other hand, would

---

[13] E. Seddon, J. Tippett, and W. E. S. Turner, "Electrical conductivity of sodium metasilicate-silica glasses," J. Soc. Glass. Tech. 16, 450 (1932).

[14] R. B. Sosman, *Properties of Silica* (Chemical Catalog Company, New York, 1927), p. 450.

have no effect on the computed molal activation energies, $Q$, for fracture, since

$$Q=(E/f)N\alpha=(EN/f)(2.3kT/Em)$$
$$=(2.3RT/m)/f.$$

In fact, the molal activation energies are given directly by multiplying by $2.3RT$ the last term of the Glathart-Preston equation

$$\log t=-a/m+1/fm.$$

### B. Effect of Temperature

The effect of temperature on the strength and fatigue of soda-lime glass rods has been measured by B. Vonnegut.[15] Table IV shows values of $m$ which I have computed from that data. The last column shows $\alpha$, based on the equation $\alpha=2.3kT/Em$. $E$ is assumed to be $1\times10^7$ p.s.i. at all temperatures, for lack of better information. The value of $\alpha$ at 20°C based on Baker's work (see Table I) is $4.53k$. Vonnegut and Glathart state that they believe their "fatigue" to be too large at 24°C which leads to too small a value for $\alpha$. Similarly, $\alpha$ at 110°C is probably a little too large. There appears to be a minimum value for $\alpha$ at about 200°C. The rise in $\alpha$, that is, in activation energy, at higher temperatures is undoubtedly due to loss of moisture from the glass. At the very low temperatures the moisture is less active, possibly because of a very slow rate of diffusion into the glass at such temperature. It is to be noted that in no case, even at 520°C, does $\alpha$ rise as high as when the glass is vacuum-baked at 350°C ($\alpha=171k$). This shows how strongly moisture is retained by silicate glasses. Vonnegut and Glathart drew the conclusion that variation in the activity of adsorbed moisture on the surface of the glass is the primary cause of strength variation, and suggest that experiments should be made "over the same temperature range in high vacuum, in the absence of adsorbed films."

### C. Evaluation of Log$k_0$

The general equation

$$\log t=-\log k_0+(E\alpha/2.3kT)/f$$

permits evaluation of $\log k_0$ by determining the value of $1/f$ when $\log t=0$. In such a case $(E\alpha/2.3kT)/f=\log k_0$. The corresponding empirical equation is $1/fm=a/m$. Table V lists $1/f$, $m$, and $a/m=\log k_0$, for soda-lime glass at several temperatures, based on Vonnegut's data. No simple interpretation of the numerical values of $\log k_0$ can be given because of the variation in moisture content following the different heat treatments. The size of the rod specimens, and their surface condition as to scratches, etc., also affect $\log k_0$. A study of the breaking strength at various times and temperatures of thoroughly dry glass would be very desirable. Such measurements should be paralleled by determinations of the modulus $E$. It is also of importance to find the systematic relationship between $E$ and moisture content at various temperatures.

### IV. FRACTURE OF METALS: STRESS-CORROSION PHENOMENA

The subject of fatigue failure of metals has received a great deal of attention. References 16–27 inclusive contain data which are of interest in connection with any theory of the mechanism of fracture.[16–27] In general this work supports the

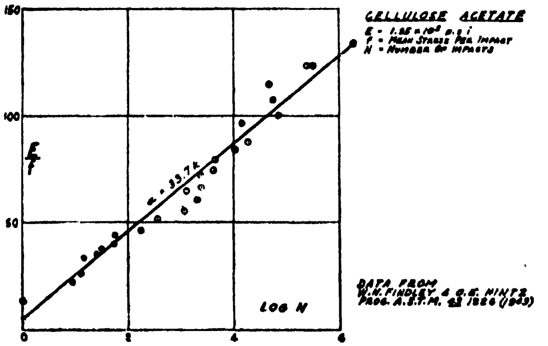

FIG. 3. $E/f$ vs. $\log N$ for cellulose acetate fractured under $N$ impacts.

TABLE IV. $m$ and $\alpha$ at various temperatures.

| Temperature | | $m$(in.$^2$/lb.) | $\alpha$ |
|---|---|---|---|
| −190°C | 83°A | $0.23\times10^{-5}$ | $8.31k$ |
| −80°C | 193°A | 0.33 | $13.48k$ |
| 20°C | 293°A | 2.70 | $2.50k$ |
| 110°C | 383°A | 2.89 | $3.05k$ |
| 200°C | 473°A | 4.20 | $2.59k$ |
| 300°C | 573°A | 3.10 | $4.26k$ |
| 420°C | 693°A | 1.42 | $11.2k$ |
| 520°C | 793°A | 0.94 | $19.4k$ |

idea that deformation or atomic rearrangement is a prelude to fracture and that even quite mild corrosive agents accelerate the process. However, I have not found fatigue data covering a time range which in any way approaches the $10^7$ factor which Baker was able to investigate in his glass work. The metallurgical data are particularly deficient in the short-time high stress region.

## V. FRACTURE OF ORGANIC "RESINS"

W. N. Findley and O. E. Hintz, Jr.[28] have published a paper entitled, "The relation between results of repeated blow impact tests and of fatigue tests." Their Fig. 5 is an $(S-N)$ diagram, stress *versus* log cycles, for repeated impact and fatigue-bending tests of cellulose acetate containing 26 percent plasticizer. Mr. Findley has very kindly furnished me with his actual data on number of blows at various stresses. His data can be represented by the equation: $\log N = -2.68 + 1/(0.523\times10^{-4}f)$, over the range from 10 cycles to $1.87\times10^6$ cycles. The deviation of the actual points from the straight line is no greater than the variation between comparable points at the same (or nearly the same) $\log N$. We shall take $m = 0.523\times10^{-4}$ in.$^2$/lb. Since the stress is not steady but periodic, we shall consider the mean stress over a cycle to be one-half of the recorded stress. On this basis $m = 1.05\times10^{-4}$ in.$^2$/lb. (See Fig. 3.) The unit activation energy $\alpha = 2.3kT/Em$. Findley and Hintz found $E = 1.95\times10^5$ p.s.i., and $t = 77$°F, which is 298°A. We shall use $T = 300$°A in the calculations. Thus $\alpha = 33.7k$. This is quite large compared to normal (wet) glasses where $\alpha$ ranged from $2k$ to $10k$. However, $Q$, the molal activation energy ranges from 1735 cal. (for failure in 10 impacts) to 8622 cal. (for failure in $10^6$ impacts). The corresponding values of $E/f$ are 25.7 and 128, respectively. It would be of interest to examine the relation between $\alpha$ and the kind and amount of plasticizer present.

A rough idea of $\lambda_0$ for the cellulose acetate can be obtained from the relation $\lambda_0 = 2\gamma/E$. We estimate that $\gamma$ is about 50 dynes/cm. Hence, $\lambda_0 = 0.7$A (approx.), which is about one-half of the typical C−O distance 1.42A. The typical C−C distance is about 1.54A.

This work on the fracture failure of cellulose acetate appears to demonstrate the validity of the theory when applied to a brittle organic plastic, having a modulus $E$ as low as $1.95\times10^5$ p.s.i. Since some glasses have $E$ values as high as $10^7$, a wide range of applicability is indicated.

At temperatures below zero Centrigrade, many of the common synthetic and natural organic polymers show brittle behavior. Strong threads of silk, cotton, hemp, etc., are brittle at ordinary temperatures. It would be of interest to study these materials in a quantitative way with the aid of the principles set forth in this paper.

## VI. DESIGNING STRONG PRODUCTS TO LAST

The modulus of elasticity is a fundamental constant of matter. On the other hand, it is wrong to assign one definite tensile strength to a material or even to an object, because its atoms can move and let it be broken at any stress, if the latter is applied long enough. Further, if the atmosphere or the medium has any chemical action on the material, its "strength" may decline rapidly.

[28] W. N. Findley and O. E. Hintz, Jr., "The relation between results of repeated blow impact tests and of fatigue tests," Proc. A.S.T.M. **43**, 1226 (1943).

The highest apparent tensile strengths are always observed where the procedure of the test places some part of the object (e.g., the surface layer) under compression. This can occur in the testing of wires, fibers, and foils, and also of more massive objects loaded on a minute area by the Hertz ball[12] (or other) method. For practical purposes the greatest progress toward highest usable strengths per unit of weight will come by paying attention to the shape factor—the use of wires, fibers, thin sheets, laminations, etc. These shapes possess a large specific surface area, which renders them more sensitive to corrosive agents. Hence, the pertinent chemistry must be well understood, and proper steps taken to make the material inert to its future environment, if this is known. The manufacturing procedures should be directed toward introducing compression into the surface region, and the product so designed and fabricated that tension stresses in service are kept to a minimum. Thus chemistry, physics, and engineering unite to form a stable tripod which carries the promise of better things for the needs of man.

TABLE V. Log$k_0$ at various temperatures.

| Temp. | $1/f$(in.$^2$/lb.) | $m$(in.$^2$/lb.) | $a/m=\log k_0$ |

I wish to express my thanks to several of my colleagues in the Research Department of the Minnesota Mining and Manufacturing Company, in particular to: C. A. Dahlquist, J. O. Hendricks, G. R. Pole, A. F. Schmelzle, H. M. Scholberg, H. N. Stephens, and W. W. Wetzel, for fruitful discussions.

I am indebted also to my friends, J. O. Almen, F. O. Anderegg, H. Eyring, J. L. Glathart, F. H. MacDougall, A. Nadai, E. L. Piret, E. F. Poncelet, F. W. Preston, and H. C. Urey, for suggestions and criticism and for the stimulus arising from their genuine interest in "how things break."

# Acceleration of Electrons by a Resonant Cavity*

FRANK L. HEREFORD, JR.**
*Physics Laboratory, University of Virginia, Charlottesville, Virginia*

(Received June 16, 1947)

Electrons were accelerated by means of a single resonant cavity operating at 75-cms wave-length. Energies as high as 0.75 Mev were attained by single-stage acceleration, the electrons entering the cavity at virtually zero velocity. By turning the emergent beam about, and reinjecting it into the cavity in the opposite direction two stage acceleration was achieved and 1.25-Mev electrons were produced. Possibilities of a "shuttle accelerator" are discussed.

AMONG the various schemes currently being applied to the acceleration of charged particles is a linear accelerator[1,2] comprising a series of cavity resonators so arranged that the stream of particles passes successively through each cavity gaining energy from the high electric field in each resonator. In most of these methods, present plans specify a finite injection energy at the first cavity which in cases where this injection energy is as high as 1 to 2 Mev will require considerable apparatus.

This paper describes a single cavity electron accelerator similar to that employed by Bowen, Pulley, and Gooden[3] in which no injection apparatus is utilized, but rather the electrons enter the acceleration region at virtually zero velocity and by means of a single trip through the cavity are accelerated to relativistic energies of the order of 0.75 Mev. Such a scheme provides a simple and compact device for the production of intense pulsed beams of high energy electrons in the relativistic energy range.

A new multiple-stage acceleration method has also been successively worked out in which the beam emerging from the cavity is turned sharply through 180 degrees by an appropriate magnetic-field configuration and caused to traverse the acceleration region in the opposite direction a half cycle after the first traversal. This method offers possibilities of a "shuttle" accelerator whereby a single cavity might yield energies in the 10-Mev range.

## EXPERIMENTAL APPARATUS

The cavity employed was of the reentrant type as shown in Fig. 1. It was operated at a wave-length of approximately 75 cm, the source of high frequency power being a Western Electric 7C22 pulse operated twin triode. This tube is tunable over a 390–425-megacycle range and has a maximum peak power rating of 500 kilowatts. It was operated in this case on a four-micro-second pulse, the repetition rate being 60 cycles per second, yielding a duty cycle of 0.00024. The pulse was formed by means of a conventional spark-gap modulator with an artificial transmission line forming the square wave.

The details of the cavity construction are shown in Fig. 2. It was made from brass and later copper plated to increase the $Q$. Tuning was accomplished by adjusting the gap distance between the inner conductors, the sylphon bellows shown in Fig. 2 making this adjustment possible during operation. The radio frequency power was fed into the cavity from the concentric line output of the 7C22 oscillator by means of a magnetic coupling loop. Another sylphon-bellows arrangement made possible adjustment of this loop during operation thus facilitating proper matching of the load to the oscillator. The loop itself is indicated in Fig. 1. It was made by slipping a section of sylphon tubing inside a length of ordinary wire shielding.

## PUMPING SYSTEM

The cavity was evacuated by a Distillation Product MC275 oil-diffusion pump backed by a Megavac. The pumping lead to the cavity was rather large, being 4″ in diameter and was covered at the cavity wall by a perforated $\frac{1}{32}''$ copper plate. This plate was made to fit the

[3] Bowen, Pulley, Gooden, Nature 157, 840 (1946).

inner wall contour of the cavity and the perforations were drilled along lines parallel to the cavity axis in order to minimize impedance to the wall currents.

By means of this system it was possible to evacuate the cavity to a pressure of $3\times10^{-6}$ mm Hg before the R.F. power was turned on. If the system had been exposed to air for an appreciable period before evacuation the pressure rose to about $4\times10^{-5}$ mm Hg in operation at resonance due to glow discharge. After several minutes of operation, however, the system cleaned up and the pressure dropped back to approximately $5\times10^{-6}$ mm Hg, where optimum acceleration conditions existed. The large 4″ diameter pumping lead to the cavity was definitely necessary in order that this condition be achieved.

### SINGLE-STAGE ACCELERATION

The source of electrons for single-stage acceleration was a 2″ length of tungsten wire wound in a helix and mounted just inside the cathode inner conductor as shown in Fig. 3(a). The filament was supported by a brass tube which slipped inside the cathode inner conductor and was adjusted by means of a sylphon bellows. Each side of the filament was coupled to the cathode inner conductor by circular mica condensers. This was necessary in order that the filament be electrically a short distance from the end of the cathode.

The essentials of the system insofar as electron optics is concerned are shown in this figure also. The gap distance of approximately 1½″ was of such length that an electron emerging at 0.75 Mev would traverse the gap in about one tenth of the 400-mc oscillator period or about $3\times10^{-10}$ second. No baffle was used over the end of the cathode inner conductor. The anode inner conductor was covered by a 0.030″ copper baffle with a ¼″ hole in the center. After traversing the acceleration region, *A*, the beam was collimated to a diameter of 0.060″, and the energy was measured by magnetic deflection, the radius of curvature being computed from the displacement on the willemite screen, *C*. The magnetic-field strength was measured by a flip coil and ballistic galvanometer and a gauss meter.

With the 7C22 operating at maximum plate voltage and the cavity properly tuned, electrons were accelerated to energies as high as 0.75 Mev. In general the extent of the spectrum was as follows:

| | |
|---|---|
| Lower limit | 0.30±10 percent Mev |
| Maximum intensity | 0.65±10 percent Mev |
| Upper limit | 0.75±10 percent Mev |

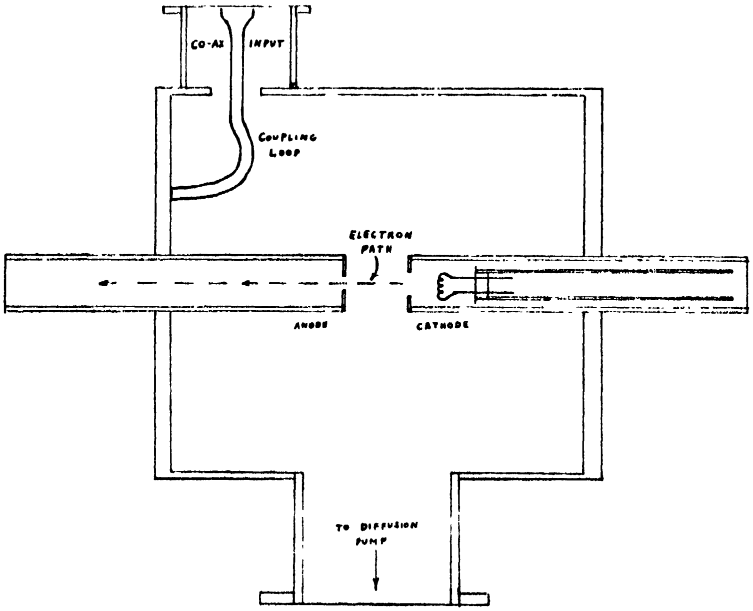

FIG. 1. A schematic drawing of the cavity as applied to single-stage acceleration.

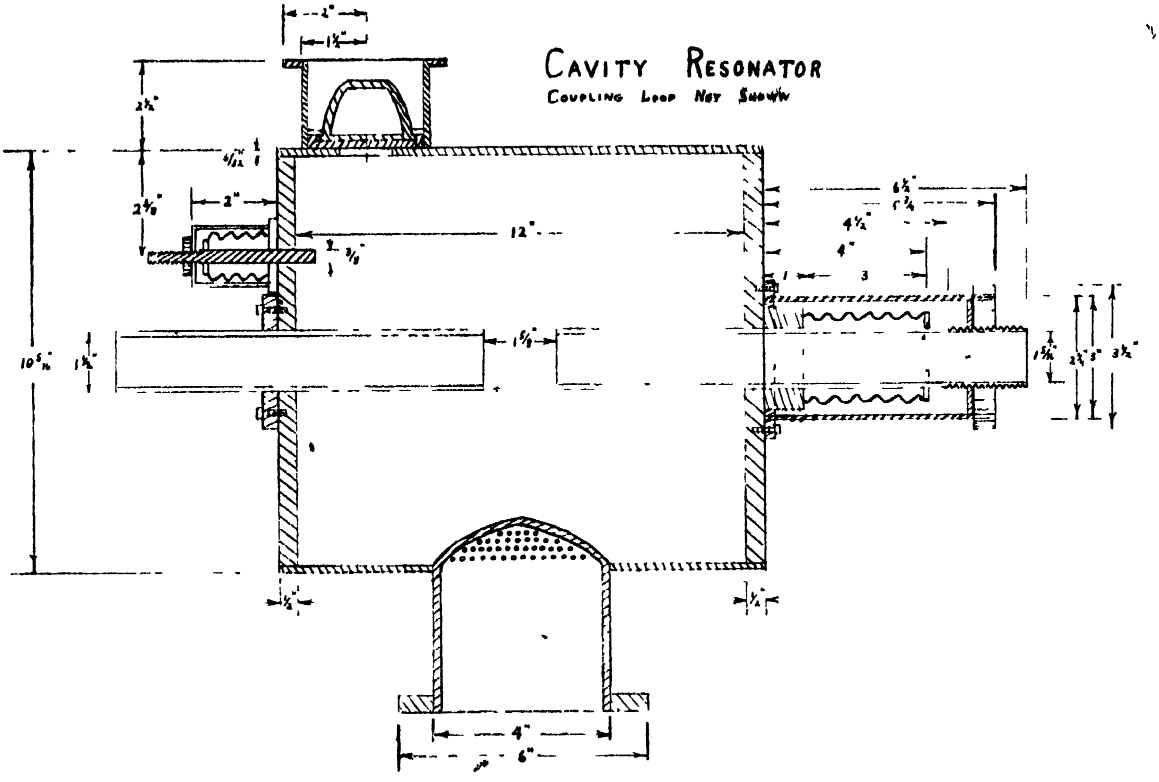

FIG. 2. Details of the cavity construction.

On several occasions an extremely narrow spectrum width was observed of the order of 50 to 100 Kev. Bowen, Pulley and Gooden[3] have reported a similar "energy bunching" effect. There seems no immediately obvious explanation of this phenomenon. A solution of the non-relativistic equations of motion of an electron in a spatially uniform electric field with a sinusoidal time variation predicts such an effect. In particular, if the energy imparted to the electron is plotted against the entrance phase angle, the curve is found to be approximately flat over a fairly large variation in phase angle. This characteristic of the curve, however, did not seem sufficiently pronounced to account for the extreme effect.

Various experiments were carried out to ascertain whether the effect was due to the focussing of only a given electron energy on the first 0.060″ aperture in the collimator, but in general changes in the electron-optics system did not effect the beam energy.

## BEAM CURRENT

By means of the scheme shown in Fig. 3(b) the current in the electron beam was measured. The beam was collimated by two $\frac{1}{4}''$ diameter apertures and electrons were collected in a Faraday cage mounted just behind the second aperture. This cage was made 7″ in length to reduce losses due to secondary electron emission from the walls.

It was possible to maintain a steady electron current to the cage of 17 microamperes. In view of the duty cycle of 0.00024 this indicated a mean beam current during the pulse of 70 milliamperes. Since the average energy was approximately 0.65 Mev, this rather high current represents a peak power loss in the $\frac{1}{4}''$ beam of 45 kilowatts. In addition to this beam there is a return beam in the opposite direction caused by the liberation of secondary electrons at the anode, some of which are emitted from the anode surface when the field is in such a direction to accelerate them. With the cavity set up for double stage acceleration as described below this return beam of secondaries was actually observed. If we assume the current in this beam to be approximately equal to that in the primary beam, we see that approximately 90-kilowatts peak power is absorbed in the electron beam alone.

The power dissipated in the cavity walls was determined by measuring the temperature rise in the walls with the R.F. power on and the cavity tuned and comparing it to the temperature rise with a heater of known dissipation in the cavity. This dissipation was found to be 220±20 kilowatts. Thus the total peak power absorbed by the cavity and the electron beam was approximately 300 kilowatts.

## DOUBLE-STAGE ACCELERATION

Using the same cavity employed in the single-stage system, double-stage acceleration was achieved by turning the beam sharply through 180 degrees as it emerged from the cavity and re-injecting it in the opposite direction. In order to carry out this scheme it was necessary to redesign the filament assembly to allow the return beam of electrons to pass through the cathode inner conductor. Furthermore, the cavity geometry was altered as indicated in Fig. 4. It was, of course, necessary that the total distance that an electron travel in emerging from the cavity, being turned about and re-injected be approximately that distance travelled in one half cycle by a 0.65-Mev electron, that being the mean energy of the beam after a single acceleration.

The double-stage system is shown in Fig. 4. The beam was not collimated after the first traversal of the gap. The two magnets used to reverse the beam direction had $\frac{3}{4}'' \times 1''$ pole faces spaced at $\frac{3}{8}''$. Magnet *A* was an electromagnet of field strength about 500 gauss, while magnet *B* was a permanent Alnico magnet of field strength about 7000 gauss. The value of $H\rho$ for 0.65-Mev electrons is 3400 gauss cms; thus the magnet *B* should turn the beam in a radius of $\frac{1}{2}$ cm.

The energy of the return beam of electrons was measured by an improved magnetic-deflection method. A wide spectrum was observed with limits as follows:

| | |
|---|---|
| Lower limit | 0.30±10 percent Mev |
| Upper limit | 1.25±10 percent Mev |

This width, however, was not due entirely to the return beam of doubly accelerated electrons. When the beam reversal magnets were removed the upper limit of the spectrum dropped to about 0.7 Mev, this beam arising from secondary emission at the anode as previously stated. Thus the lower limit of the doubly accelerated beam was approximately 0.7 Mev. The current in the return beam was considerably smaller than in the primary beam, but with improved focussing it should be possible to increase it appreciably.

There seems to be no obvious reason why such a "shuttle" acceleration method could not be applied to the production of higher energy electrons, perhaps in the 10-Mev range. With an extremely high magnetic field to reverse the beam direction the electron path in this field would be a negligible portion of the total path

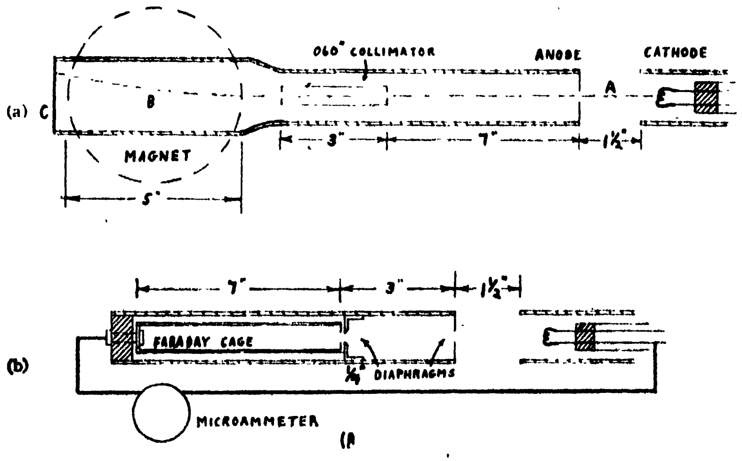

FIG. 3. (a) Schematic drawing of the single-stage system. (b) Arrangement for measurement of beam current.

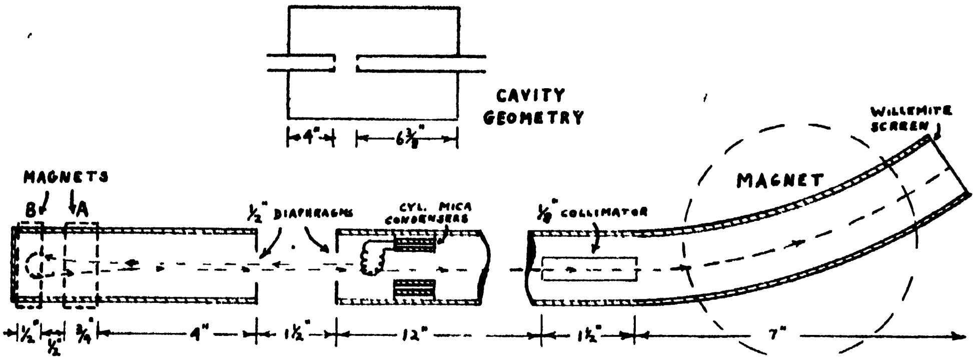

FIG. 4. The double-stage acceleration system.

per stage and consequently the increase in path due to the relativistic mass increase of the electron would not cause dephasing difficulties. Radiation losses in the reversal of the beam are of negligible value. According to an expression given by Schwinger,[4] the energy radiated in turning a 10-Mev electron about in a field of 25,000 gauss is less than 1-electron volt.

The author wishes to express his indebtedness to Professors J. W. Beams and L. B. Snoddy for the frequent and helpful advice which they gave in consultation. Their constant interest and willingness to help was sincerely appreciated. The work of Messrs. Fritz Linke and Phillip Sommer who constructed the cavity and parts also contributed much to the completion of the project.

# Infra-Red Spectra of Hydrocarbons

## II. Analysis of Octane Mixtures by the Use of Infra-Red Spectra Obtained at Low Temperatures*

W. H. AVERY** AND J. R. MORRISON

(Received June 17, 1947)

Infra-red spectra in the region 2 to 22 microns were obtained for the four trimethylpentanes, at temperatures of 0°C and $-195$°C. In agreement with theory, the band "widths" at $-195$°C are roughly half as great as at 0°C. The spectra were observed experimentally by condensation of a film of the hydrocarbon on the reflecting bottom surface of a cell mounted vertically, with its lower end immersed in ice or liquid nitrogen. A method of forming films of reproducible dimensions and thickness is described.

To provide a quantitative estimate of the advantage for analytical purposes of the use of spactra obtained at low temperatures, an expression is derived which gives the probability (for random distribution of the band positions) that at least one band can be found for each component of a mixture, which does not "overlap" bands of the other components. Application of the formula, with some simplifying assumptions, to a mixture of the 18 octane isomers, indicates that reduction of the band "width" from 40 $\text{cm}^{-1}$ to 20 $\text{cm}^{-1}$ (corresponding to the temperature change from 0°C to $-195$°C) increases the calculated probability of the existence of a "non-overlapped" band for at least 17 of the isomers from 0.003 to 0.999. The importance of this result in infra-red analyses is pointed out.

The use of spectra obtained at liquid helium temperatures is suggested as offering attractive possibilities for the analysis of complex mixtures.

### INTRODUCTION

THE theoretical background leading to the utilization of the low temperature technique for infra-red absorption measurements and its obvious advantages in the analytical field have been outlined previously.[1] The present paper deals with the applicability of the tech-

---

* The work reported here was completed early in 1942. Publication was delayed by the pressure of other work during the war.

** Present address is Applied Physics Laboratory, Johns Hopkins University, Silver Spring, Maryland.

[1] W. H. Avery and C. F. Ellis, J. Chem. Phys. 10, 10 (1942).

nique to the analysis of multi-component mixtures of paraffin hydrocarbons of eight carbon atoms, a complex problem of commercial as well as scientific interest since the available analytical method of precision distillation is arduous and time-consuming. Comparative absorption spectra of the trimethyl pentanes of 0°C and −195°C are presented to substantiate a theoretical discussion of the effect of band width in the problem of analyzing a complex mixture by spectroscopic methods.

## EXPERIMENTAL

The spectrometer has been described,[2] but the optical arrangement and the absorption cell mounting for low temperature measurements[1] have been revised considerably.

The present optical arrangement (Fig. 1) has the advantage of allowing the entrance of the light beam nearly normal to the cross section of the absorption cell, permitting the use of a smaller diameter cell without interception of a part of the beam. A Nernst glower, *N*, is located a few millimeters on one side of the focus of a 60° off-axis paraboloidal mirror, *P*.*** Radiation from the glower is reflected in a parallel beam from the mirror, *P*, and strikes the bottom of the cell, a plane reflecting (gold or aluminum) surface, $M_5$, at a nearly perpendicular incidence. After reflection from $M_5$ the radiation returns to the mirror, *P*, which focuses it on the plane mirror, $M_6$. $M_6$ and *N* are situated symmetrically on opposite sides of the focal point of the mirror, *P*. $M_6$, which is also at the focal point of the off-axis paraboloidal mirror $C_1$, directs the deflected beam to $C_1$. From $C_1$ the collimated beam is focused upon the entrance slit of the spectrometer by means of plane mirror $M_3$ and the condensing mirror $C_2$.

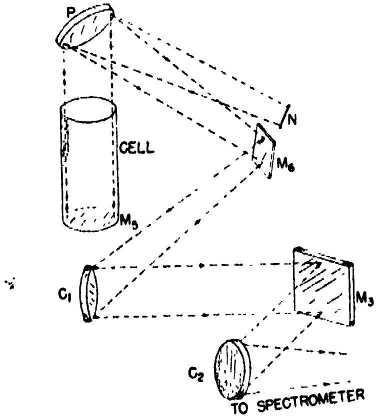

Fig. 1. Optical arrangement for low temperature spectra.

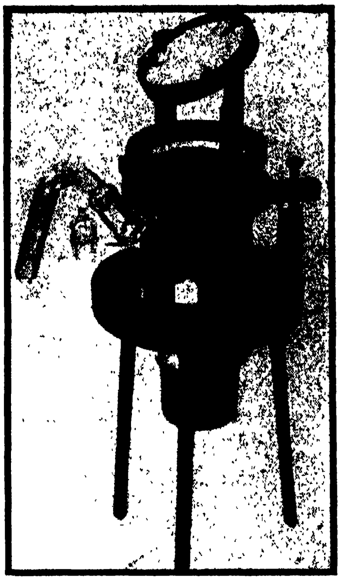

Fig. 2. Absorption cell for low temperature spectra.

The absorption cell,† 7 cm in diameter, 15 cm in depth, and fitted with a side arm for convenient sample retention during blank energy determinations, is mounted in the holder shown in Fig. 2. Both the cell holder and its supporting tripod are set into V-ways to facilitate the accurate reproduction of the cell position after filling. A similar kinematically designed arrangement permits the removal and replacement of mirror *P* without disturbing its focus. Leveling of the cell and mirror is accomplished through convenient adjustment screws.

In the original procedure a measured quantity of the sample to be examined was retained in the side arm of the absorption cell during the recording of the energy of the source in a desired spectral region. The sample was then evaporated

---

*** The mirror was prepared by the Bausch and Lomb Optical Company by cutting a section from the edge of one of their large paraboloidal searchlight mirrors.

† Obtained from the American Instrument Company.

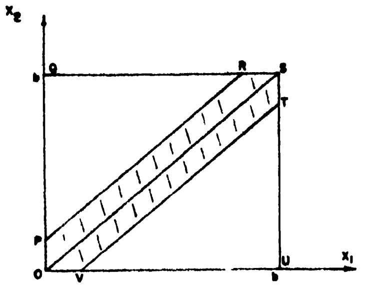

FIG. 3.

from the side arm, condensed upon the cooled cell bottom, and the same spectral region again recorded. Percentage transmissions were computed from sample to blank ratios or recorded directly by the method previously described. (A suitable factor was applied in plotting absorption curves to correct for the scattering of incident radiation from the polycrystalline film.)

The cooling of the cell bottom to −195°C was accomplished through immersion in a Dewar flask containing liquid nitrogen. By this method, however, reproducible thicknesses of deposited films were difficult to obtain since a small, variable amount of sample condensed on the cell wall adjacent to the bottom. To overcome this difficulty, a copper cylinder of a slightly smaller diameter than the cell (shown in Fig. 2) was clamped concentrically to the bottom of the cell, the cylinder rather than the cell being immersed in the liquid nitrogen. Intimate thermal contact was maintained through a thin oil film interposed between the cylinder and cell. With this arrangement the sample condensed as an accurately defined disk which did not extend to the side walls and the films were repeatedly of the same thickness to a high degree of precision. A similar technique, with the copper cylinder being immersed in an ice bath, may be used for liquid films, since films of thicknesses useful in infra-red investigations do not spread after deposition.

An absorption cell of this type presents many advantages over the conventional shim-type cell. There is no danger of contamination or evaporation of the sample; the temperature may be varied at will without condensation of water vapor or loss of sample; the sample may be recovered after examination; films of any useful thickness may be employed; the thickness may be easily varied; and, finally, the spectrum of the blank may be easily obtained.

## THE ANALYSIS OF OCTANE MIXTURES

Simplicity, accuracy, and rapidity in an infra-red analysis of a multi-component mixture depend primarily upon the location of strong absorption bands unique for each compound of interest in a spectral region relatively free from absorption by the remaining components. (An additional method has been developed[3] involving the solution, for an $n$-component system, of $n$ simultaneous equations wherein the augumentation of principal absorption by secondary absorbers caused by overlapping of bands is considered, but in this method the complexity of solution becomes increasingly great with increased values of $n$.)

Since the band widths are roughly one-half as great at −195°C as at room temperature, it is immediately obvious that the probability of locating interference-free, "characteristic" bands is increased by the utilization of the low temperature technique. A quantitative estimate of the increase is deduced in the theoretical treatment given below of the probability that an infra-red analysis can be made, taking as a criterion of possibility that at least one band of all but one of the components does not overlap a band of any other component. (It would not be necessary to find a characteristic band for each component since if all but one could be determined by the infra-red technique the last could be found by difference.) An expression is obtained applicable to any number of compounds, having any number of bands apiece and having bands of variable width from compound to compound. The position of any band is assumed to be given purely by chance.

Given $M$ compounds, designated $A$, $B$, $C$, $\cdots M$, having $n_A$, $n_B$, $n_C$, $\cdots n_M$ bands of width $w_A$, $w_B$, $w_C$, $\cdots w_M$ cm$^{-1}$ distributed at random within a spectral region $b$ cm$^{-1}$ wide, we wish to find the probability that at least one band of each $M-1$ of the compounds will occur in a region unoccupied by any bands of the other compounds.

---

[3] R. R. Brattain, R. S. Rasmussen, and A. M. Cravath, J. App. Phys. 14, 418 (1943).

Consider first the case where $M=2$, $n_A=1$, $n_B=1$. Let $x_1$ represent the position of the center of the first band $(0<x_1<b)$, $x_2$ represent the position of the band center of the second compound, $0<x_2<b$. $x_1$ and $x_2$ may be plotted as rectangular coordinates (Fig. 3); then the coordinates of every point in the square $OQSU$ will correspond to a possible disposition of the centers of the two bands. Band $A$ will overlap band $B$ whenever

$$0<x_1-x_2<\frac{w_A+w_B}{2}$$

or when

$$0<x_2-x_1<\frac{w_A+w_B}{2}.$$

$$\left(\text{Let } OP=\frac{w_A+w_B}{2}=OV=RS=ST.\right)$$

All possible values of $x_1$ and $x_2$ that satisfy the first condition lie within the shaded area of $OVTS$, while all values of $x_1$ and $x_2$ that satisfy the second condition will be found in the area $OPRS$. Let

$$\frac{w_A+w_B}{2}=w_{AB}.$$

| 3.26 | 3067 | 3.26 | 3067 |
| 2.34 | 4274 | 2.43 | 4115 |

The probability, $P_{AB}$, that two bands chosen at random will overlap is, then, the ratio of the area $OPRSTV$ to the area $OQSU$, i.e.,

$$P_{AB}=\frac{b^2-\dfrac{2(b-w_{AB})^2}{2}}{b^2}=1-\frac{(b-w_{AB})^2}{b^2}. \quad (1)$$

The probability that the bands do *not* overlap is

$$Q_{AB}''=1-P_{AB}=\frac{(b-w_{AB})^2}{b^2}=\left(1-\frac{w_{AB}}{b}\right)^2. \quad (2)$$

Suppose now that $A$ and $B$ have each three bands labelled $A_1$, $A_2$, $A_3$, and $B_1$, $B_2$, $B_3$' the probability that $A_1$ does not overlap $B_1$, $B_2$, or $B_3$ is

$$\left(1-\frac{w_{AB}}{b}\right)^2\left(1-\frac{w_{AB}}{b}\right)^2\left(1-\frac{w_{AB}}{b}\right)^2$$
$$=\left(1-\frac{w_{AB}}{b}\right)^6=Q_{AB}'. \quad (3)$$

| 3.25 | 3077 | 3.16 | 3165 |
| 2.39 | 4184 | 3.06 | 3268 |

If $B$ has $n_B$ bands of width $w_B$,

$$Q_{AB}'=\left(1-\frac{w_{AB}}{b}\right)^{2n_B}.$$

Similar expressions are obtained for the probability that $A_2$ and $A_3$ (taken separately) do not overlap any $B$ bands.

The probability that at least one of the three $A$ bands does not overlap any of the $B$ bands will be the sum:

the probability that $A_1$ does not overlap any $B$ bands but $A_2$ and $A_3$ do
+ the probability that $A_2$ does not overlap but $A_1$ and $A_3$ do
+ the probability that $A_3$ does not overlap but $A_1$ and $A_2$ do
+ the probability that neither $A_1$ nor $A_2$ overlaps any $B$ bands but $A_3$ does
+ a similar term for $A_1$, $A_3$
+ a similar term for $A_2$, $A_3$
+, finally, the probability that neither $A_1$ nor $A_2$ nor $A_3$ overlaps any $B$ bands.

Substituting, the probability that at least one $A$ band does not overlap a $B$ band is:

$$\begin{aligned}Q_{AB}&=3Q_{AB}'(1-Q_{AB}')^2+3Q_{AB}'^2(1-Q_{AB})+Q_{AB}'^3\\&=[Q_{AB}'+(1-Q_{AB}')]^3-(1-Q_{AB}')^3\\&=1-(1-Q_{AB}')^3.\end{aligned}\qquad(4)$$

If $A$ has $n_A$ bands

$$Q_{AB}=1-(1-Q_{AB}')^{n_A}.\qquad(5)$$

If there are three compounds $A$, $B$, and $C$, the probability that at least one band of $A$ does not overlap any band in $C$ is

$$Q_{AC}=1-(1-Q_{AC}')^{n_A}.\qquad(6)$$

The probability that at least one $A$ band does not overlap any bands in either $B$ or $C$ is

$$\begin{aligned}Q_{AB}\cdot Q_{AC}&=Q_{A,B,C}\\&=[1-(1-Q_{AB}')^{n_A}][1-(1-Q_{AC}')^{n_A}].\end{aligned}\qquad(7)$$

Given $M$ compounds (where $M$ is any number), the probability that at least one $A$ band does not overlap any bands in any of the compounds is

$$Q_{A,B\cdots M}=\prod_{i=B}^{i=M}Q_{Ai}.\qquad(8)$$

Similarly, the probability that at least one $B$ band will be characteristic (i.e., not overlap) is

$$Q_{B,AC\cdots M}=\overset{(B\text{ omitted})}{\prod_{i=A}^{i=M}}Q_{Bi}.\qquad(9)$$

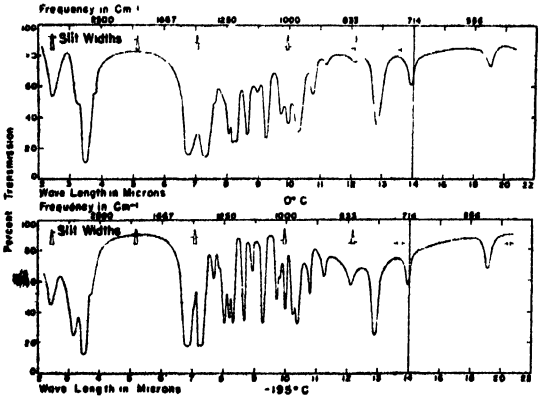

FIG. 4. Spectra of 2,2,3-trimethylpentane at 0 and −195°C.

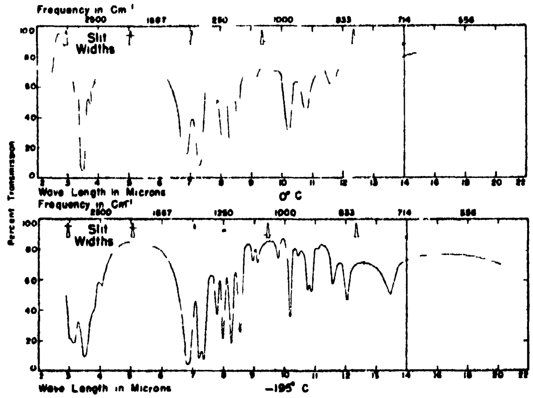

FIG. 5. Spectra of 2,2,4-trimethylpentane at 0 and −195°C.

The probability that $M-1$ compounds will have characteristic bands is††

$$P_{M-1}=\sum_{i=A}^{i=M}(1-Q_{i,A\cdots M})\prod_{j=A}^{j=M-1\ (j\neq 1)}Q_{j,A\cdots M}+\prod^{M}Q_{j,A\cdots M}.\qquad(10)$$

If the bands are all of equal width, $w$, and each

---

†† The symbol $Q_{j,A\cdot M}$ signifies that when $j$ is replaced by a given letter, that letter is to be omitted from the sequence of letters following the comma in subscript. Thus if $j=A$ we have $Q_{A,BC\cdots M}$. If $j=C$ we have $Q_{C,ABDE\cdots M}$, etc.

compound has the same number of bands, $n$, expression (10) may be simplified to

$$P_{M-1} = MQ_{A\,B\,M}^{(M-1)} - (M-1)Q_{A\,B\,M}^{M} \qquad (11)$$

$$P_{M-1} = MQ_{A,B\,M}{}^{(M-1)} - (M-1)Q_{A\,B\,.M}{}^{M} \qquad (11)$$

With these conditions,

$$Q_{AB}' = Q' = \left(1 - \frac{w}{b}\right)^{2n},$$

$$Q_{AB} = 1 - (1 - Q')^n = \left\{1 - \left[1 - \left(1 - \frac{w}{b}\right)^{2n}\right]^n\right\},$$

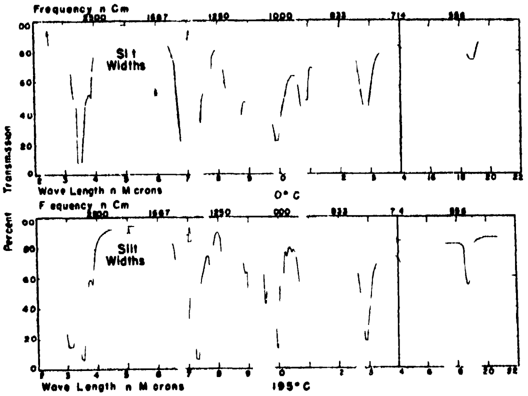

FIG. 6 Spectra of 2,3,3-trimethylpentane at 0 and −195°C

$$Q_{A\,B\,M} = \left\{1 - \left[1 - \left(1 - \frac{w}{b}\right)^{2n}\right]^n\right\}^{M-1},$$

$$P_{M-1} = M\left\{1 - \left[1 - \left(1 - \frac{w}{b}\right)^{2n}\right]^n\right\}^{(M-1)(M-1)}$$

$$-(M-1)\left\{1 - \left[1 - \left(1 - \frac{w}{b}\right)^{2n}\right]^n\right\}^{M(M-1)}$$

If $w = 0$, $P_{M-1} = M - (M-1) = 1$
If $w = b$, $P_{M-1} = 0 - 0 = 0$

If we make the assumptions, which are in approximate agreement with the facts, that all of the octane isomers have the same number of bands (15) in the region 500 to 1300 cm$^{-1}$ and that the band width at room temperature is 40 cm$^{-1}$, then: $w = 40$ cm$^{-1}$, $b = 800$ cm$^{-1}$, $n = 15$ bands, and $M = 18$ compounds

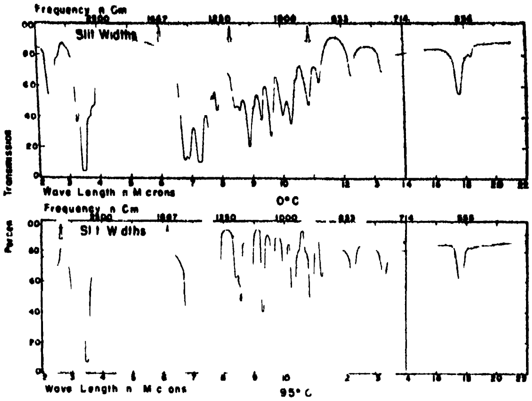

FIG. 7 Spectra of 2,3,4-trimethylpentane at 0 and −195°C.

$$Q_{A\,B\,M} = \left\{1 - \left[1 - \left(1 - \frac{40}{800}\right)^{30}\right]^{15}\right\}^{17}$$

$$= 0.628,$$

$$P_{M-1} = 18(0.628)^{17} - 17(0.628)^{18}$$

$$= 0.00268$$

When the temperature is −195°C

$$w = 40\left(\frac{78}{300}\right)^{\frac{1}{2}} = 20.4 = 20 \text{ cm}^{-1},$$

$b = 800$ cm$^{-1}$, $r = 15$ bands, $M = 18$ compounds

$$Q_{A\,B\,M} = \left\{1 - \left[1 - \left(1 - \frac{20}{800}\right)^{30}\right]^{15}\right\}^{17}$$

$$= 1 - 0.00132 = 0.99867,$$

$$P_{M-1} = 18(0.99867)^{17} - 17(0.99867)^{18}$$

$$= 0.999$$

Thus halving the band width enormously increases the probability that there will be a characteristic band for each compound.

This rather striking result has been reached through the use of the simplifying assumptions that (1) the band widths are all the same, (2) the band intensities are the same, (3) the octanes all have the same number of bands (15), and (4), that the bands are distributed at random within the interval 500–1300 cm$^{-1}$. None of the assumptions is strictly valid. However, an in-

spection of the spectra of the trimethylpentanes presented in this paper shows that (1), (3), and (4) are approximately correct. Consideration of differences in intensities instead of (2) would seriously complicate the problem. But it would appear that the general conclusion would be unchanged, i.e., that analysis would be greatly simplified by the low temperature technique. It would appear, therefore, that use of spectra obtained at −195°C would facilitate greatly the analysis of mixtures containing all of the octanes. Analyses of mixtures of greater complexity should be possible by use of spectra obtained at the temperatures of liquid hydrogen or helium.

## SPECTRA OF TRISUBSTITUTED OCTANES

Two previously published works have contained infra-red absorption measurements over extensive regions between 2 to 20 mu for compounds of this type. In 1933, Kettering and Sleator[4] obtained the spectrum of 2,2,4-trimethylpentane in the vapor phase between 1 and 16 mu, and in 1938 Lambert and Lecomte[5] obtained the liquid spectra of all of the octanes between 7 and 15 mu. However, these measurements were made with rather low resolution and consequently are unsuitable for analytical work.

The spectra obtained in the work reported here are shown in Figs. 4 to 7 while wave-lengths and frequencies of the significant bands are listed in Tables I to IV.

The film thickness employed in each experiment was 0.071 mm, representing an absorption path of 0.142 mm (since the light traversed the film twice) and each spectrum is the result of at least four determinations for the entire region 2–22 mu. Experimental difficulties attributable to interference of absorption bands of water and carbon dioxide in the air of the laboratory prevented accurate identification of the positions and intensities of the weak hydrocarbon bands

---

[4] C. F. Kettering and W. W. Sleator, Physics **4**, 47 (1933).

in the 4–6-micron region, but this region is unimportant in paraffinic surveys since the strong bands suitable for analysis occur in the region 500–1500 $cm^{-1}$.††† As a result, the curves serve only to illustrate the relative transmissions in this region.

A comparison of the positions and relative intensities of the bands at the two temperatures shows that only minor changes are produced by the change in state, with the exception of the 3-micron region. In the absence of more detailed examination of this region no explanation can be made of the pronounced bands at about 3 microns.

A comparison of the band widths in the liquid and low temperature spectra indicates close agreement between experimental and theoretical values. In nearly every case the band width at low temperature is equal (or less than) the value predicted by theory. The anticipated marked increase in resolution is also evident.

All of the pure hydrocarbons were prepared in this laboratory by the precision distillation of petroleum fractions in glass columns packed with helices. The efficiencies of the columns ranged from 60 to 100 theoretical plates. The physical properties of the samples, listed in Table V, indicate a purity of 99+ percent in every case.

TABLE V.

| Compound | *BP*, °F | $n_{20}^{D}$ | $d_4^{20}$ |
|---|---|---|---|
| 2,2,3-trimethylpentane | 229.6 | 1.40293 | 0.7160 |
| 2,2,4-trimethylpentane | 210.6 | 1.39157 | 0.6919 |
| 2,3,3-trimethylpentane | 238.6 | 1.40732 | 0.7253 |
| 2,3,4-trimethylpentane | 236.1 | 1.4045 | 0.7191 |

## CONCLUSIONS

Since a complete system of infra-red analysis cannot be developed without the spectra of all of the components for reference in locating characteristic bands, elaboration on an analytical method is reserved until the entire group of isomers has been studied. However, it is evident that such an analysis can be evolved, and through the use of diminished temperatures the method can be of a simple nature.

There exists the interesting possibility that the analyses could be further simplified by the use of liquid hydrogen or helium as cooling materials. If so, the bands would be roughly one-third to one-seventh as wide as at room temperature, assuming that the band width remains proportional to the square root of the absolute temperature.

## ACKNOWLEDGMENT

We wish to acknowledge our indebtedness to Mr. C. C. Templeton and Mr. C. F. Ellis who ably assisted in the experimental work, to Dr. H. T. Bollman, under whose direction the distillation of the samples was carried out, and to Dr. Harold Gershinowitz for his interest and advice.

---

††† In this region C–C stretching frequencies, $CH_2$, and $CH_3$ rocking and twisting, C–C–C bending frequencies, and torsional oscillations about the single bond occur. This interval is therefore most suitable for distinguishing structural differences between molecules.

# Magnetic Field Configurations Due to Air Core Coils*

JOHN P. BLEWETT**
*East Patchogue, Long Island, New York*

(Received June 17, 1947)

The field configurations around a circular loop of wire bearing current are discussed, and a tabulation is presented for the field component parallel to the axis of the loop. Formulae are derived for the current distribution which must obtain in cylindrical and ellipsoidal coils in order that the field inside be uniform. Several special cases are noted. The energy storage in the return flux is evaluated in each case.

## I. INTRODUCTION

THE designer of magnetic field coils who wishes to produce a field of a particular configuration is almost invariably hampered by the complexity of the associated mathematical analysis. If he is successful in this task, his formulae are usually so complicated that substitution in them is extremely tedious. In this paper an attempt has been made to simplify this problem, first by a partial tabulation of the fields due to a circular loop, the fundamental component of most air core coils, and, second by the calculation of several coil configurations for production of uniform fields. These basic coils can serve as components for synthesis of more complicated coil forms.

The present investigation was undertaken in connection with the design of electron accelerators having air core field coils. Since such accelerators may be operated intermittently and energy storage may be an important consideration, particular attention has been paid to the determination of energy stored in leakage fluxes.

## II. MAGNETIC FIELDS DUE TO CURRENT IN A CIRCULAR LOOP

The magnetic field configurations due to current flowing in a circular loop can be described in cylindrical coordinates using complete elliptic integrals, or in spherical polar coordinates using infinite series of spherical harmonics.[1] The latter expression converges very slowly and does not give directly the paraxial component which is usually the component of interest. We shall therefore use the former representation. The cylindrical coordinates $\rho$ and $z$ will be employed, and all quantities will be expressed in unrationalized M.K.S. units.

The radial and axial field components are as follows:

$$B_\rho=\frac{2\mu Iz}{\rho\{(a+\rho)^2+z^2\}^{\frac{1}{2}}}\left[-K+\frac{a^2+\rho^2+z^2}{(a-\rho)^2+z^2}E\right] \text{ webers per sq.m,} \quad (1)$$

$$B_z=\frac{2\mu I}{\{(a+\rho)^2+z^2\}^{\frac{1}{2}}}\left[K+\frac{a^2-\rho^2-z^2}{(a-\rho)^2+z^2}E\right] \text{ webers per sq.m,} \quad (2)$$

where

$\mu$ = permeability = $10^{-7}$ henry per meter for free space
$I$ = current in the loop in amperes
$a$ = radius of the loop in meters
$\rho$ and $z$ are expressed in meters and are measured from an origin at the center of the loop. The loop axis is the $z$ axis of the coordinate system
$K$ and $E$ are the complete elliptic integrals of the modulus

$$k^2=\frac{4a\rho}{(a+\rho)^2+z^2}. \quad (3)$$

In the regions close to the axis of the loop, or very far from the loop, $k^2$ is small, and the elliptic integrals can be expressed in the form:

$$K=\frac{\pi}{2}\left\{1+\left(\frac{1}{2}\right)^2k^2+\left(\frac{1\cdot 3}{2\cdot 4}\right)^2k^4+\left(\frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}\right)^2k^6+\cdots\right\}, \quad (4)$$

---

$$E=\frac{\pi}{2}\left\{1-\left(\frac{1}{2}\right)^2k^2-\left(\frac{1\cdot 3}{2\cdot 4}\right)^2\frac{k^4}{3}-\left(\frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}\right)^2\frac{k^6}{5}-\cdots\right\}. \tag{5}$$

If, as is usually the case, the region of particular interest is that close to the wire, it will be found that $k^2$ approaches unity. Within a distance of almost $0.5a$ of the wire, $k^2$ will be greater than 0.9. For $k^2$ greater than 0.9, the approximate expressions:

$$K=\ln 4-0.5\ln(1-k^2)$$
$$=1.39-1.15\log_{10}(1-k^2), \tag{6}$$

$$E=1/k^2 \tag{7}$$

give values correct to within about 3 percent.

Unfortunately, no approximate expressions seem to make any very material simplification in the relations (1) and (2). If the procedures of coil designing are to be expedited, it seems that there is no alternative to a tabulation. Since the axial component $B_z$ has been of primary interest as far as air core field coils are concerned, the tabulation has been completed only for $B_z$. The

computations involved the use of a computing machine and an interpolation table of $K$ and $E$ drawn up from Dwight's tables.[2] The results are collected in Table I in which the values of $aB_z/\mu I$ are given for $\rho/a$ between 0.0 and 2.0, and for $z/a$ between 0.0 and 0.36.

In Fig. 1, $aB_z/\mu I$ has been plotted as a function of $\rho/a$ for three values of $z/a$. The curves have a common characteristic form. For the values of $z/a$ which have been calculated, $B_z$ increases with distance from the axis to pass through a maximum at a radius less than that of the loop. It then decreases, goes through zero at a radius greater than that of the loop, and has a minimum at a point roughly as far outside the loop radius as was the maximum inside the loop radius. From the minimum, the field increases with increasing radius and tends asymptotically to zero. In Fig. 2 the radial coordinates and heights of the maxima and minima are plotted as functions of $z/a$.

If values of $B_\rho$ are desired, fairly good accuracy can be attained from a numerical integration using the table of $B_z$ and the relation

$$(\text{curl } B)_\phi = \frac{\partial B_\rho}{\partial z} - \frac{\partial B_z}{\partial \rho} = 0. \tag{8}$$

The integration proceeds from $z=0$, where $B_\rho$ is zero for all values of $\rho$. In several cases this method of determining $B_\rho$ has been found to be materially faster than substitution in Eq. (1).

## III. PRODUCTION OF A UNIFORM TRANSVERSE FIELD INSIDE AN INFINITE CYLINDER

In a cylinder of radius $R$ and infinite length, whose axis is the $x$ axis in a right-handed rectangular coordinate system, a uniform field $B_0$ in the $z$ direction will be produced by a current $I_x$ in the cylinder wall having current density[3]

$$I_x \doteq -\frac{B_0}{2\pi\mu}\frac{y}{R}. \tag{9}$$

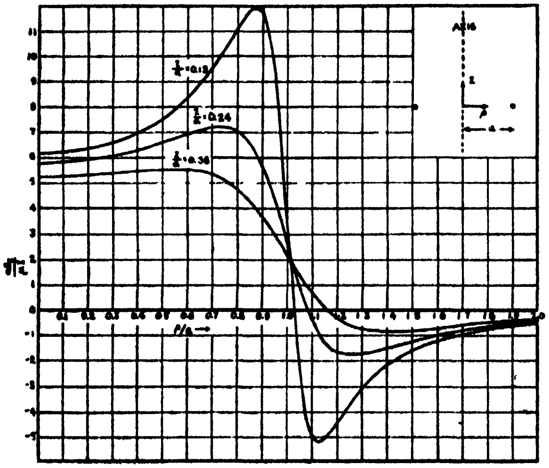

FIG. 1. Axial magnetic fields around a circular loop carrying current $I$.

---

[2] H. B. Dwight, *Mathematical Tables* (McGraw-Hill Book Company, New York, 1941), pp. 199 *et. seq.*

[3] Compare I. I. Rabi, Rev. Sci. Inst. 5, 78 (1934).

Outside the cylinder the field components will be

$$\left.\begin{aligned} B_x &= 0 \\ B_y &= 2B_0R^2\frac{yz}{(y^2+z^2)^2} \\ B_z &= B_0R^2\frac{z^2-y^2}{(y^2+z^2)^2} \end{aligned}\right\}. \tag{10}$$

The field pattern outside the cylinder is the same as that which would be produced by currents $+B_0/\delta$ and $-B_0/\delta$ parallel to the axis of the cylinder and displaced $-\delta$ and $+\delta$ from the axis in the $xy$ plane, $\delta$ being an infinitesimal.

The energy stored inside and outside the cylinder is given as usual by integrating $B^2/(8\pi\mu)$ over the appropriate volume. The energy stored per unit length in the field external to the cylinder is

$$E_0=\int_R^\infty \frac{B_0{}^2R^4\pi d(y^2+z^2)}{8\pi\mu(y^2+z^2)^2}=\frac{B_0{}^2R^2}{8\mu}. \tag{11}$$

The energy stored per unit length inside the cylinder is simply

$$E_i=\frac{B_0{}^2}{8\pi\mu}\cdot\pi R^2.$$

So in this case, $E_0=E_i$.

## IV. ELLIPSOIDAL COILS FOR PRODUCTION OF UNIFORM FIELDS

The mathematical techniques necessary for dealing with ellipsoidal coils for production of uniform magnetic fields are similar to those applying to dielectric ellipsoids in uniform electric fields.[4] We shall consider only ellipsoids of revolution in which it is desired to establish a uniform field in the direction of the axis of symmetry. In cylindrical coordinates, the equation of such an ellipsoid is

$$\frac{\rho^2}{a^2}+\frac{z^2}{b^2}=1. \tag{12}$$

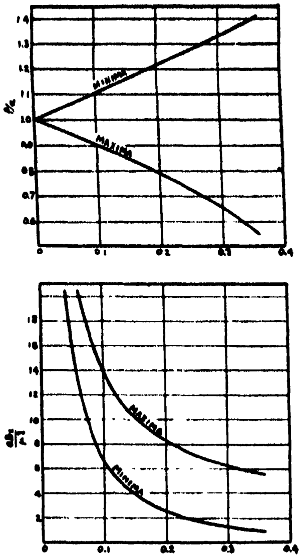

FIG. 2. Positions and heights of maxima and minima in fields of circular loop.

It is convenient to describe the external fields in terms of the parameter $s$ which describes the ellipsoids confocal with the ellipsoid of Eq. (12) through the relation

$$\frac{\rho^2}{a^2+s}+\frac{z^2}{b^2+s}=1. \tag{13}$$

The solution for $s$ of (13) is

$$s=\tfrac{1}{2}\{\rho^2+z^2-a^2-b^2\pm[(a^2+b^2-\rho^2-z^2)^2 +4(\rho^2b^2+z^2a^2-a^2b^2)]^{\frac{1}{2}}\}. \tag{14}$$

The choice of sign in (14) must be such that on the surface of the ellipsoid $s=0$ and outside of the ellipsoid $s$ is always positive. (If $s$ does not satisfy this criterion, Eq. (13) describes a family of confocal hyperboloids rather than ellipsoids.) For the most part, the criterion is satisfied by a plus sign in Eq. (14).

The external fields are derivable from a scalar potential function which, if $a$ is greater than $b$, has the form

$$V=B_0Z\left\{\frac{\dfrac{1}{(s+b^2)^{\frac{1}{2}}}-\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\left(\dfrac{a^2-b^2}{s+b^2}\right)^{\frac{1}{2}}}{-\dfrac{b}{a^2}+\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}. \tag{15a}$$

---

[4] J. A. Stratton, *Electromagnetic Theory* (McGraw-Hill Book Company, New York, 1941), Sections 3.25 to 3.27.

If $a$ is less than $b$

$$V=B_0z\left\{\frac{\dfrac{1}{(s+b^2)^{1/2}}-\dfrac{1}{(b^2-a^2)^{1/2}}\tanh^{-1}\left(\dfrac{b^2-a^2}{s+b^2}\right)^{1/2}}{\dfrac{b}{a^2}+\dfrac{1}{(b^2-a^2)^{1/2}}\tanh^{-1}\dfrac{(b^2-a^2)^{1/2}}{b}}\right\}, \tag{15b}$$

where $B_0$ is the value of the uniform field inside the ellipsoid. These functions were derived by methods similar to those used by Stratton in dealing with the dielectric ellipsoid. The fields derived from this function for the case $a$ greater than $b$, are:

$$B_\rho=-\frac{\partial V}{\partial\rho}=\frac{B_0z\rho(a^2-b^2)}{(2s-\rho^2-z^2+a^2+b^2)(s+a^2)(s+b^2)^{1/2}\left[\dfrac{b}{a^2}+\dfrac{1}{(a^2-b^2)^{1/2}}\tan^{-1}\dfrac{(a^2-b^2)^{1/2}}{b}\right]}, \tag{16}$$

$$B_z=-\frac{\partial V}{\partial z}=\frac{B_0\left\{\dfrac{z^2(a^2-b^2)}{(2s-\rho^2-z^2+a^2+b^2)(s+b^2)}-1+\left(\dfrac{s+b^2}{a^2-b^2}\right)^{1/2}\tan^{-1}\left(\dfrac{a^2-b^2}{s+b^2}\right)^{1/2}\right\}}{(s+b^2)^{1/2}\left[\dfrac{b}{a^2}+\dfrac{1}{(a^2-b^2)^{1/2}}\tan^{-1}\dfrac{(a^2-b^2)^{1/2}}{b}\right]}. \tag{17}$$

If $a$ is less than $b$, the changes necessary in (16) and (17) are obvious from a comparison of (15a) and (15b).

From the potential function of (15a) or (15b) we can deduce also the field components $B_n$ and $B_t$ normal and tangent to the surface of the ellipsoid:

$$B_n=\frac{B_0za^2}{(\rho^2b^4+z^2a^4)^{1/2}} \tag{18}$$

$$B_t=\frac{B_0\rho b^2}{(\rho^2b^4+z^2a^4)^{1/2}}\left\{\frac{\dfrac{1}{b}-\dfrac{1}{(a^2-b^2)^{1/2}}\tan^{-1}\dfrac{(a^2-b^2)^{1/2}}{b}}{\dfrac{b}{a^2}-\dfrac{1}{(a^2-b^2)^{1/2}}\tan^{-1}\dfrac{(a^2-b^2)^{1/2}}{b}}\right\}. \tag{19}$$

Inside the ellipsoid, the normal field component is the same as that outside given by (18). The tangential field component $B_t'$ at the inside surface of the ellipsoid is

$$B_t'=\frac{B_0\rho b^2}{(\rho^2b^4+z^2a^4)^{1/2}}. \tag{20}$$

From Maxwell's equations, the azimuthal current density

$$I_\phi=\frac{B_t-B_t'}{4\pi\mu}=\frac{B_0}{4\pi\mu}\frac{\rho b^2}{(\rho^2b^4+z^2a^4)^{1/2}}\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{1/2}}\tan^{-1}\dfrac{(a^2-b^2)^{1/2}}{b}}\right\}. \tag{21}$$

This is the current per unit distance measured tangent to the surface of the ellipsoid. Between $\rho$

and $\rho+d\rho$ the current will be

$$I(\rho)d\rho = I_\phi d\rho[1+(dz/d\rho)^2]^{\frac{1}{2}} = \frac{B_0 d\rho}{4\pi\mu}\frac{\rho b}{a(a^2-\rho^2)^{\frac{1}{2}}}\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}. \tag{22}$$

Similarly, between $z$ and $z+dz$ the current will be

$$I(z)dz = \frac{B_0 dz}{4\pi\mu}\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}, \tag{23}$$

which is a constant independent of $z$. From this fact we may conclude that if the current distribution is achieved by varying the thickness of the ellipsoid wall, keeping constant current density within the wall, the wall thickness in the radial direction will be a constant. It is assumed that the wall thickness remains infinitesimal compared with the ellipsoid dimensions; for thick walls the above theory is no longer correct.

## V. ENERGY STORAGE IN FIELDS OF ELLIPSOIDAL COILS

The energy stored in the field outside the ellipsoid is evaluated most easily by an application of Green's theorem. The energy is given by

$$E_0 = \int \frac{B\cdot B}{8\pi\mu}d\tau = -\int \frac{V_s B_n}{8\pi\mu}dS, \tag{24}$$

where $V_s$ is the value of $V$ (from 15a or 15b) on the surface of the ellipsoid, and $B_n$, the normal field just outside the surface, is given by (18). The integral is taken over the surface of the ellipsoid. When the appropriate substitutions have been made in (24), the integral is easily evaluated. The result is

$$E_0 = \frac{a^2bB_0^2}{6\mu}\left\{\frac{\dfrac{1}{b}-\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}{\dfrac{b}{a^2}-\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}. \tag{25}$$

The energy inside the ellipsoid where the field is uniform is

$$E_i = \frac{4}{3}\pi a^2 b\frac{B_0^2}{8\pi\mu} = \frac{a^2bB_0^2}{6\mu}. \tag{26}$$

The ratio of the energy stored outside to the energy stored inside is

$$\frac{E_0}{E_i} = \frac{\dfrac{1}{b}-\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}{\dfrac{b}{a^2}-\dfrac{1}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}. \tag{27}$$

This ratio is one measure of efficiency of a coil for intermittent operation since it indicates the relative values of useless to useful stored energy. In Fig. 3 $E_0/E_i$ is plotted as a function of the ratio $b/a$. Figure 4 shows the variation of $E_0$ as the ellipsoid parameters vary. In this figure, $6\mu E_0/(a^3B_0^2)$ is plotted as a function of $b/a$.

## VI. SPECIAL CASES OF THE ELLIPSOID

### a. The Infinite Solenoid

This familiar configuration appears when the semi-axis $b$ of the ellipsoid is allowed to become infinite. The potential $V$ outside, the external fields, and the ratio of external to internal stored energy all tend to zero. From (23) the current per unit length in the wall becomes $B_0/4\pi\mu$.

### b. The Sphere

When $b=a$, the ellipsoid becomes a sphere. From (15), (16), and (17) the external potential

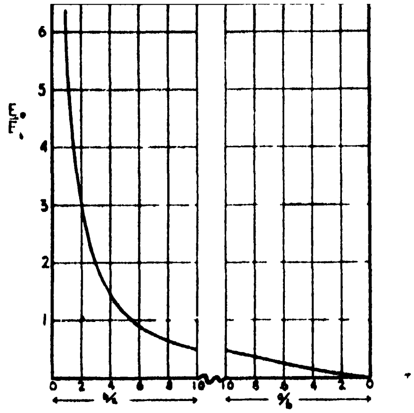

FIG. 3. Ratio of external to internal energy storage for ellipsoidal coils.

and fields are

$$V = \frac{B_0 z a^3}{2(\rho^2+z^2)^{3/2}}, \tag{28}$$

$$B_r = \frac{3B_0 z\rho a^3}{2(\rho^2+z^2)^{5/2}}, \tag{29}$$

$$B_z = \frac{B_0 a^3(2z^2-\rho^2)}{2(\rho^2+z^2)^{5/2}}. \tag{30}$$

The uniform field in the sphere is produced by a current whose density, from (21), is

$$I_\phi = \frac{3B_0\rho}{8\pi\mu a}. \tag{31}$$

From (25) the external stored energy is

$$E_0 = \frac{a^3 B_0^2}{12\mu} \tag{32}$$

and the ratio $E_0/E_i$ is given by (27)

$$\frac{E_0}{E_i} = \tfrac{1}{2}. \tag{33}$$

Spherical coils of this type have been discussed and applied to mass spectrometer design by Hipple.[5]

### c. The Plane Coil

If $b$ is reduced to zero the ellipsoidal coil becomes a flat pancake. The external potential becomes from (15):

$$V = \frac{2aB_0 z}{\pi}\left(\frac{1}{\sqrt{s}} - \frac{1}{a}\tan^{-1}\frac{a}{\sqrt{s}}\right). \tag{34}$$

From (16) and (17) the external fields are

$$B_\rho = \frac{2B_0 z\rho a^3}{\pi(2s-\rho^2-z^2+a^2)(s+a^2)\sqrt{s}}. \tag{35}$$

$$B_z = \frac{2aB_0}{\pi\sqrt{s}}\left(\frac{z^2a^2}{s(2s-\rho^2-z^2+a^2)} - 1 + \frac{\sqrt{s}}{a}\tan^{-1}\frac{a}{\sqrt{s}}\right). \tag{36}$$

In the neighborhood of this coil where $\rho$ is materially less than $a$, and $z$ is small,

$$B_\rho = \pm\frac{2B_0\rho}{\pi(a^2-\rho^2)^{\frac{1}{2}}} \text{ approx.} \tag{37}$$

the sign depending on whether $z$ is positive or negative, and

$$B_z = B_0 \text{ approx.} \tag{38}$$

From (21) the current density is

$$I_\phi = \frac{B_0\rho}{\pi^2\mu(a^2-\rho^2)^{\frac{1}{2}}}. \tag{39}$$

(The value deduced from Eq. (21) by letting $b$ tend to zero must be multiplied by a factor of two to obtain (39) since when $b=0$ the upper and lower surfaces of the ellipsoid become coincident.) From (25) the external stored energy is

$$E_0 = \frac{a^3B_0^2}{3\pi\mu}, \tag{40}$$

and the internal energy is, of course, zero.

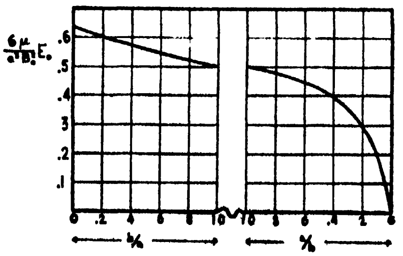

FIG. 4. External stored energy for ellipsoidal coils.

## VII. COMPARISON OF IRON CORE AND AIR CORE FIELD COILS

As a basis on which to compare iron core and air core coils for practical applications, we shall evaluate the number of ampere turns required in the two cases to provide a uniform field $B_0$ within a given region.

We assume the ellipsoidal coil to be made up of $N$ turns, each turn carrying a current $I_0$ amperes. If the number of turns between $\rho$ and $\rho+d\rho$ is $n(\rho)d\rho$ then

$$I_0\int_{-a}^{+a} n(\rho)d\rho=\int_{-a}^{+a} I(\rho)d\rho=NI_0. \qquad (41)$$

We substitute for $I(\rho)$ from Eq. (22) and perform the integration to obtain for the total number of ampere turns:

$$NI_0=\frac{B_0 b}{2\pi\mu}\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}. \qquad (42)$$

The number of ampere turns $N'I'$ required in an iron core coil for generation of a field $B_0$ webers per sq.m in an air gap of length $l$ meters is

$$N'I'=\frac{B_0 l}{4\pi\mu}=8.0\times 10^5 B_0 l \qquad (43)$$

provided the air gap is short compared with the other dimensions of the region in which the field is to be maintained. If the air gap becomes comparable with the other dimensions the number of ampere turns will be materially higher than the value given by (43), since the fields begin to suffer in strength and uniformity as edge effects become more important.

A comparison between Eqs. (42) and (43) shows that for small air gaps the iron core has marked advantages. For an air gap one-tenth of the pole-piece diameter, the iron core magnet requires only about one-eighth of the ampere turns needed by the corresponding ellipsoidal air core coil for which $b/a=0.1$. When the air gap becomes about half the pole-piece diameter, the magnets become comparable in ampere turn requirements, and for larger air gaps the ampere turn requirements remain comparable. Evidently the mechanical simplicity and compactness of the air core coil merit consideration in any case where the air gap in the corresponding iron core magnet would be greater than half the pole-piece diameter.

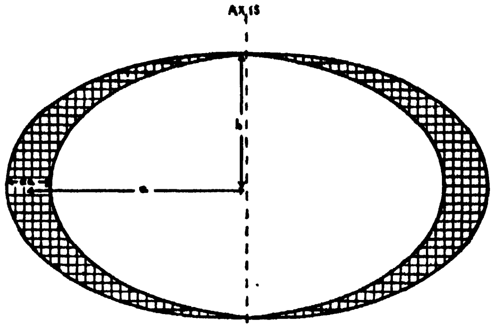

FIG. 5. Cross section through ellipsoidal coil for production of uniform field.

## VIII. POWER CONSUMPTION IN ELLIPSOIDAL D.C. FIELD COILS

The distribution of turns in the wall of the ellipsoid can be expressed rather simply using Eqs. (22), (41), and (42). The number of turns between $\rho$ and $\rho+d\rho$ is

$$n(\rho)d\rho=\frac{N\rho d\rho}{2a(a^2-\rho^2)^{\frac{1}{2}}}. \qquad (44)$$

Similarly, the number of turns between $z$ and $z+dz$ is

$$n(z)dz=\frac{Ndz}{2b}. \qquad (45)$$

The total length of wire used in the winding will be

$$\int_{-a}^{+a} 2\pi\rho n(\rho)d\rho=\frac{\pi^2 aN}{2}\ \text{meters}. \qquad (46)$$

If the coil is wound with copper wire having a cross-sectional area of $s$ sq.m. the total resistance of the winding will be

$$R_0=1.7\times 10^{-8}\frac{\pi^2 aN}{2s}\ \text{ohms}. \qquad (47)$$

From (42) and (47) the power consumption in the coil will be

$$I_0{}^2R_0=\frac{1.9\times 10^5 ab^2B_0{}^2}{Ns}\times\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}^2\ \text{watts}. \qquad (48)$$

If the thickness of the coil in the $z=0$ plane is $\alpha a$ (from (23) or (45) $\alpha a$ will also be the thickness in any plane parallel to the $z=0$ plane) then from (45)

$$Ns=2\alpha ab \tag{49}$$

and the power consumption may be written

$$I_0{}^2R_0=\frac{9.5\times 10^4 bB_0{}^2}{\alpha}\times\left\{\frac{a^2-b^2}{b^2-\dfrac{ba^2}{(a^2-b^2)^{\frac{1}{2}}}\tan^{-1}\dfrac{(a^2-b^2)^{\frac{1}{2}}}{b}}\right\}^2 \text{ watts.} \tag{50}$$

For $b/a=0.6$, 1.0, and infinity, the quantity in the bracket will have the values 1.9, 1.5, and 1.0, respectively.

Figure 5 is a sketch of the cross section through an ellipsoidal coil for which $b/a=0.6$ and $\alpha=0.2$.

## VIII. ACKNOWLEDGMENTS

The author is indebted to Professor F. W. Grover for a considerable amount of information on techniques for dealing with the circular loop problem and with elliptic integrals. Professor Grover's study of the fields around a circular loop will appear in a forthcoming paper in the *Proceedings of the Institute of Radio Engineers.* The tables of magnetic fields around a circular loop represent a long period of patient and painstaking calculation on the part of Miss M. Kay.

# Design of an Air Core Synchrotron*

JOHN P. BLEWETT**
*East Patchogue, Long Island, New York*

(Received June 17, 1947)

The analysis of the preceding paper is applied to the problem of designing a synchrotron in which the magnetic fields are produced by air core coils. The air core synchrotron is shown to be practical and to present certain advantages.

## I. INTRODUCTION

In the preceding paper an analysis has been presented of the problems, first, of the magnetic fields caused by current flowing in a circular loop, and second, of the coil configurations necessary to produce uniform fields in regions of various geometries. The magnetic field requirements of the betatron and the synchrotron will now be considered in the light of this analysis.

Air core magnets present three major advantages. First, they free the magnet designer from the upper limit of 1.8 webers per square meter (18,000 gausses) or so associated with iron cores because of the saturation characteristics of iron. Second, they do not introduce the random local inhomogeneities in field which are found in the fields of iron core magnets as a result of defects in fabrication or spottiness in previous treatment. This drawback of iron cores may be a serious one in the betatron or the synchrotron in which injection takes place just after the field has passed through zero. If all parts of the field do not pass through zero simultaneously it may be difficult to initiate a beam, particularly in the higher energy machines. The third advantage of air core coils is the obvious one that a large and costly iron structure is avoided. This is particularly important in betatrons and synchrotrons where the iron must be laminated, and the core construction is an extremely tedious and expensive proposition.

The problems which arise when a switch is made from iron to air core are mainly associated with the choice of the correct geometry for the

** Formerly Research Laboratory, General Electric Company. Now at Brookhaven National Laboratory, Brookhaven, Long Island.

current carrying conductors. Possible solutions to these problems are discussed in Sections II, III, IVa, and IVb. Other problems associated with air core coils such as cooling, auxiliary circuits, mechanical support, and so forth do not seem unduly serious. Typical solutions of several such problems are presented in Sections IVc, IVd, and IVe.

## II. AIR CORE GUIDE FIELDS FOR BETATRONS OR SYNCHROTRONS

The primary economic factor in the design of a betatron or synchrotron, aside from the magnet itself, is the capacitor bank in which the energy to appear in the magnetic field must be stored during the inactive periods. It is therefore important that as much of the field generated as possible shall be actually useful. An iron core magnet designed to produce a field of a particular type generally stores two or three times as much energy as is required for fields which actually deflect particles. This is simply because the shape of the pole piece which produces the desired field is generally not the same as the shape of the vacuum envelope in which the field is utilized. In addition wasted energy is always stored in leakage fluxes. The air core magnet can be designed to fit the vacuum envelope. It must, however, have a finite thickness to permit it to dissipate power. And it must store unused energy in return fluxes.

For toroidal regions such as those enclosed by the vacuum envelopes of betatrons and synchrotrons, air cores and iron cores are about equally economical in stored energy. The problem of generation of uniform fields in a toroidal region has not yet been solved analytically so far as the author is aware. An approximate attack is suggested, however, by the infinite cylinder case treated in Section III of the preceding paper. If the cylinder is bent in the $x, y$ plane on a radius of curvature materially greater than its own radius, the external distribution of energy will not be too violently disturbed. It follows from Eq. (11) of the preceding paper that three-quarters of the energy in the external field of the cylinder lies between the cylinder wall (radius $R$) and a cylinder of radius $2R$. This will probably still be approximately true when the cylinder has been bent into a torus. It is therefore a reasonable assumption that the energy stored in the external fields of the torus is approximately the same as the energy stored within the torus wall, just as was true in the case of the infinite cylinder. In other words, in setting up a uniform paraxial field within a toroidal region we shall store approximately twice the energy we use because of the energy stored in the external return flux. If now we arbitrarily increase the factor of two to a factor of three to take care of the excess energy stored because of the necessarily finite thickness of the coil, we shall have a design factor not far from that actually realizable.

If a roughly uniform field $B_0$ webers per sq. m is set up within a toroidal region whose cross-sectional area is $\pi r^2$ sq. m and whose mean radius is $R$ m, the energy stored in this region will be

$$E_i = \frac{\pi R r^2 B_0^2}{4\mu} \text{ joules,} \tag{1}$$

where $\mu$, the permeability, $=10^{-7}$ henry per meter for free space. To obtain the total energy stored in all fields we multiply this quantity by our factor of three to obtain

$$E = \frac{3\pi R r^2 B_0^2}{4\mu} = 2.4\times 10^7 R r^2 B_0^2 \text{ joules.} \tag{2}$$

This equation can be rewritten in terms of the energy $W$ ($=mc^2/e$ electron volts) of a particle bent in a circle of radius $R$ in a field $B_0$ through the relation

$$W = B_0 c^2 R/v \text{ electron volts,} \tag{3}$$

where $v$ is the particle velocity in meters per sec., $c$, the velocity of light, $=3\times 10^8$ m per sec. From (2) and (3)

$$E = 2.7\times 10^{-10}\frac{r^2 W^2}{R}\frac{v^2}{c^2}. \tag{4}$$

If, for example, $R$ is one meter, the vacuum envelope is a torus of three-inch tubing so $r=0.038$ m and $W$ is 100 Mev, $v$ will be approximately equal to $c$ if the particles are electrons, and $E$ will be about 4000 joules. This much energy could be stored at 5000 volts in sixteen 20-microfarad capacitors.

If this device is to be operated continuously

TABLE I.

| $W$(Mev) | $R$(m) | Number of capacitors for 5-Mev betatron | Number of capacitors for guide field |
|---|---|---|---|
| 100 | 0.5 | 7 | 30 |
| 500 | 2.5 | 35 | 150 |
| 1000 | 5.0 | 70 | 300 |

at a frequency $\omega/(2\pi)$ the power required may be deduced if an estimate can be made of the $Q$ of the coil. From the definition of $Q$,

$$\text{power required} = \omega E/Q \text{ watts.} \tag{5}$$

At 60 cycles, $Q$'s higher than 5 or 6 are hard to achieve in air core coils. For a $Q$ of 5 and the coil discussed above the power required would be about 300 kilowatts. This is rather high and might justify reconsideration of the higher $Q$'s obtainable in iron core coils. But if, for example, the machine is to be used for cloud-chamber investigations, it need be fired only once or twice a minute. In this case the power consumption drops to the negligible range below 200 watts.

The actual design of guide-field coils will be treated in more detail in Section IV.

## III. AIR CORE FLUX COILS FOR BETATRON ACCELERATION

In iron core machines the energy stored in fluxes used for betatron acceleration can be negligible if air gaps are kept out of the flux paths. This is because the energy stored for a given flux density is inversely proportional to the permeability of the medium. The air core betatron is therefore at a disadvantage so far as flux coils are concerned. To obtain order of magnitude figures for air core flux coil energy requirements we shall now consider an idealized case.

Efficient energy storage will be achieved if we keep the flux density uniform within the orbit. This could be done with a pancake coil of the sort discussed in Section VIc of the preceding paper. The flux through such a coil of radius $R$ will be

$$\phi = \pi R^2 B_0 \text{ webers.} \tag{6}$$

But from the betatron condition

$$\phi = 2\pi R^2 B_1 \text{ where } B_1 \text{ is the guide field at the orbit}$$

$$= \frac{2\pi R}{c}\frac{v}{c} W \text{ webers} \tag{7}$$

(compare Eq. (3) above). But from Eq. (38) of the preceding paper the energy stored by the flux coil is

$$E_f = \frac{R^3 B_0^2}{3\pi\mu} \text{ joules.} \tag{8}$$

From (6), (7), and (8)

$$E_f = \frac{4R}{3\pi\mu}\frac{v^2}{c^2}W^2 = 4.7\times 10^{-11} R W^2 \frac{v^2}{c^2} \text{ joules.} \tag{9}$$

If $W = 10$ Mev, $R = 0.5$ m, and $v$ is approximately equal to $c$, then $E_f = 2400$ joules. If $W = 100$ Mev, $R = 1$ m, and $v$ is approximately equal to $c$, $E_f$ will be 470,000 joules. In the former case the energy could be stored in ten 5000 volt, 20 microfarad capacitors, while in the latter case 2000 such capacitors would be required. Which, if either, of these quantities is reasonable depends, of course, on the designer's purse and viewpoint. It is evident in any case that air core betatrons for higher energies than 20 Mev will begin to be expensive.

In view of the idealized geometry considered, the figures derived from Eq. (9) are merely lower limits. It would be impractical to extend the flux coil all the way to the orbit and it would, moreover, be impractical to use a pancake coil since its external fields which would exist at the orbit are strongly radially dependent and would interfere with the guide field. A more practical design will be presented in the next section. For the practical flux coil, the factor of 4.7 in Eq. (9) should be replaced by a factor of about 14 to give

$$E_f = 1.4\times 10^{-10} R W^2 \frac{v^2}{c^2} \text{ joules.} \tag{10}$$

## IV. DESIGN OF AN AIR CORE SYNCHROTRON

In the introduction we have pointed out the advantages of air core machines. In Section II air core guide fields were shown to be economically comparable with iron core guide fields, particularly for intermittent operation, and in Section III it was shown that betatron acceleration up to 10 Mev with air core flux coils involves not unreasonable figures for energy storage. Since betatron acceleration up to four or five Mev is quite sufficient to initiate the usual sequence of events in the synchrotron, the betatron coils of an air core synchrotron could just as well be air core. Introduction of an iron core for the betatron flux would result in rather a tricky problem of synchronization between air core fields and iron core fluxes. It would therefore appear from what has gone before that a high energy air core synchrotron is quite practical. If we speak in terms of 5000-volt 20-microfarad capacitors and of a three-inch diameter vacuum envelope, the results of Eqs. (4) and (10) are as given in Table I for a few typical cases.

We now proceed to a more detailed consideration of design.

### a. Guide-Field Coils

The guide field must decrease with radius at a rate not faster than $1/\rho$ in order that the electron motion shall be stable both in $\rho$ and in $z$. For most designs this means a variation across the vacuum envelope of not more than about ten percent, and the guide-field coils will not differ much from those required to produce a uniform field. As was mentioned in Section II, this problem has not been solved analytically, but a measure of similarity exists between the torus and the infinite cylinder. We should, therefore, begin with a coil system suggested by the cylinder case, such as that shown in cross section in Fig. 1, and, by numerical work based on the tables in the preceding paper or by measurements on models, make the small changes which will result in the desired variation of field with radius.

### b. Flux coils

The flux coils will be required to build up a flux at a rate governed by the rate of rise of the guide field to the point at which the electron energy is about 5 Mev. Now the radiofrequency signal should be turned on and synchrotron acceleration initiated. The guide field should continue to rise, but the betatron flux should cease rising since further increases will result merely in useless storages of energy. In iron core machines this object is accomplished by saturation of the flux core. In an air core machine different methods must be used. One possible method is described in Section c below.

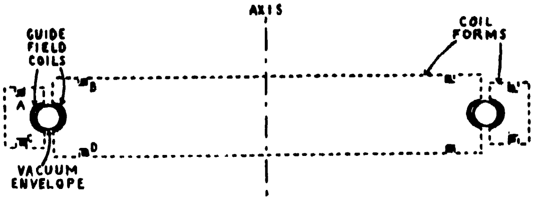

FIG. 1. Cross section through air core synchrotron.

Since the time variations of field and flux are to be different, it follows that no appreciable field from the flux coil can be permitted to exist in the neighborhood of the orbit. On the other hand, in order that we do not store large amounts of energy needlessly in the flux, it is desirable that the flux coils couple as closely as possible with the orbit. These apparently mutually exclusive requirements can be met by the compromise to be described below.

In the case of the infinite cylinder discussed in Section III of the preceding paper, had we set up currents $I_x$ in the walls proportional to the absolute value of $y$ instead of $y$, the internal field would have been zero. If, now, a wire parallel to the cylinder axis were located somewhere within the cylinder unity coupling would exist between it and the currents in the cylinder walls since no magnetic flux interposes between wire and wall. Presumably an analogous case exists for the toroid. The exact distribution of azimuthal current in a toroid wall, which would give zero internal field, has not yet been worked out. A fairly good approximation can easily be set up, however, using only four wires appropriately located in the torus wall. The four wires $A$, $B$, $C$, and $D$ of Fig. 1 lie in one possible configuration. The choice of positions for these four wires is made after a consideration of the field distributions around a circular loop discussed in Section II of the preceding paper and shown graphically in Figs. 1 and 2 of that paper. Wire $A$ is located so that the maximum in its field pattern lies at the orbit. The position of wire $B$ is such that the minimum in its field pattern lies at the orbit, and the relative currents in the two wires are so adjusted that the minimum and maximum are equal in height. In this way the axial field at the orbit and its first derivative with respect to radius are reduced to zero. The selection of parameters may be expedited by using the graph in Fig. 2 of the preceding paper. In applying this method it will become evident that the

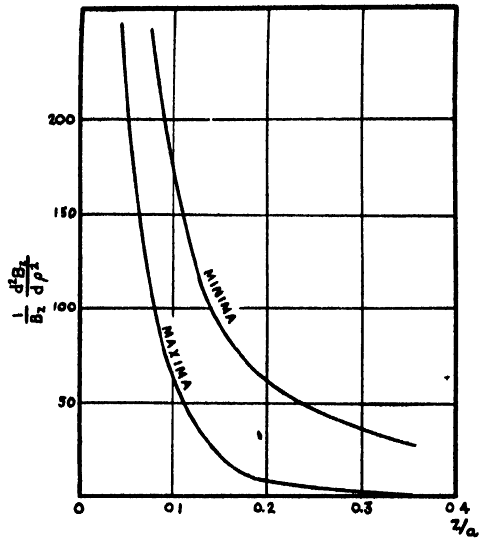

FIG. 2. Second derivatives at maxima and minima in fields of circular loop such that these extrema lie at $\rho=1$.

choice of location and size of the coils is not unique. For each coil, loci of the form $z=f(\rho)$ exist along which cancellation can be achieved by appropriate choices of current ratios. This extra degree of freedom can be utilized to permit cancellation of second derivatives. To facilitate this procedure, the ratios of second derivatives of $B_z$ with respect to $\rho$, to the values of $B_z$, have been plotted in Fig. 2 for the cases where the extrema of the field distributions lie at $\rho=1$. When the value of $z/a$ for one coil has been chosen, the $z/a$ for the second coil will be that for which the ordinates of the curves of Fig. 2 have equal values. Given $z/a$ for each coil, the correct value of $\rho/a$ may be found from Fig. 2 of the preceding paper. The results of this rather complex procedure are summarized in the graphs of Fig. 3 which give complete design data for pairs of loops which give cancellation of the field, its first and second derivatives, at the orbit. For the case where the orbit is located at $\rho=1$ the radius $a_0$ and height $z_0$ of the outer coil and the radius $a_i$ of the inner coil are plotted as functions of the height $z_i$ of the inner coil. Also included in Fig. 3 is the ratio of currents in the two coils as a function of $z_i$. This graph indicates that for the geometry shown in Fig. 1 the ratio of ampere turns in the inner coil to ampere turns in the outer coil is about 4:1.

After cancellation of axial fields and derivatives thereof has been accomplished, addition of the two coils $C$ and $D$, symmetrically located below the plane of the orbit, will give cancellation of radial fields.

It is unnecessary to add further refinements to provide cancellation of fields adjacent above and below the orbit. If $B_z$, and its derivatives with respect to radius, and $B_\rho$ are zero in the plane of the orbit, the fact that the curl and divergence of the field are zero insures the disappearance of the fields at all points in the neighborhood of the orbit.

A further improvement in cancellation and a closer approximation to the ideal case would result from the use of six or more coils so adjusted that still higher derivatives of the field would disappear. This rather formidable problem has not yet been worked out.

Experimentally it has been found that the coupling coefficient between the orbit and a set of coils in about the configuration of Fig. 1 is between 0.8 and 0.9. In other words, the energy gained per revolution by an electron in this system will be between 80 and 90 percent of the voltage per turn applied to the flux coil. This result was obtained with coils about 20 cm in

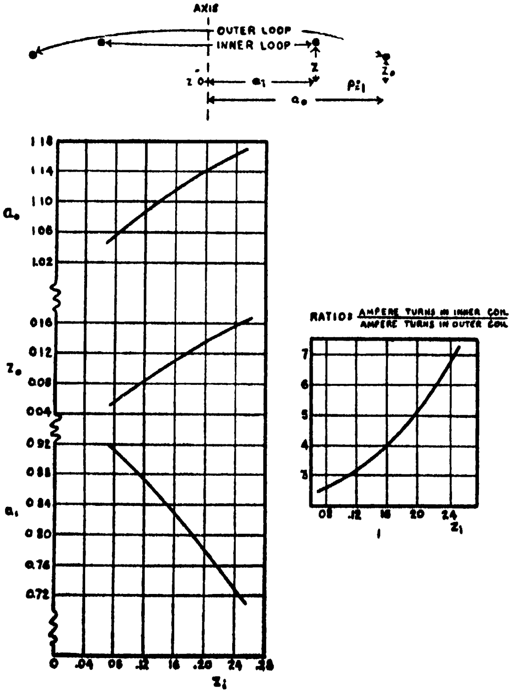

FIG. 3. Design parameters for matching second derivatives.

radius and having cross sections of about one sq. cm. The coupling coefficient might be materially lower for coils of smaller cross section.

### c. Construction of Field and Flux Coils

Two important problems must be kept in mind during the actual construction of the field and flux coils. The first is associated with the forces between conductors. In a high energy machine these forces may be of the order of several tons per meter of coil. The forces will be attractive between conductors passing currents in the same direction and repulsive between conductors passing currents in opposite directions. These forces, fortunately, are such that the coils will tend to be held in place, rather than explode, in a coil form of the convenient shape indicated by dotted lines in Fig. 1. During several months of model experiments on a small 100-Mev design for intermittent operation no difficulty was experienced with these forces.

The second problem lies in the discontinuities at points where leads enter or leave the coils. Theoretically, if entering and return leads lie very close together, no discontinuity will appear, but in practice some space must be left for insulation and detectable inhomogeneities in field do appear. This problem was solved in model experiments by making each coil several coils in parallel. The leads to the several coils were brought out at equally spaced points around the coil circumference. The entering and return leads to each coil were then carried close together and parallel to the coil axis a distance of about one coil radius. They were then bent inward and carried together to the coil axis. All connections were made on the coil axis. Measurements good to 0.1 percent on fields in the neighborhood of the orbit failed to show any measureable inhomogeneity when each coil had been made six coils in parallel. When coils are paralleled thus it is, of course, necessary to interweave the windings in such a way as to maintain uniform current density through the coil and avoid circulation of parasitic currents.

|---|---|---|---|---|---|
| Deviation of sine from linear expression (%): | 0.13 | 0.51 | 1.14 | 2.03 | 3.18 |

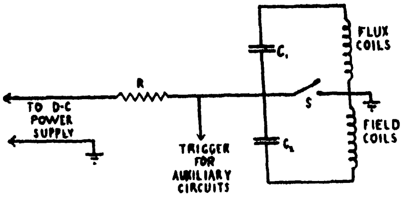

Fig. 4. Circuit for air core synchrotron.

### d. Auxiliary Circuits and Equipment

The requirement that the flux should cease rising after the electron velocity is approximately that of light (compare Section IVb above) can be met by making the flux coils part of a circuit whose resonant frequency is several times that of the circuit which includes the field coils. When a capacity $C$ charged to a voltage $V$ is discharged into an inductance $L$, the current is given by

$$i = V(C/L)^{\frac{1}{2}} \sin(t/(LC)^{\frac{1}{2}}). \tag{11}$$

For $t$ small, $i = Vt/L$ approximately. As $t$ increases the expression (11) deviates from linearity with $t$ in accordance with Table II. If these figures relate to the higher frequency flux wave, the lower frequency field wave will be essentially linear, and the table gives the percentage error from the betatron condition. The equilibrium orbit will change to a new radius, and the ratio of the change in radius to the original radius can be shown to be essentially the same as the deviation given in the above table.

Since the vacuum envelope must certainly be large enough that a variation in orbit radius of two or three percent can be tolerated, betatron acceleration will be satisfactory up to 20° or 25° of the flux wave. At this point the radiofrequency acceleration must be initiated. We shall now store energy uselessly in the flux coils until 90° in the flux wave, an inelegant feature of this method which is partly counterbalanced by the method's simplicity in execution.

As the flux wave falls off past 90° we shall have a negative betatron effect, but the stability of the synchrotron orbit has often been shown to be sufficient to offset this provided the radiofrequency signal level is sufficiently high.

A circuit for generating the desired sequence of events is shown in Fig. 4. The field and flux capacitor banks, $C_2$ and $C_1$, are charged as indicated from the same power supply. They are then discharged simultaneously by the switch $S$ which can be a large circuit breaker or a bank of ignitrons. At the moment of closing, the potential of the left-hand contact of the switch drops discontinuously to zero. This sharp wave front provides a good trigger for timing injection and radiofrequency turn on and off.

Design data for timing and injection circuits, vacuum envelopes, cooling systems, electron guns, and radiofrequency systems are available in profusion and will not be discussed here.

### e. Summary of Test Results

A program of construction of a 100-Mev air core synchrotron was initiated by the author in the Research Laboratory of the General Electric Company, but his departure from that laboratory prevented him from carrying the program to completion. Numerous model measurements were made on field and flux coils and preliminary circuit tests were performed, but the construction of circuits and electron gun did not reach the point where electrons could be accelerated.

The machine had an orbit radius of 7 inches and was designed for once per minute operation. The structure was generally as indicated above except for the guide field coils which were simply coaxial 44 turn solenoids about 3 inches long. The outer solenoid was divided into two halves in a plane normal to its axis, and it was found that a paraxial separation of about an eighth of an inch of these two half-coils gave a field in the neighborhood of the orbit which fell off approximately as the inverse half-power of radius. This coil design was not as economical as the one indicated in Fig. 1 should be, since considerable amounts of energy were stored in regions above and below the vacuum envelope.

The coils were wound on Bakelite forms generally similar to those shown in Fig. 1.

The vacuum envelope was a toroid of one-inch glass tubing. The electron gun was brought in from the top; other associated equipment was conventional in design.

Once a minute operation solved all cooling problems. It did, however, introduce a difficulty which might well be eliminated in any future machines of this type. Experience with the 70-Mev iron core synchrotron in the General Electric Research Laboratory has indicated that the serious problems in synchrotron operation are all betatron problems; if successful betatron operation can be achieved, further acceleration by radiofrequency fields is very easy. It would seem, therefore, that even though a machine is to be used for intermittent high energy operation it should still be capable of continuous low energy betatron operation. This will speed up very materially the initial tests when a number of parameters are varied in attempts to find a beam. Given a beam, further adjustments to maximize beam intensity or to carry it to higher energy are relatively simple and can be carried on at a once per minute rate without reducing the operator to a state of impatient exasperation.

No special means were included for bringing out the beam. It was hoped eventually that the beam could be deflected into the space above the orbit. It seems on paper to be much easier to move or at least to tilt the beam axially, than it is to expand it in a controlled fashion. In iron core machines, of course, the pole pieces are in the way. In an air core machine a weak auxiliary field might be sufficient to bring a sharp beam into the clear region above the coils.

## V. ACKNOWLEDGMENTS

The author is indebted to Mr. L. Redmond for his invaluable assistance in the performance of the experiments discussed above. Mr. A. M. Gurewitsch, Dr. R. V. Langmuir, Dr. E. E. Charlton, Dr. G. Ragan, and Dr. J. L. Lawson and many others of the author's former associates in the General Electric Research Laboratory have contributed materially in assistance and suggestions. Finally, it is a pleasure to acknowledge the continued advice and support of Dr. A. W. Hull.

# A Sound Velocity Method for Determining the Compressibility of Finely Divided Substances

R. J. URICK
*Naval Research Laboratory, Washington, D. C.*

(Received June 23, 1947)

A method is presented whereby the adiabatic compressibility of a finely divided material can be found from sound velocity and density measurements of a suspension of the particles in a liquid. The method is based on the assumption that the velocity of sound in a suspension is the same as it would be in an ideal solution of the two substances. This is verified experimentally by measurements of sound velocity in kaolin-water suspensions and xylene-water emulsions, and the method is illustrated by the determination of compressibility of the oil droplets in an oil emulsion and of the blood corpuscles in horse blood. Considerable accuracy is attainable for materials which are not too incompressible compared to the suspending liquid.

## INTRODUCTION

THE ultrasonic interferometer has been employed for many years for the determination of the adiabatic compressibility of liquids. This instrument serves to measure the wavelength of sound waves in the liquid, and thereby the velocity of sound, and a simple calculation yields the compressibility once the density of the liquid is known. Extensive tables of compressibility of pure liquids are available.[1]

In 1930, K. H. Herzfeld[2] suggested that this method might be extended to the study of solid substances by grinding them, suspending the particles in a liquid, and measuring the velocity of sound in the suspension. He derived an expression for the adiabatic compressibility of the solid in terms of the velocity, density of solid and liquid, and the compressibility of the liquid. This was based on extensive theoretical considerations of the effect of scattering by numerous small rigid spherical particles in the sound field. The result was applied for this purpose by Randall[3] a short time later, but extremely small, or even negative, compressibilities were found.

The failure of Herzfeld's formula to find experimental verification seems to have been followed by a long period of neglect in the application of the ultrasonic interferometer to substances other than homogeneous liquids and gases.

In the present paper a simple expression will be derived for the velocity of sound in a suspension based on the assumption that the mixture behaves the same as would an ideal solution of the two substances. The result will be verified by some data on kaolin-in-water suspensions and on some emulsions of xylene and water. These considerations permit a determination of the adiabatic compressibility of the particles in a suspension from measurements of sound velocity and density, and this method will be illustrated by the computation of the compressibility of (1) the oil particles in some oil-in-water emulsions and (2) blood corpuscles in horse blood.

## SOUND VELOCITY IN IDEAL MIXTURES

In approaching the subject of the velocity of sound in a suspension or emulsion of one substance in another, it is simplest to consider what takes place in a homogeneous ideal mixture of the two materials. In so doing, we must make the assumption that the suspended particles are infinitesimally small compared to the wavelength of the sound, and that accordingly the effects of scattering on the sound velocity may be neglected. This is seen to be not too unreasonable an assumption when it is realized that at a frequency of one megacycle the size of the particles in a course dispersion is less than a hundredth of the wave-length of sound in water. Making this assumption, we may proceed to find the sound velocity in the same manner as for an ideal solution of one substance in the

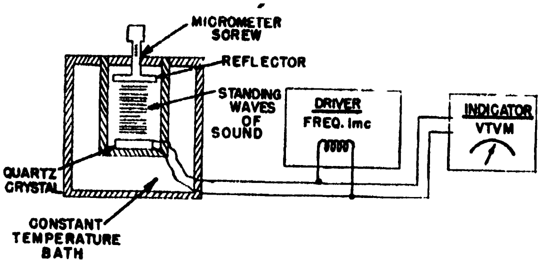

FIG. 1. Diagram of 1-megacycle acoustic interferometer.

other.[4] In this case both the density and the compressibility of the mixture are additive properties of the corresponding quantities for the two materials, depending upon the proportional amount of each substance in the mixture. Thus, $\rho_0=\rho_2\beta+\rho_1(1-\beta)$ and $\kappa_0=\kappa_2\beta+\kappa_1(1-\beta)$, where $\rho_0$, $\kappa_0$ are the density and compressibility of the suspension, $\rho_2$, $\kappa_2$ are the density and compressibility of the suspended particles, $\rho_1$, $\kappa_1$ are the density and compressibility of the suspending substance, $\beta$ is the volume percentage of particles. The subscripts 0, 1, and 2 refer to the suspension, suspending liquid, and the suspended particles, respectively. Hence, the velocity of sound in the mixture is

$$V_0=\frac{1}{(\rho_0\kappa_0)^{\frac{1}{2}}}=\left[\frac{1}{[\rho_2\beta+\rho_1(1-\beta)][\kappa_2\beta+\kappa_1(1-\beta)]}\right]^{\frac{1}{2}}.$$

After dividing by $V_1^2=1/\rho_1\kappa_1$, this expression may be simplified in form by writing, $\gamma=V_1/V_0$, the ratio of the velocity of the suspending liquid to that of the suspension, $a=(\rho_2-\rho_1)/\rho_1$, $b=(\kappa_2-\kappa_1)/\kappa_1$, and we may then obtain

$$\gamma^2=(1+a\beta)(1+b\beta). \qquad (1)$$

Thus the velocity ratio $\gamma$ is a parabolic function of the concentration $\beta$ and will therefore have a maximum or a minimum at some particular concentration $\beta_m$. This concentration,

$$\beta_m=-(a+b)/2ab$$

will be physically realizable, of course, only if it happens to lie between 0 and plus 1. It will be seen later that a minimum of velocity was found for mixtures of kaolin and water.

### THE INTERFEROMETER

The ultrasonic interferometer consists of a piezoelectric crystal mounted in an enclosed chamber. At the opposite end is a reflecting plate capable of being moved parallel to the direction of propagation of the sound by a micrometer screw. The crystal is driven through a loosely coupled coil by a source of constant frequency, and the voltage across the crystal is indicated by a meter. This system is shown schematically in Fig. 1. As the micrometer screw is moved outward or inward, the meter is found to exhibit regular deflections at intervals of a half wave-length, because of the reaction of the standing wave system upon the driving crystal. Thus, the micrometer serves to measure the half wave-length, and since the frequency is known, the velocity of sound in the chamber is readily found. The interferometer chamber is surrounded by a bath whose temperature can be kept constant to 0.01° or so. It is estimated that the interferometer enabled velocity measurements to be made with an average error of 1 part in 3000 or 0.03 percent.

The driving frequency was kept constant at 1 megacycle. At this frequency the wave-length of wound in water is 1.5 mm; the particle size of the suspensions to be described was in the range 1 to 10 microns.

## KAOLIN SUSPENSIONS

The validity of the additive formula for sound velocity may be demonstrated by some data on suspensions of kaolin in water. Kaolin is a complex aluminum silicate occurring in nature in a rather high degree of purity. It is a residual weathering product and a common constituent of natural clays and muds. It is an admirable material for providing solid aqueous suspensions since it disperses readily in water, does not gel, and needs no grinding to render the particles fine. By using a suitable deflocculant, such as sodium pyrophosphate, in an amount necessary to give a pH of 9–10, suspensions of kaolin with a volume concentration of 35–40 percent can be made rather readily with sufficient fluidity for use in the interferometer. Care was taken to remove the air mixed into the suspension by the dispersion process. A size analysis showed that 90 percent of the particles were between 0.4 and 5.0 microns in diameter, with a median size of 1.1 microns. The concentration of kaolin was determined by density measurements, using a density of 2.60 for kaolin.

Figure 2 shows a plot of sound velocity in such mixtures against percentage by volume of kaolin. The velocity is plotted as the ratio of velocity in the suspension to that of the liquid (water and deflocculant) in which the kaolin particles are suspended. The velocity at first falls as kaolin is added to the liquid, reaches a minimum at 20 percent kaolin by volume, then rises. The two solid curves are computed from Eq. (1) for a compressibility ratio of 0.05 and zero times the compressibility of the suspending liquid. The zero compressibility-ratio curve refers, of course, to the limiting case of an incompressible solid. Also plotted in this figure is a curve computed from Herzfeld's formula mentioned above.

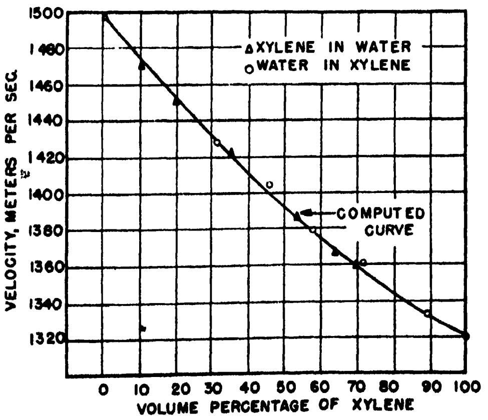

FIG. 3. Sound velocity *vs.* concentration for xylene-water emulsions.

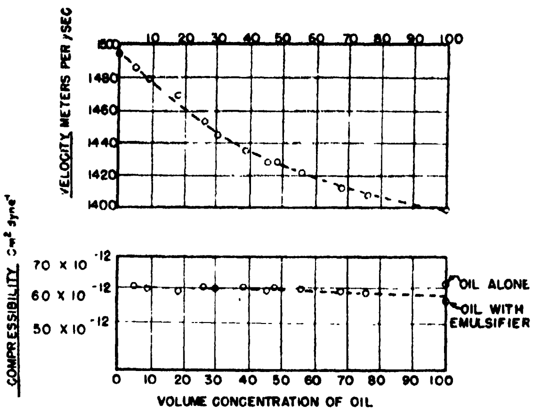

FIG. 4. Sound velocity *vs.* concentration for transformer oil-in-water emulsions.

## EMULSIONS

The applicability of the additive formula can be further illustrated by some emulsions of xylene-in-water and its inversion, water-in-xylene. A xylene-in-water emulsion consists of small separate globules of xylene suspended in a continuous volume of water; such emulsions were made by using sodium oleate as emulsifier. On the other hand, in a water-in-xylene emulsion the globules are water and the continuous liquid is xylene; these were prepared with the aid of sorbitan monooleate as emulsifier. As is common in emulsion technology, phase reversal was avoided by adding a small part of the discontinuous medium (say xylene in the xylene-in-water emulsions) to all of the other medium plus all the emulsifier, then shaking to produce an emulsion, and repeating the process for more and more of the first medium, until all of it was emulsified. The type of emulsion finally obtained was checked by the simple method of observing the miscibility of the emulsion with water and with xylene. Measurement of particle size in these emulsions with a microscope indicated a median particle size of approximately 5 microns.

Velocity measurements made over a range of concentration for the two types of emulsions are

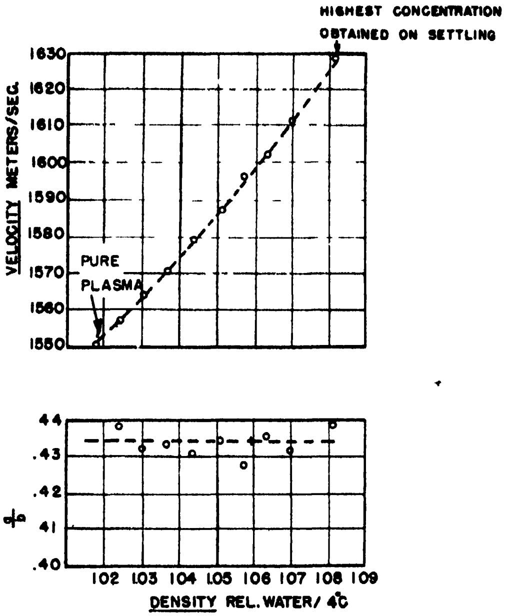

FIG. 5. Sound velocity and the ratio $a/b$ for various dilutions of horse blood with plasma.

shown in Fig. 3. It is interesting to observe that both types of emulsions have the same sound velocity at the same concentration of xylene, indicating that the sound velocity is determined by the composition of the emulsion. The measured sound velocity and density of the end members, xylene and water, enable their compressibility to be found, and Eq. (1) yields the velocity for different mixtures of the two. The velocity so computed is plotted as the solid line in this figure.

## DETERMINATION OF COMPRESSIBILITY

The additive formula provides a method for determining the compressibility of a material which occurs as, or can be rendered into, fine particles. Since the density of the particles is known, it is necessary only to suspend them in a liquid of known or measurable density and sound velocity, and measure the density and velocity of the suspension. For this purpose, we may write Eq. (1) as

$$b=\frac{\kappa_2-\kappa_1}{\kappa_1}=\frac{1}{\beta}\left(\frac{\gamma^2}{\rho}-1\right) \qquad (2)$$

where $\rho$ is the ratio of the density of the suspension to that of the suspending liquid.

The application of this formula may be illustrated by some data obtained on emulsions of transformer oil in water. These emulsions were made by adding 8 percent by weight of triethanolamine oleate to the oil as emulsifier, and agitating thoroughly with water to produce an emulsion. This particular emulsifier is very soluble in oil but only slightly soluble in water. An emulsion of high oil concentration was made in this manner, and those of lower concentration were obtained through successive dilutions with water. Occluded air was removed by placing the emulsion in a vacuum until no further air was seen to come off. Velocity and density measurements were made on eleven such emulsions of varying percentage of oil, and also on water alone and on the oil with and without emulsifier. Figure 4 shows sound velocity plotted against concentration, and in the lower part of the figure, the computed values of compressibility of the oil. These values are seen to be nearly, but not quite constant, and lie intermediate between the measured values for the oil with and without emulsifier. The slight change of compressibility with concentration in this case may represent the effect of partial leaching out of emulsifier from the oil by the successive dilutions with water.

In a similar manner there may be obtained an approximate value of compressibility of the kaolin particles in the suspensions of Fig. 2. Using the data for the three highest kaolin concentrations, $b$ may be found to be $-0.984$, $-0.972$, and $-0.977$ and thus the ratio of compressibilities of kaolin to water $(1+b)$ equal to 0.016, 0.028, and 0.023. Apparently no great percentage accuracy is attainable for substances of such low compressibility as kaolin, since the much larger compressibility of the suspending liquid all but masks the slight effect of the compressibility of the particles themselves.

An alternative method of computation is available in case the concentration $\beta$ is not immediately obtainable. If in Eq. (1) we substitute

$$\beta=\frac{\rho_0-\rho_1}{\rho_2-\rho_1}$$

we may obtain this equation in the form

$$\frac{\rho(\rho-1)}{\gamma^2-\rho}=\frac{a}{b}.$$

The ratio $a/b$, denoting the ratio of the difference of density to the difference of compressibility, is a property of a suspension independent of the concentration of suspended substance, and can be found from density and velocity measurements on any one suspension and the suspending liquid.

This may be exemplified by data on some fresh horse blood obtained from the Naval Medical Research Institute. Blood can be considered to be a suspension of several types of blood corpuscles in a clear pale yellow fluid called the plasma. The red blood cells, or erythrocytes, with a diameter of about 8 microns, outnumber the other types of corpuscles by about 800 to 1, and consist of the red substance, hemoglobin, surrounded by a thin flexible membrane.

By allowing a quantity of fresh blood to settle, samples of clear plasma and concentrated red cells were obtained. Velocity and density measurements were made on these two end members, and also on samples of intermediate red cell concentration obtained by mutual dilution. This data is plotted in Fig. 5, with density, representing concentration of red cells, as abscissa. The lower portion of the plot shows the values of the ratio $a/b$ found from the velocity and density measurements. It is seen to have a constant value, within 3 percent, of $-0.433$. In order to obtain the compressibility of the corpuscles, from this value, we must know their density. This was found by centrifuging a sample of previously measured density. The percentage volume of corpuscular material (or hematocrit reading) yields the density of the corpuscles. This value, 1.091, together with the average value of $a/b$, and the compressibility of the plasma, $40.9\times10^{-12}$ cm$^2$ dyne$^{-1}$ (found from its density and velocity) give as a result the value of $34.1\times10^{-12}$ cm$^2$ dyne$^{-1}$ as the compressibility of the blood corpuscles. Thus, the corpuscles are found to be 16.7 percent less compressible than the plasma in which they are immersed.

## SUMMARY

A method is described by which the adiabatic compressibility of small particles can be found. It requires the measurement of the velocity of sound and of the density on both a suspension of the particles, and on the suspending liquid. The limitations of the method in regard to particle size are undetermined, but a coarse suspension such as blood seems to yield velocities (at a frequency of 1 megacycle) predictable by the simple theory outlined. The requirement of having a sample of the suspending liquid available for measurement is easily met by allowing the mixture to settle, or by centrifuging. It is necessary to control the temperature of the sample to 0.1°C, since the velocity change between suspension and the pure liquid is often slight. The accuracy obtainable is rather small for relatively incompressible solids, such as kaolin, but is probably fairly great for particles having a compressibility not too much smaller than that of the suspending liquid.

# End-Effect in Rotational Viscometers

CHARLES H. LINDSLEY AND EARL K. FISCHER
*Institute of Textile Technology, Charlottesville, Virginia*

(Received July 7, 1947)

In the classical equations for the traction on concentric cylinders by a viscous substance, it is assumed that traction on the top and bottom of the inner cylinder (bob) is negligible in comparison with that on the curved surface. In viscometers of practical dimensions, however, it is necessary to compensate for the end-traction or end-effect by adopting one of several expedients in design or by determining the magnitude of the effect and accounting for it in terms of increased length of bob.

In the experiments reported in this paper, the method of multiple bobs has been used, and the variation of end-effect with the following factors studied: (1) radius of bob; (2) clearance between cylindrical surfaces; (3) separation between bottom of bob and cup; and (4) viscosity.

The magnitude of the end-effect increases with radius and with clearance. For separations at the bottom greater than 1 cm and for viscosities above 1 poise the end-effect is nearly constant, but must be determined for each cup and bob combination. At lower viscosities the correction must be determined either by calibration with a standard liquid of about the same viscosity as the unknown, or by the multiple-bob method.

It is shown that trapping a layer of air beneath the bob is not effective in making the traction on the bottom negligible. The end-effect is almost as large for a bob with an open bottom as for a closed one.

When the method of multiple bobs is used, data with an accuracy of ±2 percent can be obtained without calibration. When the instrument constant is determined with standard liquids or computed from a value for the end-effect previously found, data of somewhat lower accuracy result, but the uncertainty should be within ±5 percent.

## INTRODUCTION

THE co-axial-cylinder viscometer is generally considered the most versatile instrument for the measurement of viscosity. It may be used on suspensions that exhibit anomalous flow properties as well as on Newtonian liquids, and it is suitable for determinations over a wide range of viscosities at variable rates of shear. The literature on instruments of this type is extensive, but relatively few studies have been made on several factors, inherent in the design, which seriously affect the validity of the measurement.

One of the most important of these factors is the contribution of the ends of the inner cylinder or bob to the total retarding force between the bob and the liquid surrounding it. This end-effect has not received the consideration it needs. Accordingly, the present investigation was undertaken with the following objectives: (1) critical evaluation of various methods for eliminating or measuring the end-effect; (2) experimental measurement of the end-effect for cups and bobs of several sizes; and (3) determination of the variation of the end-effect with viscosity and with clearance between cup and bob. To carry out these objectives a commercial Stormer viscometer was used after modification, but the results can be applied to any rotational viscometer equipped with cylindrical cups and bobs.

The mathematical analysis for the determination of viscosities in rational units by the method of rotating co-axial cylinders leads to the expression:[1]

$$T=4\pi\left[\frac{R_c^2\times R_b^2}{R_c^2-R_b^2}\right]h\eta\omega \tag{1}$$

where $T$ is the driving (or retarding) torque on the bob, $R_c$ the radius of the cup, $R_b$ the radius of the bob, $h$ the length of the bob, $\eta$ the viscosity of the liquid between cup and bob, and $\omega$ the speed of rotation at equilibrium. The radii and length being known, $T$ and $\omega$ are found experimentally, and hence $\eta$ may be calculated. For materials that exhibit plastic-flow properties the equation given by Reiner and Riwlin[2] is now considered to account fairly well for the results obtained.

---

## METHODS FOR CORRECTING FOR TRACTION ON BOB ENDS

In the derivation of Eq. (1) it is assumed that the traction of the viscous liquid on the top and bottom of the inner cylinder is negligible in comparison with the traction on the curved surface. No adequate mathematical treatment has yet been given of the contribution of the ends to the total traction on the bob. It is necessary, therefore, to take it into account in one of the following ways: (1) use of a very long bob of small radius, with small clearance between cup and bob, to make the correction negligible; (2) calibration of the instrument with liquids of known viscosity, thus absorbing the end-effect in the instrument constant; (3) reduction of the relative motion of the liquid above and below the ends of the bob by mechanical expedients; and (4) measurement of the effect experimentally in order to include it in the calculations of viscosity and yield value.

The first method imposes many difficulties in the design of suitable apparatus. The second method is widely used, but one should be aware of the fact that the correction (and hence the instrument constant) changes with viscosity as will be shown in the experimental portion of this paper. Mooney and Ewart[3] devised an ingenious way of including the correction in the instrument constant: the bottom of their bob was a very flat cone (half angle 87.03°) with the apex resting on the center of the bottom of the cup. With this arrangement they showed that the rate of shear across the bottom was the same as that along the cylindrical surface; the constant obtained on calibration should therefore hold much better over a wide range of rotational speeds and viscosities than is the case with a bob of conventional type.

The third method was used in the instruments of Čouette,[4] Drew,[5] and Hatschek.[6] Stationary guard rings of the same radius as the inner (suspended) bob were placed as closely as possible above and below the bob. These rings prevented the liquid at the ends from rotating as the cup turned without interfering with the traction on the cylindrical surface, and thus eliminated the end-effect. Such instruments require machining and alignment of high precision and are difficult to clean. They are, therefore, suitable for standardization and research but are hardly practical for routine control use.

A widely used method, purporting to eliminate or greatly reduce the end-effect is to make the bottom of the bob slightly concave so that air is trapped in the cavity when the bob is immersed in the liquid to be measured (Fig. 1C). The assumption is that since the bottom of the bob rotates against a layer of air, of very low viscosity, the traction will be negligible. We have not found any experimental evidence in the literature that validates this assumption. Mercier[7] provided a raised portion in the bottom of the cup that almost closed the recess in the bob in order to exclude the liquid. His experimental data do now show whether he succeeded, however.[8] Nevertheless, Mooney and Ewart[3] refer to Mercier's "ingenious design (which) practically eliminates shearing stresses over the bottom surface." Goodeve[9] describes an instrument in which the cylindrical cup and bob are replaced by co-axial truncated cones, the ends of which are dished out. In the first paper he states that this reduces the end-effects to negligible values, and calculates viscosities using the measured dimensions of the cones; yet he gives no evidence to show that valid results are so obtained. In the second paper he only claims that the drag on the lower end is reduced by the trapped air, adding that "the reduction is not as large as might be expected because surface tension draws the fluid up into the rim"; he therefore calibrates the instrument with liquids of known viscosity,

[7] P. Mercier, J. Rheology 3, 391–412 (1932).

[8] There is a strange gap in Mercier's discussion of his experimental results (reference 7, p. 405). It would appear that a considerable portion of the discussion had been omitted from the printed paper. The graphical presentation of his data gives no indication of success or failure in eliminating the end-effect. Furthermore, the graph indicates that the instrument was used at speeds as high as 4000 r.p.m. It is remarkable, to say the least, that he was able to operate this type of instrument, with a clearance of only 1 mm between cup and bob, at such speeds without getting turbulence and centrifugal effects that would cause deviations from a linear relationship.

[9] C. F. Goodeve and G. W. Whitfield, Trans. Faraday Soc. 34, 511–520 (1938), and C. F. Goodeve, J. Sci. Inst. 16, 19–27 (1939).

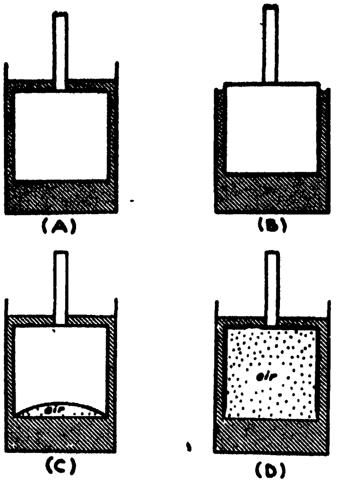

Fig. 1. Types of Cylindrical Bobs: A. Closed bob, completely immersed; B. Closed bob, immersed to different depths; C. Bob with concave bottom; D. Open bob.

including the end-effect in the empirically determined instrument constant.

In the absence of any sound experimental evidence of the effectiveness of this method in eliminating end-effect, we have studied the behavior of cylindrical bobs with open bottoms and find an effect almost as large as for a closed bob of the same dimensions. The effect as measured includes, of course, the drag on the top, which is the same for both bobs, but this can be shown to be smaller than the bottom effect. The method therefore does not accomplish the purpose for which it was designed and introduces a new uncertainty, namely, the extent to which the liquid does rise inside the bob.

The fourth method of evaluating the end-effect has been used by several investigators. In principle the traction on two bobs of the same radius but different lengths is measured, and by a difference calculation, the effect of the ends may be determined. Searle[10] designed an instrument with a long inner cylinder, the height of liquid about it being changed by raising or lowering the surrounding cup (cf. Fig. 1B). The time $T$ for one revolution was determined for several values of a falling weight $W$ used to turn the inner bob. For any given depth of immersion $h$, the product $WT$ was constant, and when $WT$ was plotted against $h$ for several depths, a straight line was obtained with a negative intercept $h_0$ on the $h$-axis. This intercept may be interpreted as an increment in bob length; that is, a bob having no end-effect, when immersed to a depth $h+h_0$, would exert the same traction as the actual bob immersed to depth $h$.

Lillie[11] made a careful study of the end-effect with an instrument designed primarily to measure viscosities of molten glass. He used two sets of five bobs each, those within each set having a constant radius but differing in length. Substitution in Eq. (1) for the dimensions of cup and bob and for the experimental quantities $T$ and $\omega$ gave a value for the "apparent viscosity" for each bob used with a given liquid. When these values were plotted against the reciprocals of the corresponding bob lengths ($h$), a straight line was obtained; its intercept on the axis $1/h=0$ (i.e. for a bob of infinite length) gave what Lillie termed the "true viscosity." Substitution of this value for $\eta$ in Eq. (1), $h$ being considered unknown, gave a value $h^*$ that might be called the effective length of each bob. The difference between this value and the actual length, $h^*-h=h_0$, was a measure of the end-effect quite analogous to $h_0$ as found by Searle.

## EXPERIMENTAL PROCEDURES

A commercial model Stormer viscometer was used after some important modifications had been made. The water jacket supplied with the

instrument was wound with resistance wire (18 ft. of 22-gauge Nichrome) and then with several layers of asbestos paper. Current for this heating coil was supplied through a Variac and controlled by a fixed-contact mercury thermoregulator and a suitable relay. At 30°C the temperature could be held to within ±0.1°. Other thermoregulators were available to give temperatures up to 90°C. At high temperatures, however, enough heat may be lost through the shaft of the bob to lower the temperature of the bob and of the liquid in contact with it and thus introduce appreciable error. A plastic bob with brass shaft was made for use at high temperatures; the heat transfer at the surface of such a bob is far less than with an all-metal bob.

The construction of the cup and bob supplied with the instrument makes them unsuited for determination of viscosity in absolute units. Several cylindrical cups and bobs were machined from brass of such sizes that a variety of rates of shear for any given rate of rotation was possible. The dimensions are shown in Table I. The larger bobs were hollow to reduce inertia and weight on the bearing. Duplicates of two bobs were made with the lower ends left open to permit a study of the end-effect for concave bobs (Fig. 1D).

In order to evaluate the results obtained by the several procedures followed, four viscosity samples, certified at 30°C, were obtained from the National Bureau of Standards, the viscosity ranging from 0.2648 to 153.9 poises. A description of these standards has been given recently by Swindells.[12] In addition, a series of four bodied linseed oils (litho-varnishes) were obtained to give better coverage of the range.

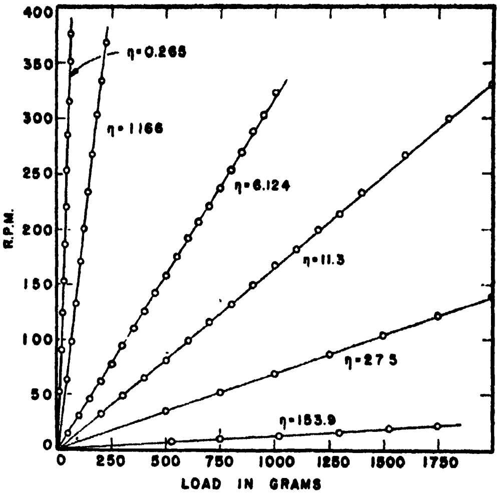

FIG. 2. Experimental values for load and r.p.m. for oils showing Newtonian flow.

The procedure in using the viscometer follows. The cup and bob were carefully aligned, the bob being raised about 1.3 cm above the bottom of the cup. The cup was then filled to the top with the sample to be measured. After the sample had reached 30°C (the temperature at which all measurements here reported were made), at least ten measurements of the time of rotation with different loads were taken. The ratio of load to r.p.m. was calculated and found to be nearly constant for each sample so long as the rotation was held below 400 r.p.m. (Fig. 2). This constancy indicated that the oils were Newtonian in their flow properties.

## THE SINGLE-BOB METHOD

Some preliminary measurements were made with one of the standard samples (N-13) following the method of Searle, that is, by immersion of one bob to varying depths. The intercept was found to be 0.29 cm with bob 1 and cup 1. With this value for the end-effect added to the actual

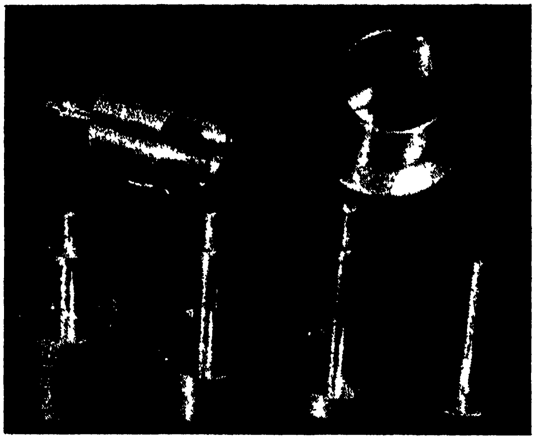

FIG. 3. Four bobs of equal radius but different height; open bob; cup.

length of the bob, the viscosity of the sample was found by Eq. (1) to be 6.36 poises, in approximate agreement with the certified value of 6.12 poises. The principal source of error in the method lies in the inaccuracy with which depth of immersion of the bob is measured. In spite of this drawback, the method affords a rapid and easy means of obtaining viscosities in cgs units with an accuracy of about 5 percent, and only one machined cup and bob are needed.

## THE MULTIPLE-BOB METHOD

For more accurate results a method similar to that used by Lillie is preferred: the end-effect may be first eliminated and afterwards evaluated (if desired) by using a set of bobs equal in radius but different in length (Fig. 3). For each bob the ratio of load to r.p.m. is determined in the usual way. From the ratios for any pair the viscosity is calculated by the following modification of Eq. (1). Let $L$ be the torque exerted by the liquid against the ends of the bob, and $T$ the total torque exerted against the ends and cylindrical surface. Equation (1) may then be written for two bobs of length $h_1$ and $h_2$:

$$T_1=4\pi r^2 h_1\eta\omega_1+L$$

and

$$T_2=4\pi r^2 h_2\eta\omega_2+L$$

where

$$r^2=R_c^2\times R_b^2/(R_c^2-R_b^2).$$

If $T_1$ and $T_2$ are chosen so that $\omega_1=\omega_2$, these equations may be solved for $\eta$:

$$\eta=\frac{T_1/\omega_1-T_2/\omega_2}{4\pi r^2(h_1-h_2)}. \tag{2}$$

Since $T/\omega$ is constant for all values of $\omega$ for a Newtonian liquid, the average values of $T_1/\omega_1$ and $T_2/\omega_2$ may be used, and not just those for which $\omega_1=\omega_2$. With the Stormer viscometer the weight or load may be substituted for torque thus:

$$T=Wgl$$

where $g$ is the acceleration of gravity and $l$ the effective length of the arm on which the weight acts. It is also more convenient to express angular velocity in r.p.m. than in radians per second:

$$\omega=\frac{2\pi}{60}\cdot\text{r.p.m.}$$

If we designate by $P$ the experimentally determined ratio $W$/r.p.m., Eq. (2) becomes·

$$\eta=\frac{K}{r^2}\times\frac{\Delta P}{\Delta h} \tag{3}$$

where

$$K=\frac{60gl}{8\pi^2}.$$

For the Stormer viscometer $l$ is the radius of the drum on which the cord is wound plus the cord radius, divided by the gear ratio. In our instrument $l=1.456/11$, and the constant $K$ has the value 99.0.

To illustrate the use of this equation, data obtained with bobs 1, 5, 6, and 7 in cup 1 are shown in Table II. For $\Delta P$ and $\Delta h$ the differences between the $P$ and $h$ values for bob 1 and each of the other bobs are taken. (Three other combinations are possible but are not so useful.) The average of the three calculated viscosities is 6.27 poises, in fair agreement with the certified value of 6.124. Since the relative effect of the ends is less for bobs 1 and 5 than for bobs 6 and 7, the first two should yield a more accurate value for $\eta$. This expectation is borne out by the agreement with the certified value.

In Table III are given the viscosities of four of the certified samples determined by the method just illustrated in detail. Although the viscosities calculated using bob 7 were not included in the averages, to have done so would not have changed the results significantly. The figures indicate that viscosities over a wide range may be determined in absolute units with an accuracy of about 2 percent.

With the value of $\eta$ so determined the same experimental values of $P$ are used to calculate the effective length of the bob $h^*$, and from it the end-effect $h_0$ expressed as increment in length, by means of the equation:

$$h^* = \frac{K}{r^2} \times \frac{P}{\eta} = h + h_0. \tag{4}$$

Such calculations are illustrated in the last two lines of Table II. It is interesting that even for a very thin bob (No. 7) for which the traction on the end is nearly 90 percent of the total, the end-effect is nearly the same as for a bob more than 40 times longer.

One would expect the end-effect to increase as the bottom of the bob is brought closer to that of the cup; moving in the other direction, one would expect that above a certain point there would be no significant change with increasing separation. This behavior was demonstrated by determining the end-effect with a short bob (No. 5) at varying depths of immersion. The results are shown graphically in Fig. 4. Above 1 cm the variation of end-effect with depth is insignificant. The height of liquid above the top of the bob is not critical, so long as it is at least 2 mm.

A different approach to the measurement of end-effect was attempted by use of bobs open at the bottom as noted above. At the same time a check on the effect of the top of the bob was made by carrying out runs with the top just level with the top of the cup filled with liquid and with it submerged 5 mm below the surface of the liquid. The results are shown in Table IV. The second column shows the combined effect of top and bottom; the third column the effect of the bottom, while the difference (fourth column) shows the effect of the top. The uncertainty in the values for end-effect in this series of measurements is estimated as about 1 mm. The apparent inversion for the data of bob 1, cup 1 may be ascribed to this factor.

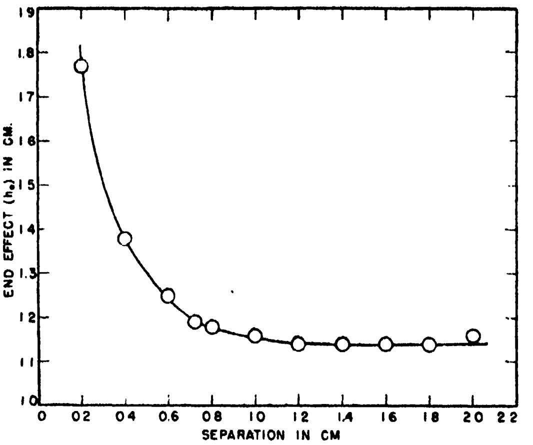

FIG. 4. Variation in end-effect with separation between bottom of bob and cup.

With the limitations on precision in such measurements in mind, the following observations may be made: (1) virtually the same traction is exerted at the bottom of the bob whether it is open or closed; (2) in general the bottom exerts a greater traction than the top, due probably to the greater freedom of the liquid above the bob to rotate with it. The first result was quite unexpected, and is contrary to much that is stated or implied in the literature and in the design of several viscometers. It was therefore checked by repeating the comparison of closed and open bobs in liquids differing markedly in viscosity. The results are shown in Table V. Since a number of variables are involved, the most valid comparisons are made for each pair of figures for open and closed bobs. In the last column in which end-effect is expressed as percent of effective bob length, it will be seen that although the results with the open bob are less

TABLE IV. End-effect for bobs closed and open at the bottom, with tops immersed or exposed.

than those with the closed bob, the reduction is not nearly so high as one would expect.

Since the end-effect as normally measured varied with separation between bottom of bob and cup, it was of interest to see if a similar change would be observed with an open bob. The results obtained are shown in Fig. 5: the end-effect is slightly less when the bob has no bottom, but otherwise is quite similar.

## VARIATION OF END-EFFECT WITH CLEARANCE AND VISCOSITY

The influence on the end-effect of the following factors was studied: radius of the bob, clearance between bob and cup, and viscosity of the liquid being measured. Table VI summarizes many determinations with different cup and bob combinations; most of the values given are averages of several measurements made with bobs of the same radius but different lengths (as illustrated by the data for $h_0$ in Table II) and with oils of viscosities between 1 and 154 poises. The precision of the measurements as shown by variation in $h_0$ for different oils appears low, amounting to as much as 25–30 percent, but this is because errors are magnified since $h_0$ is obtained by difference. For example, if the effective length of a bob 3.5 cm long is found to be 4.5 cm, the end-effect is 1.0 cm; then an error of 5 percent in $h^*$ makes an error of 22 percent in $h_0$. It is clear, however, that the effect increases with clearance and that, for a given clearance, the effect may be somewhat larger the larger the radius of the bob. In explanation, perhaps more disturbance is created in the liquid by the end of the bob with relatively large clearances than when these surfaces are close together. The same explanation may account for the lower precision attained at the larger clearances.

TABLE VI. Variation of end-effect with clearance between cup and bob for several bob radii.

| Bob radius, cm | Clearance, cm | End-effect, cm |
|---|---|---|
| 1.27 | 0.48 | 0.8 |
| | 1.08 | 1.2 |
| 1.57 | 0.18 | 0.6 |
| | 0.78 | 1.0 |
| | 0.97 | 1.4 |
| | 1.24 | 1.4 |
| 2.10 | 0.08 | 0.6 |
| | 0.24 | 0.8 |
| | 0.44 | 1.2 |
| | 0.70 | 1.4 |

TABLE VII. Variation of end-effect with viscosity (clearance 0.18 cm).

| Viscosity at 30°C | End-effect |
|---|---|
| 0.017 poise | 11.5 cm |
| 0.058 | 2.94 |
| 0.145 | 1.94 |
| 0.265 | 1.28 |
| 1.166 | 0.60 |
| 1.48 | 0.65 |
| 6.124 | 0.52 |
| 9.2 | 0.60 |
| 11.3 | 0.59 |
| 27.5 | 0.56 |
| 153.9 | 0.49 |

Table VII shows the variation of the end-effect with viscosity observed with the combination of cup 1 and bob 1. Entirely similar data were obtained with other combinations. For viscosities above 1 poise the effect is nearly constant (about 0.6 cm in the example shown). As one goes to lower viscosities, however, the end-effect becomes progressively greater. The greater the clearance between cup and bob, the more rapidly the end-effect increases as viscosity decreases. These facts too can be explained by assuming that at low viscosities the rotating ends of the bob interfere with laminar motion of liquid between the cylindrical surfaces.

Even with these variations, if only those combinations of cup and bob are used for which the clearance is small (say, less than 0.8 cm), a value for the end-effect may be found which permits determination of viscosity in poises over a wide range. This is illustrated by the data in Table VIII. Viscosities were calculated from Eq. (4), with the best value for $h_0$ and hence for $h^*$ determined by the multiple-bob method described above. It should be noted that at no point in the determination of the viscosities in Table VIII have the certified or known values for the samples been used. Over this range the correction for end-effect may be applied to give viscosities with an accuracy within ±5 percent.

## DISCUSSION

The advantages of the co-axial cylinder viscometer are so numerous that it deserves wider use for industrial measurements. As it is commonly used, however, the data obtained cannot be expressed in rational units and, as a consequence, the technical literature is cluttered with meaningless measurements. The unsatisfactory state of instrumentation in this field is in part responsible, but the mechanical changes necessary to convert a standard commercial Stormer viscometer are comparatively simple and can be made at relatively small cost. The modified instrument makes possible the measurement of viscosities based on accepted physical principles and yields data which are dimensionally consistent and experimentally reproducible. The precautions necessary for satisfactory operation —aside from such obvious matters as temperature control, centering of bob and cup, etc.— are to a large extent elucidated by the experimental data presented above.

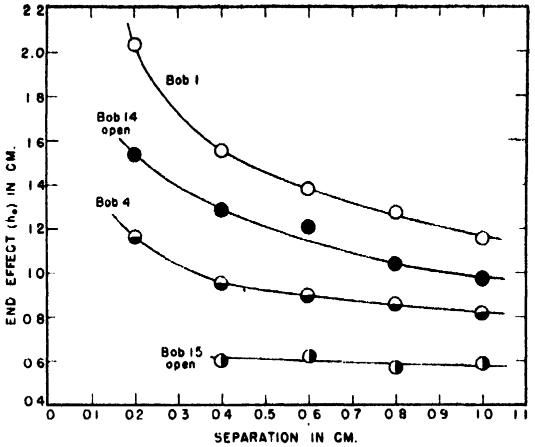

FIG. 5. Variation in end-effect for closed and open bobs.

In making cups and bobs for the Stormer viscometer, the important dimensions are the

inside diameter of the cup and the diameter and length of the bob. Machining tolerances should be within 0.002 cm (0.001 in.). For most measurements two cups and bobs, making available three clearances, will be found enough; we have found cups 1 and 2 and bobs 1 and 4 most useful.

Because of the nature of the study we were making, the end-effects were determined without any reference to standard viscosity samples except for final confirmation. For this purpose the method of multiple bobs is recommended. For most applications and industrial uses, however, a simple calibration with standard samples is more convenient and entirely satisfactory. It is enough to determine $P$, the ratio of load to r.p.m., as described above, and substitute for it and the known value of $\eta$ in the equation $\eta = K_v \cdot P$ in order to determine the constant $K_v$. This constant combines the end-effect with all the various instrument constants, dimensions of cup and bob, etc.

Within the range from 1 to 150 poises (and probably considerably higher) calibration with a single standard sample will be found sufficiently accurate for most purposes. Below 1 poise, however, since the end-effect has been shown to become increasingly large, calibration should be made with a standard the viscosity of which is close to that of the material to be measured. If this is not possible, the multiple-bob method should be used.

A separation of at least 1 cm should be kept between the bottom of the bob and cup, and an overlay of about 5 mm of liquid above the top of the bob is desirable. In addition to constancy in end-effect, one advantage of the bob immersed well below the liquid level when measuring solutions or suspensions is that evaporation of all except the most volatile solvents introduces small or negligible effects during the course of measurement.

## ACKNOWLEDGMENT

The authors are indebted to Mrs. Dorothy P. Stubbs and Mr. Samuel E. Miller who made many of the experimental measurements.

# The Theory of Disk-Loaded Wave Guides

E. L. Chu* and W. W. Hansen
*Department of Physics, Stanford University, Stanford University, California*

(Received July 11, 1947)

The properties of circular wave guides loaded with apertured disks are discussed both qualitatively and quantitatively. Formulae and curves are given for various quantities including the wave and group velocities, the attenuation, and the power flow.

## INTRODUCTION

IN the normal circular wave guide shown in Fig. 1a, the running waves of field propagate with a phase velocity greater than that of light. By the introduction of apertured disks, as shown in Fig. 1b, which also defines some of our notation, this velocity can be reduced as much as desired. In addition to altering the phase velocity, the loading disks change the group velocity and, two parameters being available, the two velocities can be controlled independently. Finally, the periodic spacing of the disks introduces a high frequency cut-off, in addition to the low frequency one already present, so that the loaded structure has many of the characteristics of a band pass filter. We propose to report here certain calculations on the properties of such structures, which we call disk-loaded wave guides.

While the main formulae we use are of general interest, some special formulae and many of the numerical examples are developed to fit the special circumstances of an important possible use of disk-loaded guides—namely, that of accelerating electrons. Indeed, interest in this problem has been the primary motive for developing the theory that follows.

Before describing the details of the calcula-

---

[*] On leave from the Institute of Physics, Academia Sinica, Shanghai, China.

tions, it will be useful to consider several qualitative descriptions of the operation of such a structure.

One point of view regards the disk-loaded guide as derived from an infinite sequence of end-to-end cylindrical cavity resonators by opening up "coupling holes" between adjacent cavities. Then if we consider the behavior at various frequencies, as is done in Fig. 2, we start at zero frequency with Fig. 2a showing the electric-field lines terminating on the disks and decreasing rapidly in strength as we go from left to right. Here we are below the low frequency cut-off, the device acts as an attenuator, and curvature of electric-field functions toward the axis, when going in the $r$ direction, is canceled by curvature away from the axis in the $z$ direction to give the zero total curvature required at zero frequency. As we increase the frequency, the curvature away from the $z$ axis decreases until at the resonant frequency of the uncoupled resonators without holes ($\lambda = 2.61b$) the fields are in phase everywhere in the guide, there is no attenuation, and the field curvature is all in the $r$ direction, as shown in Fig. 2b. This field configuration may be regarded as obtained by removing disks of radius $a$ from the inter-resonator boundaries of a sequence of resonators all oscillating in phase, such removal not altering the fields since the currents on opposite sides of any removed disk are equal and opposite. As we further increase the frequency, so running the cavities off resonance, it becomes necessary to supply reactive power to each cavity. This comes through the coupling hole from the adjacent cavity which must then be of somewhat different phase. The resultant field pattern is sketched in Fig. 2c and it must now be remembered that this represents a running wave. As the frequency is further increased, the phase shift per section increases until it becomes 180° at which point the fields are as shown in Fig. 2d. As the frequency is further increased, more phase shift is impossible, attenuation again sets in and the fields are as in Fig. 2e. Thus we see that the two cut-off frequencies correspond to the two modes of cavity oscillation shown in Figs. 2f and 2g.

A second point of view regards the disk-loaded guide as derived from an ordinary guide by the introduction of loading disks which may at first be taken as having small radial extent. From this point of view the fields of Fig. 2a are obvious and Fig. 2b is nearly so; we merely have to remark that, at cut-off, the disks do not influence the electric field since they are at right angles thereto. As we enter the pass region, the disks do not suppress the propagation so long as the disks are closer together than half a loaded-guide wave-length, for in such a case the reflections from succeeding disks cannot add up but must, over a long distance, cancel. This ceases to be so when the guide wave-length decreases to the point that the disks are a half-wave apart, for then the reflections add and transmission is impossible. We then enter the attenuation region as in Fig. 2d.

The third point of view, and the one most closely connected with the mathematics here used to reduce qualitative ideas to quantitative, starts with the fields, and more particularly the fields near the axis, as given, and seeks a structure that fits the fields, as opposed to the above, and usual, procedure of starting with a structure and finding the fields.

Thus we start by requiring a field which, for $r<a$, is finite, axially symmetric, and represents a wave running in the $z$ direction with (real) wave number $k_3$. These conditions completely specify the wave functions—the only possible solution of Maxwell's equations is

$$\begin{aligned} E_z &= E_0 J_0(k_1 r) e^{-jk_3 z}, \\ E_r &= E_0 j(k_3/k_1) J_1(k_1 r) e^{-jk_3 z}, \\ B_\phi &= E_0 j(k/k_1) J_1(k_1 r) e^{-jk_3 z}, \end{aligned} \tag{1}$$

with all other components zero. Here $E_0$ is a constant, we use Gaussian units and a positive time factor, and

$$k_1^2 + k_3^2 = k^2 = 4\pi^2/\lambda^2.$$

It would appear that since $k_3$, which regulates the wave velocity, is unrestricted we can make waves which go with any velocity whatever. But we note that, the velocity being given by $v/c = k/k_3$, a velocity less than that of light implies a $k_3$ which is greater than $k$, and so an imaginary value of $k_1$. While the above are still solutions, their characteristics change when $k_1$ becomes imaginary, and we must investigate their properties for both real and imaginary $k_1$.

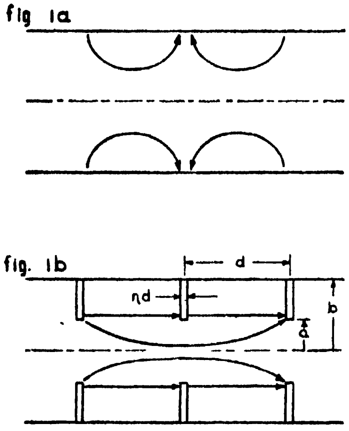

FIG. 1. The sketch of Fig. 1a shows the configuration of electric-field lines in an unloaded circular wave guide, while Fig. 1b shows the fields in a guide loaded by means of apertured disks, and also defines the notation used in describing the guide dimensions. The special case shown has the loads one-quarter wave apart—any other spacing is, of course, possible.

For real $k_1$ the Bessel function is oscillatory so that $E_z$ passes through zero for an infinite number of values of $r$. A qualitative field plot for this case is given in Fig. 3a. When $k_1$ is positive imaginary, however, $J_0$ and $J_1$ are monotonic increasing functions of $r$, so that the $E$ lines cannot reverse directions with the result that the field is qualitatively as shown in Fig. 3b.

Now, having specified the fields, we ask what metallic boundaries we can introduce to confine them to a finite region in space. In the case of fields like those of Fig. 3a one answer is well known: we can introduce a conducting tube in the position indicated by the dotted lines, in which case the electric field is everywhere perpendicular to the conductor and the currents carried by the conductor support the discontinuity in magnetic field. But this is impossible for the fields of Fig. 3b, for they never become perpendicular to the axis.

But another, and more general, possibility becomes apparent if we consider a special type of boundary. If we use a conducting sheet, the correct boundary conditions are $E_{\tan}=0$, $B_{\tan}\neq 0$, or $E/B=0$. But if we now add to the sheet a number of closely spaced conducting fins, each $\lambda/4$ long and perpendicular to the main sheet, we have a boundary which will sustain an electric field without a magnetic field since each pair of adjacent fins acts as a quarter-wave resonant line. The correct boundary conditions are then $E/B=\infty$. Moreover, it is easy to see that by choosing a fin depth between zero and $\lambda/2$, it is possible to obtain any desired value of $E/B$.

Thus, by using such a finned boundary we can contain any field and in particular the one assumed above. Thus we are led to the disk-loaded guide, and conclude that waves in such a structure can be made to run with any velocity desired.

In carrying out an analysis along the above lines it is plain that the results will approach exactness as the fins get closer and the phase shift per fin approaches zero. On the other hand, as the fin spacing is increased no qualitative changes occur until the phase change per fin becomes $\pi$, at which point the approach breaks down completely. This corresponds, of course, to the high frequency cut-off.

We can now conclude our introductory remarks by specifying the quantities given and to be computed and the approximations to be made.

The six quantities $a$, $b$, $d$, $\eta d$, the skin depth $\delta$ characterizing the guide material, and $\lambda$, may be regarded as given, and may obviously be reduced to five by measuring lengths in terms of $\lambda$. These five we take as $ka$, $kb$, $kd$, $\eta$, and $\lambda/\delta$. Usually $\lambda/\delta$ is large, in which case it may be

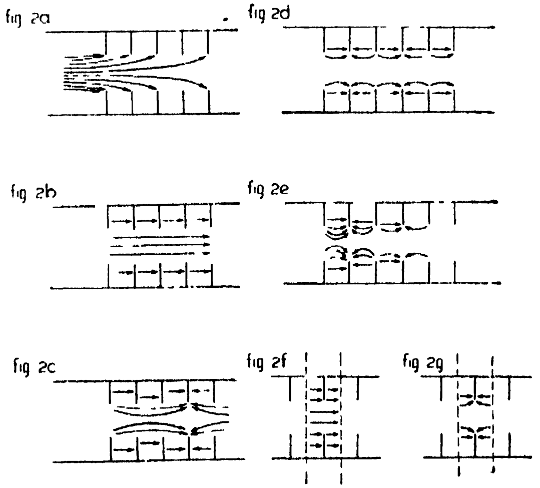

FIG. 2. Sketches a–e show the qualitative behavior of the $E$ lines in a loaded guide as the frequency is raised from zero to above the high frequency cut-off. Illustrations f and g show how a cavity can be constructed from a section of the guide by the addition of conducting planes, shown as dotted lines. The two indicated modes of oscillation of this cavity correspond to the low and high frequency edges of the pass band for the loaded guide.

disregarded in wave-length calculations and will appear only in loss calculations. Moreover, we will often assume that $kd$ is negligibly small, in which case there remain three quantities $ka$, $kb$, and $\eta$. Further, $\eta$ may sometimes be negligible also.

In principle there are only two quantities to compute, the wave number in the $z$ direction, which we call $k_3$ and which would be called the propagation constant in filter theory, and a characteristic impedance $Z_i$, to be defined more precisely later. As to $k_3$, a slightly more convenient quantity is $k_3/k = 1/\beta$, where the wave velocity is $\beta_c$. We also note that $k_3$ is complex so that we must compute both real and imaginary parts, the latter being a measure of the attenuation.

Although $k_3$ and $Z_i$ contain all the information, it is useful to compute also certain related quantities. These will be defined as the occasion arises but we may mention that the group velocity and the axial field for a given power are important, and that it is useful to compute not only the attenuation but the $Q$.

As to the approximations involved, they depend on the calculational approach used. As indicated in the qualitative discussion, at least three procedures are possible. First, we can treat the structure as a series of resonators perturbed by the coupling through the center holes. For such a calculation we must have $a \ll b$, $a \ll d$. Second, we may consider the loading to be nearly continuous, in which case we must have $d \ll a$, $d \ll b-a$. Third, we may consider a cylindrical wave guide, perturbed by the addition of loading disks. For this calculation we take $b-a \ll d$, $b-a \ll b$. For the computation of $k_3$ we have used all three methods. For the attenuation, impedance, and other quantities which are less critical we have usually used approximations based on the second approach. Thus it happens that the numerical majority of our results depend on this second approach, which will now be explained in detail.

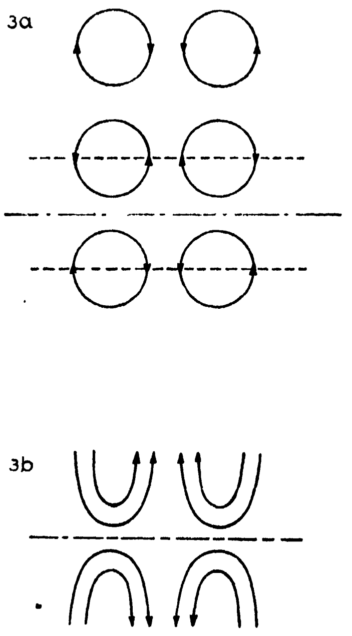

fig. 3a

fig. 3b

FIG. 3. Sketch a shows qualitatively the shape of $E$ lines given by Eq. (1) for real values of $k_1$, while b shows them for imaginary $k_1$. In the former case a cylindrical conducting boundary can be introduced at the radius indicated by the dashed lines.

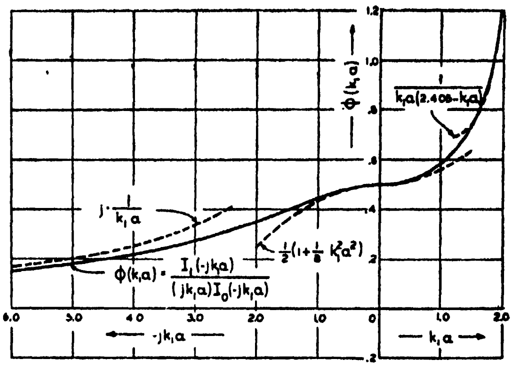

FIG. 4. This shows $\phi$ as a function of $k_1a$, real values of the argument being on the right-hand side, and imaginary values on the left. Various approximate formulae are shown in dotted lines.

## CALCULATIONS

### 1. Phase and Group Velocity

In (1) we have already given the fields to be used for $r < a$. For $a < r < b$ we take

$$E_z = CE_0Z_0(kr)e^{-ik_3(z)},$$

$$E_r = 0, \tag{2}$$

$$B_\phi = CE_0jZ_1(kr)e^{-jk_3(z)},$$

with $C$ a constant and $Z_0$ a Bessel function that is zero at $r=b$,

$$Z_0 = J_0(kr)N_0(kb) - N_0(kr)J_0(kb), \tag{3}$$

and

$$Z_1 = J_1(kr)N_0(kb) - N_1(kr)J_0(kb). \qquad (4)$$

Here $(z)$ is equal[1] to zero when $-d/2<z<d/2$, to $d$ for $d/2<z<3d/2$, etc., with the loading disks at $z=d/2$, $3d/2\cdots$. Otherwise said, $(z)$ is equal to the value of $z$ midway between the two nearest loading disks. Also, the fields are to be zero in the space occupied by the disks.

Plainly these are solutions of Maxwell's equations, and they satisfy the boundary conditions on the cylinder $r=b$ and on the plane surfaces of the disks. To join this function to that for $r<a$, we (a) make the values of $B_\phi$ match at $r=a$, and (b) make $(1-\eta)E_z$ from (2) at $r=a$ equal $E_z$ from (1). To do this we must adjust the constant $C$ and also find a $k_1$ such that the equation

$$\phi(k_1a)=\frac{1}{k_1a}\frac{J_1(k_1a)}{J_0(k_1a)}=\frac{1}{(1-\eta)ka}\frac{J_1(ka)N_0(kb)-N_1(ka)J_0(kb)}{J_0(ka)N_0(kb)-N_0(ka)J_0(kb)}=\frac{1}{1-\eta}\alpha(kd,\,kb) \qquad (5)$$

is satisfied.

This makes $B_\phi$ continuous at $r=a$, $z=(z)$, and the average value of $E_z$ likewise, and this is the best that can be done with these approximate functions. Besides the fact that $E_z$ and $B_\phi$ are not continuous at $r=a$, for general values of $z$, we note $E_r$ is finite for $r<a$ and zero for $a<r$. This is also correct on the average, for charge accumulates on the edges of the loading disks because of the difference in current from section to section.

The above is easy to understand, and is certainly right in the limit $k_3d\rightarrow 0$. If $k_3d$ is finite, the correct procedure would be to take $E_z$ at $r=a$ to be of the form $\cos k_3zf[z-(z)]$, where $f$ is some suitable function of the distance from the

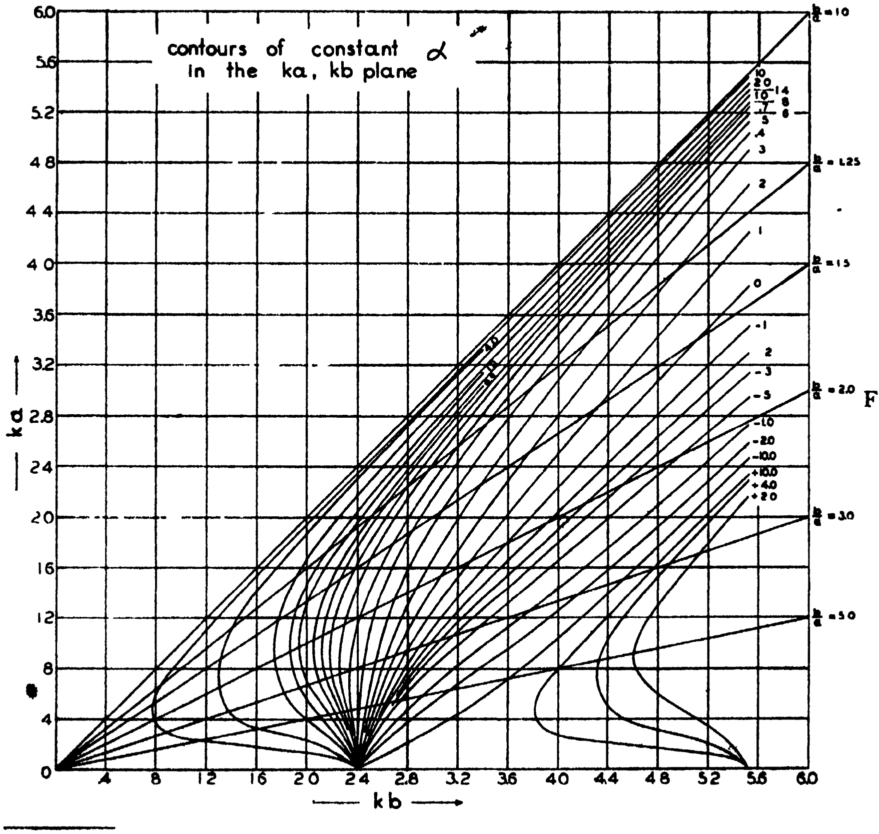

FIG. 5. Shows contours of constant α in the $ka$, $kb$ plane.

---

[1] This notation is similar in spirit, though not in detail, to the standard notation $(x)$ for "the integral part of $x$."

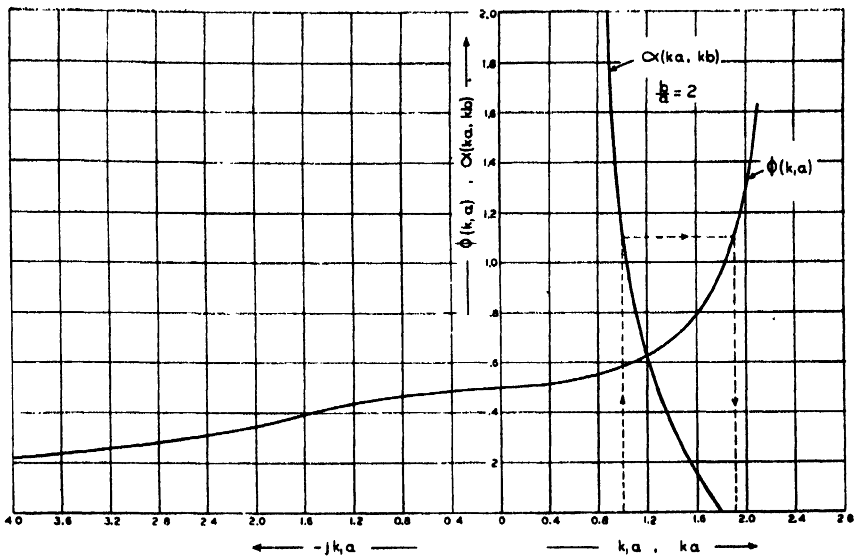

FIG. 6. The functions $\phi$ and $\alpha$ are plotted against $k_1a$ and $ka$ for $b/a = 2$.

center of the cell in which $z$ lies.[2] This function would then be expanded as a Fourier integral for $r<a$ and as a Fourier series for $a<r$, whereupon if the assumed form of $E_z$ is correct, the computed values of $B_\phi$ will match everywhere on $r=a$. To carry such a calculation out in detail would be possible but not simple. In certain cases, however, some progress can be made. In particular, if $d \ll a$ and $d \ll b-a$, a good guess for $f$ will be $[1-(4z^2/d^2)]^{-\frac{1}{2}}$. If we take this form for $f$ without verification we need match only at one point, say at the center of a cell, and if we furthermore carry only one Fourier term in the magnetic-field series for both $r<a$ and $a<r$, we get a crude but tractable result, namely, that one merely multiplies the left-hand side of (5) by $J_0(k_3d/2)$ to get

$$J_0(k_3d/2)\cdot\phi(k, a) = \alpha(ka, kb)/1-\eta. \tag{6}$$

This correction, while reaching a maximum value of $J_0(\pi/2)=0.571$ at $k_3d=\pi$, rises slowly and for small values of $k_3d$ is often negligible. In much of what follows, it will be omitted in the interests of simplicity.

To solve this equation, we need values of $\phi$ and $\alpha$. In Fig. 4 we give a plot of $\phi$ for both real and imagihary values of $k_1a$, together with various useful and easily derived approximate formulae. And in Fig. 5 we give a contour map of $\alpha$ in the $ka$, $kb$ plane.

In obtaining this map, and for various future purposes, the following easily derived approximate expressions are useful

$$\begin{aligned}
&\alpha \cong (1/k^2a^2)(1/\ln\xi), \quad \xi=b/a. \quad ka \ll 1, \quad kb \ll 1,\\
&\alpha \cong (1/k^2a^2)[1/\ln(2/\gamma ka)], \quad \gamma=1.781,\\
&\qquad\qquad ka \ll 1, \quad J_0(kb)\neq 0,\\
&kb \cong 2.405+1.545(1/2-\alpha)k^2a^2,\\
&\qquad\qquad ka \ll 1, \quad kb \cong 2.405,\\
&\alpha=(1/ka)\cot(kb-ka), \quad 1 \ll ka, \quad 1 \ll kb.
\end{aligned} \tag{7}$$

For given $b$ and $a$, and therefore fixed $b/a=\xi$, $\alpha$ is now a function of $k$ or of $ka$, which can be determined from Fig. 5. A typical curve of $\alpha$ *vs.* $ka$, for $kb/ka=2$ is plotted in Fig. 6. On this same graph, we have plotted $\phi$ as a function of $k_1a$.

To solve (5) for given $k$ and $\eta=0$, we enter the chart at $ka$ and follow the vertical dotted line to an intersection with the $\alpha$-curve, proceed horizontally to find an equal value of $\phi$, and then drop down to the axis to find the value of $k_1a$. Finally, we compute $(k_3/k)=(1-(k_1a/ka)^2)^{\frac{1}{2}}$ and so are able to construct a graph of $k_3/k$ *vs.* $ka$ or $kb$.

It is instructive to follow the results qualitatively as $ka$ increases from zero. For $ka$ small, $\alpha$ and so $\phi$ are large and we easily find $(k_3/k) \cong j(2.405/ka)(1-(ka/2.40)^2)^{\frac{1}{2}}$, i.e., the guide acts

---

[2] A justification of this statement would be simply a paraphrase of Floquet's theorem on the solutions of Hill's equation. See, for example, Whittaker and Watson, *Modern Analysis* (Cambridge University Press, New York, 1945), p. 412.

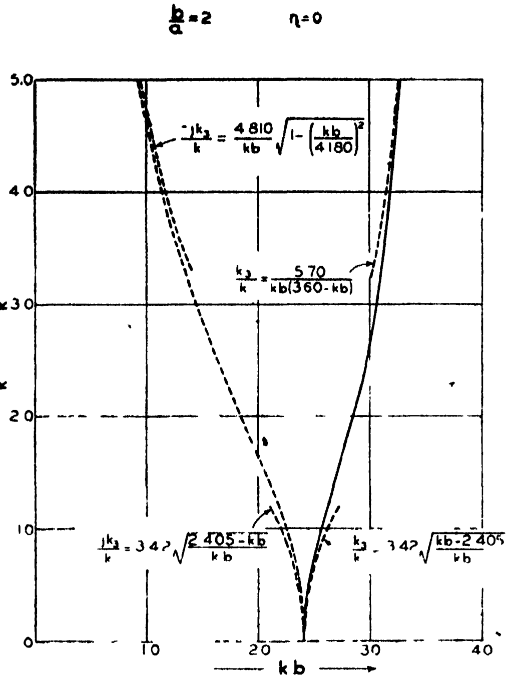

FIG. 7. Shows $k_3/k$ as a function of $kb$ for $b/a=2$, $\eta=0$, $kd\cong0$. Also shown are a number of approximate formulae.

as an attenuator, and with the attenuation characteristic of a tube of radius $a$. The wave number $k_3$ first becomes real when $k_1a=ka$, i.e., at the intersection of the two curves, where $\alpha$ and $\phi$ are usually about 0.5. Moreover, at this low frequency cut-off, which occurs at $kb=2.405$, $k_1$ is a linear function of $k$ and so $k_3/k$ has the approximate form $(k_3/k)\cong(2(kb-2.405)/2.405)^{\frac{1}{2}}\cdot(-dk_1/dk)^{\frac{1}{2}}$, and so the curve has a vertical tangent at cut-off. As we further increase $ka$, $k_1a$ decreases and the next interesting point is at $k_1a=0$, where $k_1a$ changes from real to imaginary, and $k_3/k$ passes through unity. Nothing striking happens to $k_3/k$, it being easily verified that its derivative is given by

$$\frac{dk_3}{dk}=\frac{k}{k_3}\,\frac{k_1}{k_3}\,\frac{d\alpha/dka}{d\phi/dk_1a}\,\frac{1}{1-\eta},\qquad k_1a\neq0, \tag{8}$$

and

$$\frac{dk_3}{dk}=1-\frac{1}{1-\eta}\,\frac{8}{ka}\,\frac{d\alpha}{dka},\qquad k_1a\cong0. \tag{9}$$

These formulae are of some importance, for they give the reciprocal of the group velocity, and this quantity is often of direct interest, especially in the special case $k_1=0$, $k_3=k$ where the wave velocity is $c$.

As $ka$ increases further, $\alpha$ and so $\phi$ approach zero, $k_1$ becomes large and imaginary, and $k_3$ large and real. An approximate formula, valid in

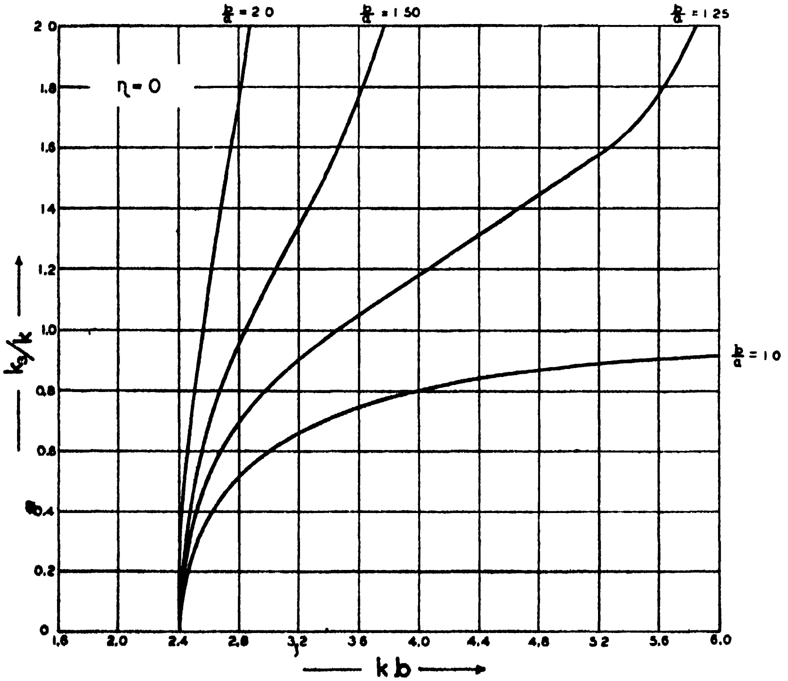

FIG. 8. Shows $k_3/k$ as a function of $kb$ for a variety of ratios $b/a$.

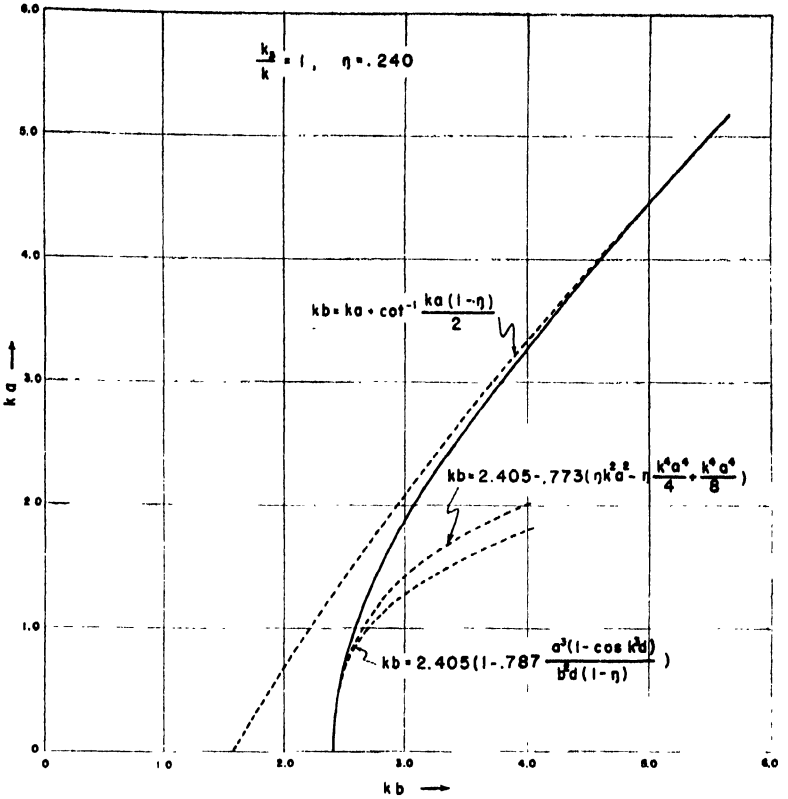

FIG. 9. The value of $ka$ that makes $k_3=k$ is plotted against $kb$. The full curve is based on the assumption that $d \ll a$, $d \ll b-a$, as are two of the dotted curves which give approximations to the solid curve. Also shown dotted is a result valid in the limit $a \ll d$, $a \ll b$.

this region, is

$$(k_3/k)=0.571((1-\eta)/ka(ka-k^+a))dka/d\alpha,$$

with $k^+a$ the value of $ka$ which makes $\alpha=0$.

As remarked before, the present theory is not good in this region, for when $k_3d=\pi$, the wave functions are not well approximated by single Fourier terms. Nevertheless, a good guess at the high frequency cut-off may be had by assuming it to occur at $k_3d=\pi$.

To illustrate the above quantitatively we have prepared Fig. 7 which shows $k_3/k$ as a function of $kb$ for $kb/ka=2$, $\eta=0$, together with a number of approximate formulae. In Fig. 8, $k_3/k$ is plotted as a function of $kb$ for several values of $kb/ka$. Both these figures assume that $k_3d$ is small.

Guides operated at $k$ and loading values such as to give $k_3/k=1$, i.e., phase velocity equal to that of light, have been of special interest to us, and in Fig. 9 we plot for various values of $kb$ the value of $ka$ that gives $k_3/k=1$. Two approximations are also shown, namely,

$$kb=2.405+0.772[\eta k^2a^2-\eta(k^4a^4/4)+(k^4a^4/8)], \quad ka \ll 1, \quad kd \ll 1, \quad (10)$$

$$kb=ka+\cot^{-1}(ka/2)(1-\eta), \quad 1 \ll ka, \quad kd \ll 1/ka. \quad (11)$$

We may note that as $ka$ approaches zero it must inevitably become smaller than $kd$, in which case our analysis breaks down. Nevertheless, if $d \ll b$ there is a region in which (10) is useful.

We may now develop the theory for the case $a \ll d$. Here we proceed by considering the loaded tube as derived from a sequence of uncoupled cavities perturbed by the introduction of coupling holes. The problem is solved by variational methods, the behavior of the trial function near the coupling hole being approximated by finding a solution of the appropriate static problem. The result is

$$kb \cong 2.405\left[1+0.787\frac{a^3}{b^2d(1-\eta)}(1-\cos k_3d)\right], \quad (12)$$
$$\eta d \ll a \ll d, \quad a \ll \lambda,$$

and this result is also plotted in Fig. 9.

On the other end of the possible range of values of $a$ we may have $b-a \ll d$, and in this

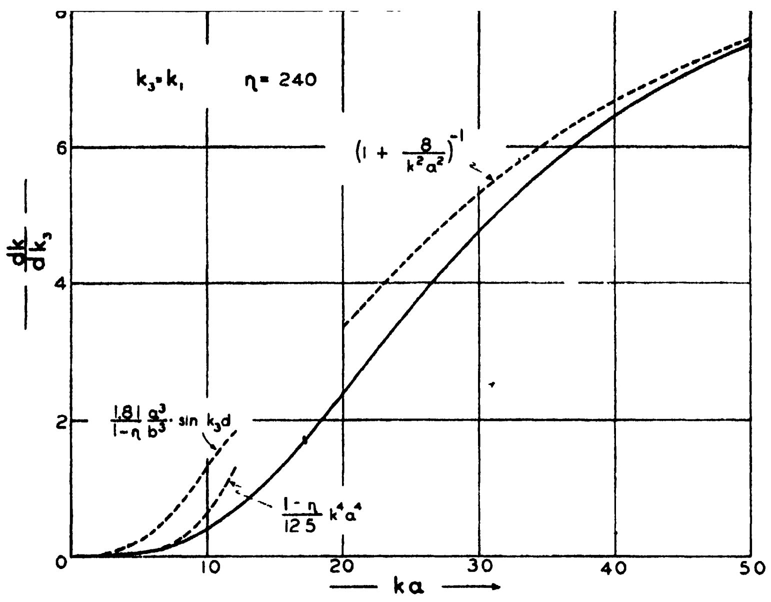

FIG. 10. The quantity $dk/dk_3$, which is the group velocity divided by $c$, is shown as a function of $ka$. The solid line is computed from a theory valid when $d \ll a$, $d \ll b-a$, as are two approximate results shown dotted. Also shown is the result of a theory valid when $a \ll d$, $a \ll b$.

case it is obviously best to take as the unperturbed problem an unloaded guide and introduce the loading disks as perturbations. There are then two cases, $(b-a) \ll \eta d$ and $\eta d \ll b-a \ll d$.

In the first case we may take as a perturbed field simply the unperturbed fields with the volume occupied by the loading rings removed. The results are most easily expressed by giving $k$ in terms of the various dimensions and $k_3$, thus

$$k = k_3[1+(2.405/k_3b)^2]^{\frac{1}{2}} \times[1+5.77(\eta k[b-a]/[kb]^2)], \quad (b-a) \ll \eta d. \quad (13)$$

In the other case, when $\eta d < b-a < d$, the loading disk may be considered as thin, and we use as a perturbed field the unperturbed one minus a potential function such that the boundary conditions on $E$ are satisfied over the ring while $E$ is undisturbed at large distances from the ring. This function is found by a solution of Laplace's equation, under the simplifying assumption that the cylindrical problem may be unrolled into a plane one, i.e., $b-a \ll b$. From this electric field a corresponding magnetic field is derived and the change in frequency computed in terms of the surface integral of $E_1 \times B_2$, with $E_1$ the original field and $B_2$ an addition due to the perturbation. The result is, then

$$k = k_3[1+(2.405/k_3b)^2]^{\frac{1}{2}} \times[1-\pi/2(k_3/k)^2([b-a]^2/bd)]. \quad (14)$$

The group velocity for guides loaded to give a phase velocity of $c$ has also been of interest, and in Fig. 10 we plot $dk/dk_3$ against $ka$ for $kb = 2.66$ together with various approximate formulae. One of these approximate formulae, good for $a \ll d$, is obtained simply by differentiating (12), the other two are derived on a basis best explained in a following section.

### 2. Impedance, Power Flow, and Energy Storage

As is usual in distributed constant problems, any number of definitions of characteristic impedance are possible: the one that is useful for connecting guides of different impedances is defined as equal to the ratio of the transverse voltage to the wall current. If we evaluate this in the midplane of a loading disk using the fields of (1) and (2) we find the impedance in e.m.u. to be

$$Z_t = c\frac{k_3}{k}\frac{2(1-J_0(k_1a))}{k_1aJ_1(k_1a)}. \quad (15)$$

For many purposes it is more useful to know the power flow, and this can be expressed either in terms of $E_0$, the peak axial field, or in terms of the integral of $E_r$, designated above as the transverse voltage. The power flow is easily evaluated from the Poynting vector, the result being

$$P=(1/256\pi^2)k^3k_3a^4[8/(k_1a)^2] \times [J_1^2(k_1a)-J_0(k_1a)J_2(k_1a)](E_0\lambda)^2/c. \quad (16)$$

A plot of $8/(k_1a)^2$ times the bracketed Bessel functions is given in Fig. 11.

A special case of interest is that for which $k_3=k$, $k_1=0$, in which case we find

$$E_0\lambda=(4/\pi)(Pc)^{\frac{1}{2}}(\lambda/a)^2, \quad k_3=k. \quad (17)$$

If one wishes to use radial voltage, the conversion can be accomplished by using the formula connecting the peak value of $E_r$ and $E_0$,

$$(1/E_0\lambda)\int_0^a E_r dr=(kk_3/2\pi k_1^2)(1-J_0(k_1a)). \quad (18)$$

### 3. Energy Storage

The mean energy stored per unit length is of interest, not only in itself, but also in connection with $Q$ calculations to follow and for use in an alternative method of finding the group velocity. This latter use derives from the relation

$$(\text{Energy stored/cm})(\text{group velocity})=P, \quad (19)$$

and owes its usefulness to the facts that $P$ is easy to compute and that it is often not hard to approximate the energy storage, whereas approximations to $dk/dk_3$ have not been obvious.

We may note that when the group velocity is computed from (19) it comes out in terms of integrals of squares of Bessel functions, whereas when computed from $dk/dk_3$ it depends on derivatives of Bessel functions and it is, at first sight, hard to see in detail why the results are the same. We will not go into this matter, but remark that it is similar to the well-known theorem whereby the derivative of an impedance, with respect to frequency, can be found from the energy stored in the impedance.

We will not write down the exact formulae for energy storage, since the result is easy to obtain analytically and most tedious to use numerically.

Two approximations are useful, however. In

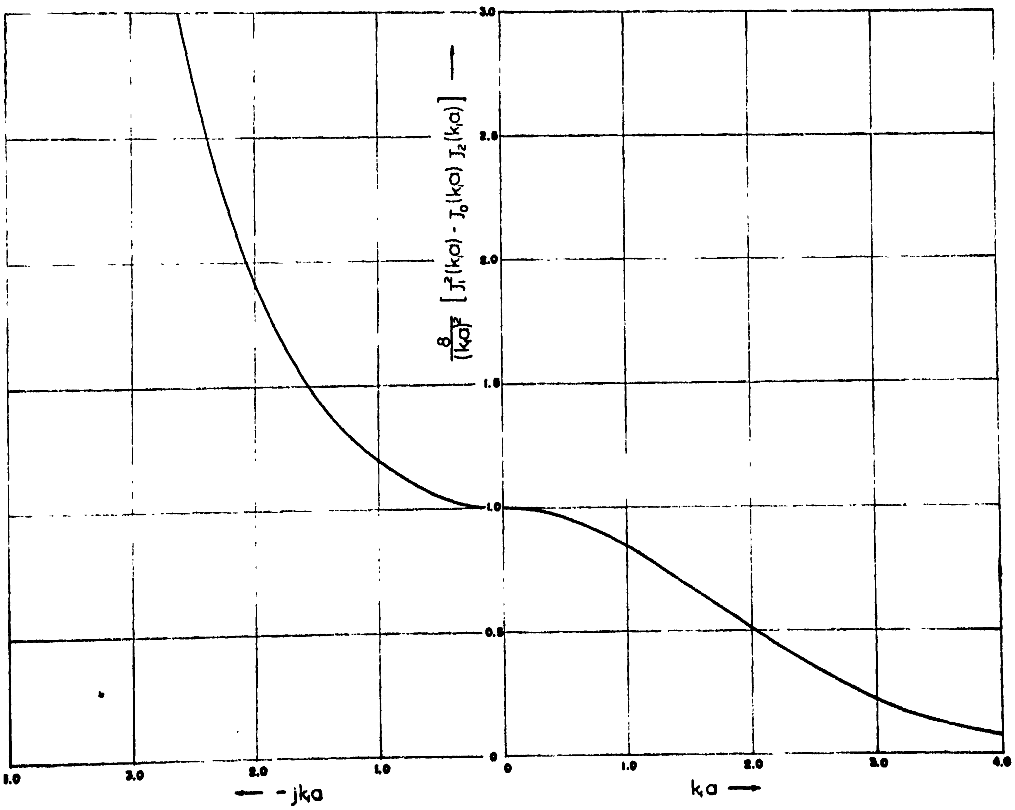

FIG. 11. Plot of a function useful in computing power flow in loaded wave guides.

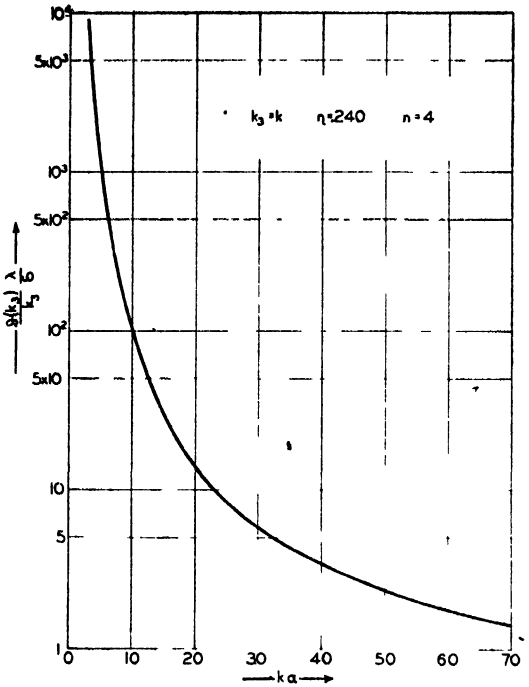

FIG. 12. The imaginary part of the propagation constant, multiplied by $\lambda/k_3\delta$ is plotted against $ka$. The radius $b$ is such as to give $k_3=k$, there are 4 loading disks per wavelength, and the fields of Eqs. (1) and (2) are used

the first place, if $ka\rightarrow 0$ we can approximate $B_\phi$ quite well as $[2.405E_0/(1-\eta)kb]J_1[2.405(r/b)]$ in which case the energy storage, as computed by doubling the magnetic energy, comes out as

$$\text{Mean energy/cm}\cong 0.195E_0^2/(1-\eta)k^2,\qquad ka\ll 1,\tag{20}$$

and combining this with the expression for power flow we get one of the approximations for $dk/dk_3$ used in Fig. 10.

Next, consider the special case $k_3=k$ and let $kb\rightarrow\infty$, so that $kb\cong ka+(2/(1-\eta)ka)$. Then we have $B_\phi=E_0kr/2$ for $r<a$, and we can take $B_\phi\cong(E_0/1-\eta)(1/(kb-ka))=\text{constant}$ for $a<r<b$. This approximation is obviously good for large $ka$ and is surprisingly close for small $ka$, being only 1.55 times too small for $ka=0$. Using these fields, we find

$$\text{Mean energy/cm}\cong\frac{E_0^2}{8k^2}\left(\frac{k^4a^4}{8}+\frac{1}{1-\eta}\,\frac{kb+ka}{kb-ka}\right),\qquad k_3=k,\quad 1\ll ka,\tag{21}$$

and this may be further simplified by using (11) to relate $kb$ and $ka$. Doing so, we get the remaining approximate formula of Fig 10.

## 4. Losses

If a power $P$ crosses some plane transverse to the guide, the power at some distance down the guide will be smaller because of losses, i.e., $dP/dz$ is finite. Before computing the losses, we must first consider how the results are to be expressed. At least three forms are useful. First, we may compute the voltage attenuation $I(k_3)=(1/2P)(dP/dz)$; second, we can find $Q=2\pi\nu$ (energy stored/cm)/$(dP/dz)$; and third, we can compute $(dP/dz)/(E_0\lambda)^2$.

The first two may be related by way of (19), thus

$$Q=(1/2)[k/I(k_3)](dk_3/dk).\tag{22}$$

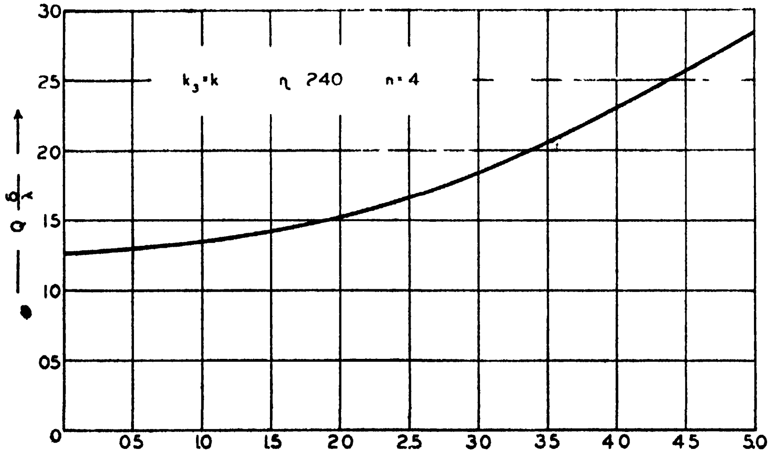

FIG. 13. The quantity $Q\delta/\lambda$ is plotted against $ka$ under the same assumptions as in Fig. 12.

The actual calculation is simple enough in principle, the losses being evaluated as $B^2\delta/8$ per cm² per cycle, with $\delta=(\rho/2\pi\omega)^{\frac{1}{2}}$ the skin depth. The detailed results will not be written down since the formulae, while easy to obtain, are too complex to allow one to determine their behavior by inspection.

The results of a typical calculation are given in Figs. 12, 13, and 14, which give $I(k_3)/k_3(\lambda/\delta)$, $Q(\delta/\lambda)$, and $(\lambda^2/\delta)(dP/dz)/(E_0\lambda)^2$ as functions of $ka$, when $kb$ is such that $k_3=k$ and there are four loading disks per wave-length.

While the general formulae are quite complex, some approximations will now be given which are usefully simple. All of these are for the special case $k_3=k$.

First, let $ka\ll 1$. Then we find, by using the same field as that used for (20),

$$\frac{I(k_3)}{k_3}=\frac{\delta}{\lambda}\frac{6.25}{k^4a^4(1-\eta)^2}[n+2.61(1-\eta)],$$

$$ka\ll 1,\quad k_3=k, \tag{23}$$

$$Q=(\lambda/\delta)[1-\eta/n+2.61(1-\eta)], \tag{24}$$

$$[1/(E_0\lambda)^2](dP/dz)=0.0308(\delta/\lambda^2c)$$
$$\times[1/(1-\eta)^2][n+2.61(1-\eta)], \tag{25}$$

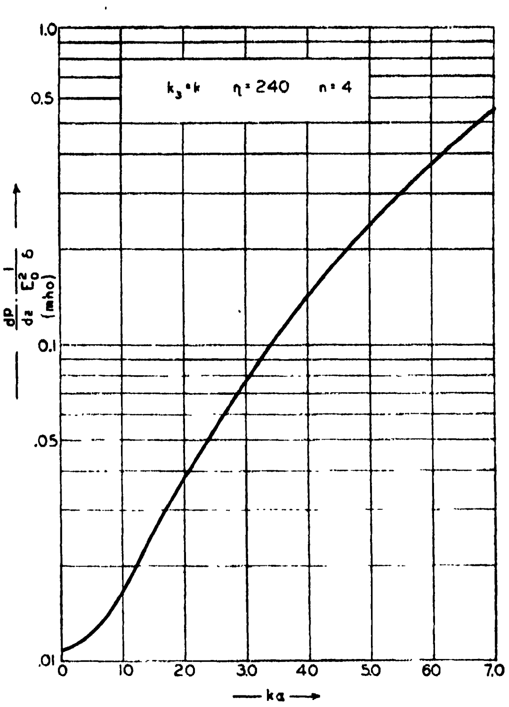

FIG. 14. The power loss per cm per volt/cm squared, divided by $\delta$, as measured in mho, is plotted against $ka$, the conditions being as described for Fig. 12.

with $n=2\pi/kd$, the number of loading disks per wave-length.

Next, let $1\ll ka$ and use the approximation of (21), when we find

$$\frac{I(k_3)}{k_3}\cong\frac{\delta}{\lambda}\frac{8\pi}{k^4a^4}\left[\frac{kb}{(1-\eta)(kb-ka)^2}+\frac{n}{2\pi(1-\eta)^2}\frac{kb+ka}{kb-ka}+\frac{n}{2\pi}\frac{\eta k^2ad}{(1-\eta)^2(kb-ka)^2}\right], \tag{26}$$

$$Q\cong\frac{\lambda}{\delta}\left[\frac{k^4a^4}{8}+\frac{1}{1-\eta}\frac{kb+ka}{kb-ka}\right]\Big/\left[\frac{2\pi kb}{(1-\eta)(kb-ka)^2}+\frac{n}{(1-\eta)^2}\frac{kb+ka}{kb-ka}+\frac{n\eta k^2ad}{(1-\eta)^2(kb-ka)^2}\right], \tag{27}$$

$$\frac{1}{(E_0\lambda)^2}\frac{dP}{dz}=\frac{\delta}{\lambda^2c}\frac{1}{8}\left[\frac{kb}{(1-\eta)(kb-ka)^2}+\frac{n}{2\pi(1-\eta)^2}\cdot\frac{kb+ka}{kb-ka}+\frac{n}{2\pi}\frac{\eta k^2ad}{(1-\eta)^2(kb-ka)^2}\right]. \tag{28}$$

When $ka$ is sufficiently large, these may be simplified by using the approximate relation (11), with results

$$I(k_3)/k_3\cong(\lambda/b)(\delta/\lambda), \tag{29}$$

$$Q\cong(b/2\lambda)(\lambda/\delta), \tag{30}$$

$$\frac{1}{(E_0\lambda)^2}\frac{dP}{dz}\cong\frac{1}{32}\frac{k^3b^3\delta}{\lambda^2c}. \tag{31}$$

A qualitative understanding of the above formulae is useful and simple. For $k_3=k$ we have $E_r=B_\phi=E_0kr/2$ for $r<a$, and we will not do too badly by continuing $B_\phi$ in a linear manner to $r=b$. Thus the power flow will be proportional to $k^4a^4$, the energy stored to $k^4b^4$ and the energy loss on the walls will vary like $k^3b^3$, all for constant axial field. Thus the group velocity, which depends on the ratio of power transmitted to energy stored, at first rises rapidly as $ka$ increases and

then levels off as $ka$ approaches $kb$. Likewise, the linear attenuation, which depends on the ratio of power loss to power transmission, starts by decreasing rapidly as $ka$ increases. When $ka$ is large, the decrease is slower, being simply due to greater cross-sectional area for the wave to carry power as compared to the perimeter bounding the wave and introducing losses. On the other hand, $Q$ which depends on the ratio of energy stored to energy loss, depends mainly on $kb$ which at first increases only slowly with rising $ka$. Thus $Q$ at first drops slowly, though finally varying like $1/ka$, for essentially the same reason as the attenuation.

## CONCLUSION

Many of the important properties of disk-loaded wave guides have been developed, both qualitatively and quantitatively, and have been described by formulae, both approximate and exact, and a number of curves, which will, it is hoped, illustrate the more important points. Special attention has been paid to the wave number $k_3$ which has been computed by three methods. On the other hand, the formulae for loss and power flow are, for the most part, based on an approximation valid when the disk spacing is small, i.e., the loading is nearly continuous.

In a problem with so many variables, it is impossible, in a finite article, to cover all the proportions and conditions that might be of interest and we therefore do not feel apologetic when we point out some of the gaps in the present treatment. First, more accurate methods of calculating $k_3$ are certainly possible; the virtue of our methods is that they give closed or nearly closed formulae and so can be used to explore a wide range of variables without undue labor. Second, we have hardly touched on the behavior in the vicinity of the high frequency cut-off. Third, the loss and power-transmission calculations have been restricted to one method. And fourth, many of the illustrative graphs have been for a single case. Despite these lacunae, we hope that our results will be of use to others.

Finally, it is a pleasure to record the assistance of Mr. E. T. Jaynes with many of the early calculations and to acknowledge the liberal help of the Navy under Contract N6-ori-106.

# Equations for the Inductances of Three-Phase Coaxial Busses Comprised of Square Tubular Conductors

THOMAS JAMES HIGGINS
*Illinois Institute of Technology, Chicago, Illinois*

AND

HENRY PETER MESSINGER
*University of Illinois, Urbana, Illinois*

(Received July 15, 1947)

Equations are derived for calculating the associated inductances of the conductors of three-phase coaxial busses comprised of square tubular conductors. It is assumed that the conductors are nonmagnetic, are of such lengths that end effects are negligible, are right-cornered, and carry currents uniformly distributed over their cross sections. The general equations are obtained through use of geometric mean distance theory. Approximate equations, the conductors being considered as indefinitely thin, are epitomized in a table which yields values sufficiently accurate for most design work. In turn, these approximate equations are reduced to simple equations which also yield values sufficiently accurate for much design work. These equations for inductance lead to corresponding equations for the reactive voltage drops. Use of these various equations and the relative accuracy to be expected of them is illustrated by calculating the inductances and reactive voltage drops of typical busses.

The changes in the inductances due to rounding the edges of the conductors and the changes produced in both the inductances and the resistances by skin and proximity effects are investigated. The changes in the inductances due to rounding the edges can be approximated by use of a known equation. The changes in the inductances due to power frequency skin and proximity effects prove to be negligible; the changes in the resistances can be calculated by use of known skin-effect factors and newly derived proximity-effect factors.

Calculation of the inductances of three-phase coaxial busses constructed of tubular conductors made up of two channels or angles placed flange to flange is discussed. Finally, attention is called to a relatively little known means of obtaining balanced three-phase operation of geometrically unbalanced three-phase busses.

BY virtue of its axial-symmetric geometry, the coaxial-tubular bus possesses certain very desirable electrical and mechanical characteristics. Low inductance contributes to good voltage regulation. Reduced skin and proximity effects minimize line losses and average temperature rise under load. Axial-symmetric distribution of skin and proximity effects reduces current density distortion and attendant hot-spot concentrations, hence enables a greater current rating for a specified maximum copper temperature. As electromagnetic forces between conductors are largely eliminated, mechanical bracing against short-circuit forces can be correspondingly reduced. The nested conductors require less space for installation and a smaller supporting structure than they would if arranged side by side.

Yet, despite these desirable characteristics, the paucity of published descriptions of actual installations[1–4] indicates that few coaxial busses have been constructed to date. However, until the last few years factory distribution loads at frequencies greater than 60 cycles were not common. Again, most 60-cycle loads were supplied over relatively short distances. As these conditions are such that satisfactory operation can be obtained with the more conventional, though less electrically effective, construction of conductors placed side by side, this limited use of coaxial busses is not surprising. Now, however, by virtue of manufacturing procedures and techniques developed during the war, the bus designer is faced with the necessity of designing heavy-distribution busses which are not only long but also are to operate at frequencies of several hundred cycles and higher. But, the electrical characteristics of the coaxial bus especially suit it to satisfactory operation under either or

both of these conditions. Hence, it is to be expected that in the near future coaxial busses will find greater use than they have hitherto.

At present coaxial busses are constructed of circular tubular conductor, of square tubular conductor, and of structural tubular conductor comprised of two slightly separated channels or angles placed flange to flange. To predetermine the operating characteristics of these busses requires knowledge of the a.c. resistance, the a.c. inductance, the copper temperature under load, and the mechanical forces exerted during short-circuit. Equations[5,6] for calculating all four of these quantities are available for single or three-phase busses constructed of circular-tubular conductor and for single-phase busses constructed of square or structural tubular conductor. But for three-phase busses constructed of square or structural tubular conductor, though equations are available for calculating the a.c. resistance,[7,8] the copper temperature,[8] and the short-circuit force,[9] equations for calculating the a.c. inductance, *usually the determining factor in the design of a bus*, are not available.

Such equations are derived in this paper, it being assumed that the conductors are non-magnetic, of such lengths that end effects are negligible, right-cornered, and carry currents distributed uniformly over their cross sections. Of these four conditions, the first two are satisfied in practice. The third, however, though essential to tractable analysis, is usually not true in practice. Square tubes, channels and angles, drawn, rolled, bent, or otherwise formed in one piece, have rounded edges. But the error introduced by neglecting the rounded edges is small. Commonly, the result obtained, though a bit low, is yet sufficiently accurate for the work in hand. In any case, the incremental inductance associated with the rounded edges can be approximated closely by a simple semi-empirical equation derived by Dwight and Wang.[10] Finally, though skin and proximity effects render the current density over the cross sections of the conductors slightly non-uniform, detailed analysis[6] indicates and experiment confirms[11] that at power frequencies the a.c. inductance is practically identical with the d.c. inductance.

These four postulates granted as consistent with practice, derivation of the desired equations, though lengthy, is not difficult. The conductor cross sections are considered as combinations of parallel-sided square areas. By virtue of geometric-mean-distance theory the inductance associated with a particular conductor is expressed in terms of the self and mutual geometric mean distances of these areas. These geometric mean distances can be calculated from known equations. Accordingly, determination of the inductance as a function of the parameters defining the geometry of the bus reduces, essentially, to specific determination of the geometric mean distances involved and substitution of them in the general equation for the inductance.

The general equation comprises 48 terms. A simpler approximate equation similarly derived, but on the assumption that the conductors can be considered as being indefinitely thin (hence have cross sections comprised of line segments), affords values sufficiently accurate for many design purposes. As a further convenience to numerical computation, this equation is expressed in terms of a parameter whose values are to be ascertained from a given table of values. Finally, over the range commonly encountered in practice this parameter proves to be substantially constant. For this case the approximate equation reduces to absurdly simple equations that yield the inductance with negligible computation. These various equations lead to corresponding equations for the reactive voltage drops.

The desired equations, having been obtained

and checked, are used as illustrated by calculation of the inductances of typical busses constructed of square tubular conductor. Changes in inductance and resistance resulting from rounded corners on the conductors and from skin and proximity effects are discussed in detail. Procedures for calculating the inductance of coaxial busses constructed of channels or angles are advanced. Finally, attention is directed to a relatively little known means of obtaining balanced three-phase operation of geometrically unbalanced three-phase busses.

## I. DERIVATION OF THE GENERAL EQUATION

Consider a three-phase bus comprised of three coaxial square tubular conductors (Fig. 1). From well-known theory[12, 13] the inductances associated with the conductors are

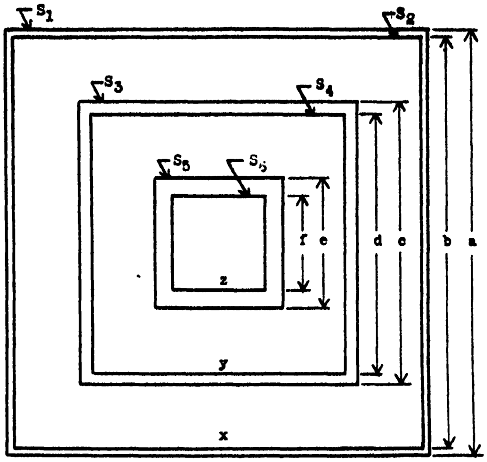

FIG. 1. Cross section of coaxial bus comprised of square tubular conductors.

$$L_x=(-2/I_x)\sum_{i=x}^{z} I_i \log D_{xi}, \tag{1}$$

$$L_y=(-2/I_y)\sum_{i=x}^{z} I_i \log D_{yi}, \tag{2}$$

$$L_z=(-2/I_z)\sum_{i=x}^{z} I_i \log D_{zi}, \tag{3}$$

where, typically, $L_x$ is the inductance associated with conductor $x$; $I_x$ is the current (expressed as a complex number) associated with conductor $x$; and $D_{xi}\equiv D_{ix}$ is the geometric-mean distance of the cross sections of conductors $x$ and $i$. The units of the various physical quantities are as discussed in Section V.

The geometric mean distances $D_{xx}$, $D_{xy}$ and $D_{xz}$ are (as derived in detail in Appendix I)

$$\begin{aligned}\log D_{xx}=&[1/12(a^2-b^2)^2][12a^4\log a+12b^4\log b+(a^4-6a^2b^2+b^4)\log(a^2+b^2)-(a+b)^4\log(a+b)\\&-(a-b)^4\log(a-b)+8ab(a^2-b^2)\tan^{-1}(a-b)/(a+b)+(a+b)(a-b)^3\pi\\&+10(a^4+b^4)\log 2]-0.5\log 2+\pi/4-25/12,\end{aligned}\tag{4}$$

$$\begin{aligned}\log D_{xy}=&[-1/24(a^2-b^2)(c^2-d^2)][(a+d)^4\log(a+d)+(a-d)^4\log(a-d)-(a^4-6a^2d^2+d^4)\\&\times\log(a^2+d^2)-(b+d)^4\log(b+d)-(b-d)^4\log(b-d)+(b^4-6b^2d^2+d^4)\log(b^2+d^2)\\&-(a+c)^4\log(a+c)-(a-c)^4\log(a-c)+(a^4-6a^2c^2+c^4)\log(a^2+c^2)+(b+c)^4\log(b+c)\\&+(b-c)^4\log(b-c)-(b^4-6b^2c^2+c^4)\log(b^2+c^2)-8ad(a^2-d^2)\tan^{-1}(a-d)/(a+d)\\&+8bd(b^2-d^2)\tan^{-1}(b-d)/(b+d)+8ac(a^2-c^2)\tan^{-1}(a-c)/(a+c)-8bc(b^2-c^2)\\&\times\tan^{-1}(b-c)/(b+c)-\{(a+d)(a-d)^3-(b+d)(b-d)^3-(a+c)(a-c)^3\\&+(b+c)(b-c)^3\}\pi]-0.5\log 2+\pi/4-25/12,\end{aligned}\tag{5}$$

$$\begin{aligned}\log D_{xz}=&[-1/24(a^2-b^2)(e^2-f^2)][(a+f)^4\log(a+f)+(a-f)^4\log(a-f)^4-(a^4-6a^2f^2+f^4)\\&\times\log(a^2+f^2)-(b+f)^4\log(b+f)-(b-f)^4\log(b-f)+(b^4-6b^2f^2+f^4)\log(b^2+f^2)\\&-(a+e)^4\log(a+e)-(a-e)^4\log(a-e)+(a^4-6a^2e^2+e^4)\log(a^2+e^2)\\&+(b+e)^4\log(b+e)+(b-e)^4\log(b-e)-(b^4-6b^2e^2+e^4)\log(b^2+e^2)-8af(a^2-f^2)\\&\times\tan^{-1}(a-f)/(a+f)+8bf(b^2-f^2)\tan^{-1}(b-f)/(b+f)+8ae(a^2-e^2)\tan^{-1}(a-e)/(a+e)\\&-8be(b^2-e^2)\tan^{-1}(b-e)/(b+e)-\{(a+f)(a-f)^3-(b+f)(b-f)^3-(a+e)(a-e)^3\\&+(b+e)(b-e)^3\}\pi]-0.5\log 2+\pi/4-25/12.\end{aligned}\tag{6}$$

[13] L. F. Woodruff, *Principles of Electric Power Transmission* (John Wiley and Sons, New York, 1939), edition 2, Chap. 2.

Substituting from Eqs. (4)–(6) in Eq. (1), collecting terms, and utilizing the relationship $I_x+I_y+I_z=0$ yields

$$\begin{aligned}
L_x=&[-1/6(a^2-b^2)^2][12a^4\log a+12b^4\log b+(a^4-6a^2b^2+b^4)\log(a^2+b^2)-(a+b)^4\log(a+b)\\
&-(a-b)^4\log(a-b)+8ab(a^2-b^2)\tan^{-1}(a-b)/(a+b)+(a+b)(a-b)^3\pi+10(a^4+b^4)\log 2]\\
&+(I_y/I_x)[1/12(a^2-b^2)(c^2-d^2)][(a+d)^4\log(a+d)+(a-d)^4\log(a-d)\\
&-(a^4-6a^2d^2+d^4)\log(a^2+d^2)-(b+d)^4\log(b+d)-(b-d)^4\log(b-d)+(b^4-6b^2d^2+d^4)\\
&\times\log(b^2+d^2)-(a+c)^4\log(a+c)-(a-c)^4\log(a-c)+(a^4-6a^2c^2+c^4)\log(a^2+c^2)\\
&+(b+c)^4\log(b+c)+(b-c)^4\log(b-c)-(b^4-6b^2c^2+c^4)\log(b^2+c^2)-8ad(a^2-d^2)\\
&\times\tan^{-1}(a-d)/(a+d)+8bd(b^2-d^2)\tan^{-1}(b-d)/(b+d)+8ac(a^2-c^2)\tan^{-1}(a-c)/(a+c)\\
&-8bc(b^2-c^2)\tan^{-1}(b-c)/(b+c)-\{(a+d)(a-d)^3-(b+d)(b-d)^3-(a+c)(a-c)^3\\
&+(b+c)(b-c)^3\}\pi]+(I_z/I_x)[1/12(a^2-b^2)(e^2-f^2)][(a+f)^4\log(a+f)+(a-f)^4\\
&\times\log(a-f)^4-(a^4-6a^2f^2+f^4)\log(a^2+f^2)-(b+f)^4\log(b+f)-(b-f)^4\log(b-f)\\
&+(b^4-6b^2f^2+f^4)\log(b^2+f^2)-(a+e)^4\log(a+e)-(a-e)^4\log(a-e)+(a^4-6a^2e^2+e^4)\\
&\times\log(a^2+e^2)+(b+e)^4\log(b+e)+(b-e)^4\log(b-e)-(b^4-6b^2e^2+e^4)\log(b^2+e^2)\\
&-8af(a^2-f^2)\tan^{-1}(a-f)/(a+f)+8bf(b^2-f^2)\tan^{-1}(b-f)/(b+f)+8ae(a^2-e^2)\\
&\times\tan^{-1}(a-e)/(a+e)-8be(b^2-e^2)\tan^{-1}(b-e)/(b+e)-\{(a+f)(a-f)^3-(b+f)(b-f)^3\\
&-(a+e)(a-e)^3+(b+e)(b-e)^3\}\pi]. \qquad (7)
\end{aligned}$$

This is the desired equation for the inductance associated with conductor $x$. Comparison of Eqs. (1) and (2) indicates that the corresponding equation for $L_y$ follows from Eq. 7 by interchanging $x$ with $y$, $a$ with $c$, and $b$ with $d$. Similarly, comparison of equations 1 and 3 indicates that the corresponding equation for $L_z$ follows from Eq. 7 by interchanging $x$ with $z$, $a$ with $e$, and $b$ with $f$.

## II. CORROBORATION OF THE GENERAL EQUATION

Consider a three-phase bus comprised of conductors $x$, $y$, $z$ carrying currents $I_x$, $I_y$ and $I_z$ which satisfy the relationship $I_x+I_y+I_z=0$. One conductor, say $x$, can be considered as carrying current $I_x$ and the two remaining conductors can be considered as connected in parallel and carrying the return current $(I_y+I_z)$. In effect, therefore, the bus is a single-phase bus with going conductor $x$ carrying current $I_x$ and subdivided return conductor comprised of parallel components $y$ and $z$ carrying current $(I_y+I_z)=-I_x$. The inductance of such a bus is

$$L=L_x+L_yL_z/(L_y+L_z). \qquad (8)$$

If now conductors $y$ and $z$ are considered as identical and superimposed (whence $y\equiv z$), the resulting single-phase bus is, effectively, comprised of two coaxial square tubular conductors. Accordingly, if Eq. 7 is correct, Eq. (8) should yield the known equation of such a bus. By virtue of $y\equiv z$, we have $e\equiv c$ and $f\equiv d$. Utilizing these identities in Eq. (7) for $L_x$ and in an analogous equation for $L_y\equiv L_z$, substituting the resulting expressions in Eq. (8), and collecting terms yields, corroboratively, the known solution (Eq. 9 of reference 6) for a single-phase bus comprised of two coaxial square tubular conductors.

## III. APPROXIMATIONS TO THE GENERAL EQUATION

The general equation for the inductance associated with a conductor comprises 48 terms: 29 logarithmic, 9 arctangentic, and 10 algebraic. But by use of the proper tools (an electric calculating machine and the 15-place Work Projects Administration[14, 15] tables of natural logarithms and arctangents), the computation incident to the calculation of the associated inductances of a given bus can be effected without difficulty. The computation, however, will be lengthy (the computation incident to example 1 below required approximately 15 hours to perform on a 10-row electric calculating machine by one of the authors, experienced in such computation). For this reason it is most desirable to have approximate equations which enable rapid determination of values sufficiently accurate for much (in many

---

[14] *Tables of Natural Logarithms* (Columbia University Press, New York).

[15] *Tables of Arctangents* (Columbia University Press, New York).

instances, all) of the computation incident to the final design of a bus.

A means of deriving such equations stems from the writers' earlier investigation[6] of the inductance of a single-phase coaxial bus comprised of square tubular conductors. Therein, values of inductance calculated from the general equation were found to be in excellent agreement with values of inductance calculated from much simpler approximate equations. These equations are derived on the basis that the cross sections of the conductors are comprised of line segments of dimensions equal to the external dimensions of the actual conductors.

Consider, then, the cross section of each conductor as comprised of four line segments (Fig. 2). As previously, the associated inductances are given by Eqs. (1)–(3). Therein, however, the geometric mean distances are now those pertinent to the cross sections of Fig. 2. The geometric mean distances $D_{xx}$, $D_{xy}$ and $D_{xz}$ are (as derived in detail in Appendix II)

$$\log D_{xx}=\log a+(1/4)\log 2+\pi/4-3/2, \qquad (9)$$

$$\begin{aligned}\log D_{xy}=&(1/8ac)[(a+c)^2\log(a+c)\\&-(a-c)^2\log(a-c)+2ac\log(a^2+c^2)\\&-2(a^2-c^2)\tan^{-1}(a-c)/(a+c)\\&+0.5(a^2-c^2)\pi]-0.5\log 2\\&+\pi/4-3/2, \qquad (10)\end{aligned}$$

$$\begin{aligned}\log D_{xz}=&(1/8ae)[(a+e)^2\log(a+e)\\&-(a-e)^2\log(a-e)+2ae\log(a^2+e^2)\\&-2(a^2-e^2)\tan^{-1}(a-e)/(a+e)\\&+0.5(a^2-e^2)\pi]-0.5\log 2\\&+\pi/4-3/2, \qquad (11)\end{aligned}$$

Substituting from Eqs. (9)–(11) in Eq. 1, collecting terms and utilizing the relationship $I_x+I_y+I_z=0$ yields

$$\begin{aligned}L_x=&-2\log a-(3/2)\log 2\\&-(I_y/I_x)(1/4ac)[(a+c)^2\log(a+c)\\&-(a-c)^2\log(a-c)+2ac\log(a^2+c^2)\\&-2(a^2-c^2)\tan^{-1}(a-c)/(a+c)\\&+0.5(a^2-e^2)\pi]-(I_z/I_x)(1/4ae)\\&\times[(a+e)^2\log(a+e)-(a-e)^2\log(a-e)\\&+2ac\log(a^2+e^2)-2(a^2-e^2)\\&+\tan^{-1}(a-e)/(a+e)+0.5(a^2-e^2)\pi]. \qquad (12)\end{aligned}$$

Correspondingly, equations for $L_y$ can be obtained from Eq. (12) by interchanging $x$ with $y$ and $a$ with $c$. Similarly, corresponding formulas for $L_z$ can be obtained in interchanging $x$ with $z$ and $a$ with $e$.

Simple algebraic manipulation of the expressions for the mutual geometric mean distances yields equations especially convenient to computation. Thus, designate $K(r)$ by

$$\begin{aligned}K(r)=&(1/4)[\log(1+A^2)-2\log(1-A^2)\\&-(1/2r)(1-r)^2\log A\\&+(r^{-1}-r)(\pi/4-\tan^{-1}A)+2\log r\\&+\log 2+\pi-6], \qquad (13)\end{aligned}$$

where $A=(1-r)/(1+r)$ and $r=(1-A)/(1+A)$. A table of values of $A$, $r$ and $K(r)$ is given in Appendix III.

Then Eqs. (9)–(11) can be written in the form

$$\log D_{xx}=K(1)+\log a, \qquad (14)$$

$$\log D_{xy}=K(c/a)+\log a, \qquad (15)$$

and

$$\log D_{xz}\doteq K(e/a)+\log a. \qquad (16)$$

Similarly,

$$\log D_{yy}=K(1)+\log c, \qquad (17)$$

$$\log D_{zz}=K(1)+\log e, \qquad (18)$$

and

$$\log D_{yz}=K(e/c)+\log c. \qquad (19)$$

Substituting as indicated in Eqs. (1)–(3), noting that $K(1)=-0.5413$, and utilizing the identity $I_x+I_y+I_z=0$ in appropriate fashion yields

$$\begin{aligned}L_x=&-2\{-0.5413-K(e/a)\\&+(I_y/I_x)[K(c/a)-K(e/a)]\}, \qquad (20)\end{aligned}$$

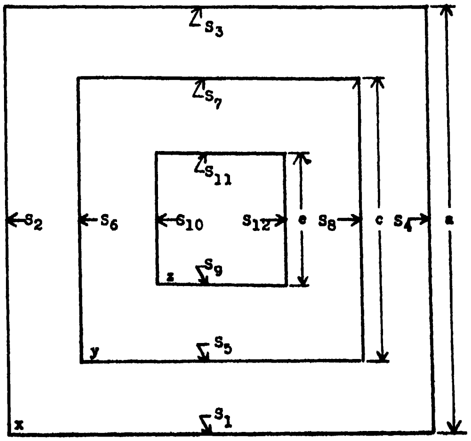

FIG. 2. Cross section of coaxial bus comprised of square tubular line-segment conductors.

$$L_y = -2\{-0.5413 - K(e/c) + (I_x/I_y)\log a/c + (I_x/I_y)[K(c/a) - K(e/c)]\}, \quad (21)$$

$$L_z = -2\{-0.5413 + \log e/c - K(e/c) + (I_x/I_z)\log a/c + (I_x/I_z) \times [K(e/a) - K(e/c)]\}. \quad (22)$$

Now Table I of Appendix III evidences that for $1 \geq A \geq 0.1$, hence $0 \leq r \leq 0.82$, $K(r)$ is substantially constant ranging from $-0.553 \geq K \geq -0.561$. The values of $r$ found in practice approximate the upper limit. Accordingly, selecting $r = 0.75$ as representative, whence

$$K(c/a) \cong K(e/a) \cong K(e/c) \cong -0.556,$$

Eqs. (20)–(22) reduce to the simple approximate equations

$$L_x = -0.030, \quad (23)$$

$$L_y = -0.030 - 2(I_x/I_y)\log a/c, \quad (24)$$

$$L_z = -0.030 - 2\log e/c - 2(I_x/I_z)\log a/c, \quad (25)$$

valid for $c/a$, $e/a$, and $e/c$ not greater than approximately 0.8.

For purposes of computation, the approximate Eqs. (20)–(22) possess considerable advantage over the general Eq. (7). The latter comprises 48 terms, the former only a few. Moreover, these few terms involve the simplest of calculations. The logarithmic term can be read from a slide rule or from standard tables; the values of $K$ from Table I, calculated from Eq. (13). And even this table can be dispensed with in much work. Equations (23)–(25) afford sufficiently accurate values. Thus, in virtue of the fewness and simplicity of the terms comprising the approximate equations, they afford rapid computation.

## IV. EQUATIONS FOR REACTIVE VOLTAGE DROP

In practice, calculation of associated inductance and reactance is incidental to calculation of what is actually desired: namely, the reactive voltage drop on the conductor, equal to $j2\pi fI (= jwI)$. Saving in time of computation results, however, from calculating the reactive voltage drop directly from appropriate equations, to be obtained by multiplying the previously derived equation for indictance by $jwI$. Thus from Eqs. (1)–(3) we have

$$E_x = (-2jw) \sum_{i=x}^{z} I_i \log D_{xi}, \quad (26)$$

$$E_y = (-2jw) \sum_{i=x}^{z} I_i \log D_{yi}, \quad (27)$$

$$E_z = (-2jw) \sum_{i=x}^{z} I_i \log D_{zi}. \quad (28)$$

Particularly useful approximate equations are to be obtained from Eqs. (23)–(25). Thus

$$E_x = -j0.03wI_x, \quad (29)$$

$$E_y = -2jw[0.015I_y + I_x \log a/c], \quad (30)$$

$$E_z = -2jw[I_z(0.015 + \log e/c) + I_x \log a/c]. \quad (31)$$

In similar obvious fashion, corresponding equations can be obtained from Eqs. 7 and analogous equations, from Eq. 12 and analogous equations, and from Eqs. (20)–(22).

## V. UNITS TO BE EMPLOYED

Equations (1)-(3) are valid for the c.g.s. electromagnetic system of units. Hence, the various equations for inductance yield values expressed in abhenrys per centimeter of bus length. Inasmuch, however, as the coefficients and arguments of the various terms comprising these equations can be written in dimensionless form (as, for example, in Eqs. (20)–(25)) we note that in substituting in these equations the currents, and likewise the linear dimensions of the conductors, can be expressed in any like unit.

On the other hand, inasmuch as the voltage drop on a conductor equals $jwLI$, in Eqs. (26)–(31) and in analogous equations the currents must be expressed in abamperes (1 abampere = 10 amperes), though the linear dimensions can yet be expressed in any like unit. The voltage drop, of course, will be in abvolts per centimer of bus length.

For convenience in computation we note the following. Multiplying abhenrys per centimeter by $3.048 \times 10^{-5}$ yields millihenrys per foot of bus length; multiplying by $11.48 \times 10^{-6}$ yields 60-cycle reactance in ohms per foot of bus length. Multiplying abvolts per centimeter by $3.048 \times 10^{-7}$ yields volts per foot of bus length. If in

Eqs. (26)–(31) and in analogous equations the currents are expressed in amperes and the resulting values multiplied by $3.048\times 10^{-8}$ the voltage drops obtained are in volts per foot of bus length. Finally, $\log u(\equiv \log_e u) = 2.3026 \log_{10} u$, where $u$ is an arbitrary number.

## VI. SOME ILLUSTRATIVE EXAMPLES

To illustrate the use of the general and approximate equations and to gain knowledge of the accuracy to be expected of values calculated with the approximate equations, we consider the following examples.

Example 1. The problem is to calculate the six geometric mean distances and the associated inductances of a bus having cross section as in Fig. 1 with dimensions: $a=6$ inches, $b=5.6$ inches, $c=4.5$ inches, $d=4$ inches, $e=3$ inches, $f=1.2$ inches. The bus carries balanced currents $I_x = -0.5-j0.866$, $I_y = -0.5+j0.866$, and $I_z=1$ abampere.

Substituting these values in Eqs. (4)–(6) and analogous equations, rearranging terms, obtaining values of the logarithmic and arctangentic terms from the Work Projects Administration Tables, and effecting all calculations on a 10-row electric calculating machine yields

$$\log D_{xx} = 1.2261, \quad \log D_{xy} = 1.2019,$$
$$\log D_{yy} = 0.9222, \quad \log D_{xz} = 1.2011,$$
$$\log D_{zz} = 0.3576, \quad \log D_{yz} = 0.8733.$$

Substituting in Eqs. (1)–(3) as indicated and collecting real and imaginary terms yields

$L_x = -0.0484$ abhenry per centimeter of bus length,

$L_y = 0.2306-j0.572$ abhenry per centimeter of bus length,

$L_z = 1.359+j0.572$ abhenry per centimeter of bus length.

In calculating these values all logarithmic and arctangentic terms were taken to nine decimal places; values stemming from consequent arithmetic manipulations were held to the same number of decimals. Inasmuch as each of these final values of inductance stems from algebraic addition of some 50 terms, the ratio of the largest to the smallest approximating $10^6$, it is essential that some such degree of preciseness be held. But, since the resulting values of $L$ is physically significant to only two or three decimal places, it is not unlikely that a study of the number of decimal places to be held in the various stages of computation would reveal that a smaller number than actually used still would be satisfactory. Inasmuch, however, as 15-place tables were employed and the calculation was performed on a 10-row electric calculating machine, the added labor is negligible, and there is no uncertainty as to the effect of cumulative errors on the accuracy of the first several digits of $L$.

Example 2. The problem is to calculate the geometric mean distances and the associated inductances of a bus having cross section as in Fig. 2 with dimensions and currents equal, respectively, to the external dimensions ($a=6$ inches, $c=4.5$ inches and $e=3$ inches) and currents of the bus of example 1.

Substituting these values in Eqs. (9)–(11) and analogous equations and performing the indicated arithmetic yields

$$\log D_{xx} = 1.2504, \quad \log D_{xy} = 1.237,$$
$$\log D_{yy} = 0.9628, \quad \log D_{xz} = 1.232,$$
$$\log D_{zz} = 0.5573, \quad \log D_{yz} = 0.946.$$

Utilizing these values in Eq. (12) and analogous equations yields

$L_x = -0.0328+j0.002$ abhenry per centimeter of bus length,

$L_y = 0.2574-j0.502$ abhenry per centimeter of bus length,

$L_z = 1.0634+j0.50$ abhenry per centimeter of bus length.

Confirmatively, to three decimal places the same values of geometric mean distance and of associated inductance are yielded by the values of Table I conjoined with Eqs. (14)–(22).

Finally, from Eqs. (23)–(25) we have

$L_x = -0.030$ abhenry per centimeter of bus length,

$L_y = 0.257-j0.497$ abhenry per centimeter of bus length,

$L_z = 1.069+j0.498$ abhenry per centimeter of bus length.

Example 3. The problem is to calculate the reactive voltage drops on the conductors of the busses for examples 1 and 2.

The voltage drops can be calculated from

Eqs. (26), (27) and (28) by substituting therein the values of logarithmic mean distances calculated in examples 1 and 2. Alternatively, they can be calculated by multiplying the associated inductances by appropriate values of *jwI*. Utilizing the latter procedure and using inductances calculated from Eq. (7) yields

$E_x = 2jw(0.0141+j0.0209)$ abvolt per centimeter of bus length,
$E_y = 2jw(0.190+j0.243)$ abvolt per centimeter of bus length,
$E_z = 2jw(0.6795+j0.286)$ abvolt per centimeter of bus length.

Using inductances calculated from Eqs. (12) and analogous equations and from (20), (21) and (22) yields

$E_x = 2jw(0.0082+j0.0142)$ abvolt per centimeter of bus length,
$E_y = 2jw(0.153+j0.237)$ abvolt per centimeter of bus length,
$E_z = 2jw(0.532+j0.250)$ abvolt per centimeter of bus length.

Using inductances calculated from Eq. (23)–(25) yields

$E_x = 2jw(0.0075+j0.013)$ abvolt per centimeter of bus length,
$E_y = 2jw(0.151+j0.236)$ abvolt per centimeter of bus length,
$E_z = 2jw(0.532+j0.249)$ abvolt per centimeter of bus length.

Comparison of the values calculated from the approximate Eqs. (20)–(22) with those calculated from the simple approximate Eqs. (23)–(25) indicates that in general the simple approximate equations furnish sufficiently accurate values. Comparison of both sets with the values calculated from the general Eq. (7) reveals that the former are somewhat higher. Though these values would be sufficiently accurate for preliminary—and in most instances, final—design purposes, it is yet desirable to have means of calculating somewhat more accurate values without incurring the heavy labor incident to calculation with Eq. (7). Such a means of calculation is suggested by the writers' previous work[6] on single-phase coaxial square tubular busses. Therein it is shown that a bus comprised of coaxial circular tubular conductors has an inductance which differs little from that of a bus comprised of coaxial square tubular conductors having (1) the same thicknesses and (2) internal and external dimensions equal to the internal and external diameters of the corresponding circular conductors. Analogously, it is to be expected that the inductances of similarly dimensioned three-phase busses will be in close agreement. If so, it is to be conjectured that this agreement is better than that between corresponding values for the square tubular conductors calculated from the given geometry and from the approximate assumption of line-segment cross sections. That such is true is substantiated by the following illustrative examples.

Example 4. The problem is to calculate the inductances and reactive voltage drops of the conductors of a bus having cross section as in Fig. 3 with dimensions and currents identical with those of example 1.

Calculating the pertinent geometric mean distances as detailed in Appendix IV, substituting as indicated in Eqs. (1) and (3) and (26)–(28), and collecting terms yields the desired values:

$L_x = -0.023$ abhenry per centimeter of bus length,
$L_y = 0.271 - j0.537$ abhenry per centimeter of bus length,
$L_z = 1.384 + j0.537$ abhenry per centimeter of bus length,

and

$E_x = 2jw(0.006+j0.010)$ abvolt per centimeter of bus length,
$E_y = 2jw(0.165+j0.252)$ abvolt per centimeter of bus length,
$E_z = 2jw(0.692+j0.269)$ abvolt per centimeter of bus length.

Example 5. The problem is to calculate the inductances and reactive voltage drops of the conductors of a bus having cross section as in Fig. 4 with dimensions and currents identical with those of example 2.

Calculating the pertinent geometric mean distances as detailed in Appendix IV, substituting as indicated in Eqs. (1)–(3) and (26)–(28), and collecting terms yields the desired values:

$L_x=0$ abhenry per centimeter of bus length,
$L_y=0.297-j0.498$ abhenry per centimeter of bus length,
$L_z=1.099+j0.498$ abhenry per centimeter of bus length,

and

$E_x=0$ abvolt per centimeter of bus length,
$E_y=2jw(0.144+j0.249)$ abvolt per centimeter of bus length,
$E_z=2jw(0.549+j0.249)$ abvolt per centimeter of bus length.

Comparison of the two sets of values calculated in examples 4 and 5 with the corresponding first two sets of example 3 reveals

(i) That—corroborative of expectation—corresponding values for square and for circular conductors are in good agreement;

(ii) That—corroborative of conjecture—the values of example 4 afford a somewhat better approximation to the first set of values in example 3 than do the second set of values of example 3, calculated on the assumption of line-segment cross section.

### VII. CORRECTIONS FOR ROUNDED EDGES

To eliminate excessive edge heating caused by skin effect, square tubular conductors of commercial manufacture have rounded edges. Thus square tubular conductors of the sizes specified in examples 1 and 3 have rounded edges of outer, inner and mean radius indicated as follows:[16] $a=6$ inches; $t=(a-b)/2=0.2$ inch; $r_0=0.75$ inch; $r_i=0.55$ inch; $r_m=0.65$ inch, $c=4.5$ inches; $t'=(c-d)/2=0.25$ inch; $r_0=0.625$ inch; $r_i=0.375$ inch; $r_m=0.5$ inch, $e=3$ inches; $t''=(e-f)/2=0.9$ inch; $r_0=1$ inch; $r_i=0.1$ inch; $r_m=0.55$ inch.

Dwight and Wang[10] have derived, semi-empirically, that the approximate increase in self geometric mean distance caused by rounding the edges of a conductor of square cross section is

$$\Delta \log D_s=-[k^2\log k^{-1}+0.716k^2+0.5k^3+\cdots] \text{ abhenrys per centimeter of conductor length,} \tag{32}$$

where $k=0.463r_m/s$, $r_m$ is the mean radius of the rounded edge, $s$ the mean side of the square cross section, and $r_m$ is small compared with $s$, the accuracy increasing as $r_m/s\rightarrow 0$.

From Eqs. (1)–(3) it follows that the approximate increase in associated inductance is

$$\Delta L=2[k^2\log k^{-1}+0.716k^2+0.5k^3+\cdots] \text{ abhenrys per centimeter of conductor length.} \tag{33}$$

For conductor $x$, $s=a-t=5.8$ inches and $r_m=0.65$ inch. Hence, $k=0.052$, $\Delta L_x=0.020$, and $\Delta E_x(=jwI_x\Delta L_x)=2jw(-0.0049-j0.0093)$.

For conductor $y$, $s=c-t'=4.25$ inches and $r_m=0.5$ inch. Hence, $k=0.0545$, $\Delta L_y=0.0216$, and $\Delta E_y=-2jw(-0.005+j0.009)$.

For conductor $z$, $s=e-t''=2.1$ inches and $r_m=0.55$ inch. Hence, $k=0.122$, $\Delta L_z=0.011$, and $\Delta E_z=2jw(0.006)$.

Adding these corrections to the first set of values of examples 1 and 3 yields

$L_x=-0.029$ abhenry per centimeter of bus length,
$L_y=0.252-j0.572$ abhenry per centimeter of bus length,
$L_z=1.370+j0.572$ abhenry per centimeter of bus length,

and

$E_x=2jw(0.009+j0.012)$ abvolt per centimeter of bus length,
$E_y=2jw(0.185+j0.252)$ abvolt per centimeter of bus length,
$E_z=2jw(0.686+j0.286)$ abvolt per centimeter of bus length.

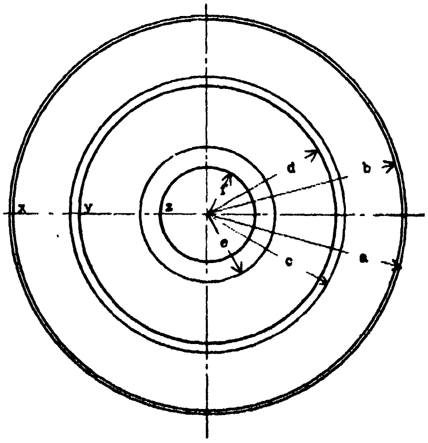

FIG. 3. Cross section of coaxial bus comprised of circular tubular conductors.

---

[16] *Chase Electrical Handbook* (Chase Brass and Copper Company, Inc., Waterbury, Connecticut, 1941), pp. 80–81.

The facts that rounding the corners of a conductor will result in a change of associated inductance and that the changes just calculated from Eq. (33) are of the correct order of magnitude are confirmed by comparing, in turn, the first set of values of example 1 (for the bus of Fig. 1), the values just listed (for a bus stemming from that of Fig. 1 through rounding the corners of the conductors), and the values of example 4 (for the bus of Fig. 3). Now a circular tubular conductor can be considered the limiting case of a rounded square tubular conductor, its internal and external sides being equal to the internal and external diameters of the circular conductor. Hence the values just listed should be—as they are—intermediate between the corresponding values for the square conductors of Fig. 1 and the circular conductors of Fig. 4.

## VIII. CORRECTIONS FOR SKIN AND PROXIMITY EFFECTS

As the frequency increases from zero to a specified value the currents in the conductors of the bus with cross section as in Fig. 3 tend to concentrate in thin surface strata on the adjacent surfaces of the conductors: the inner surface of conductor $x$ and the outer surface of conductor $y$, the inner surface of conductor $y$ and the outer surface of conductor $z$. This phenomenon results in a change of the associated inductance (and resistance) of each conductor. Detailed mathematical analysis[6, 11, 17] reveals that at 60-cycles the changes in the associated inductances of practically dimensioned busses such as those of example 4 are negligible.

In view of these negligible changes in the inductances of this coaxial circular tubular bus, the small differences between the inductances of this bus and those of the coaxial square tubular bus of example 1—especially, after applying corrections for the rounded edges, and the general geometric similarity between these two busses, we conclude that in practically dimensioned rounded square tubular busses in general 60-cycle skin and proximity effects are negligible insofar as the inductances of the bus are concerned. This conclusion is in accord with the results of analytic and experimental investigations of the inductances of single-phase coaxial[6, 11] and coplanar busses comprised of square tubular or rectangular conductors.

On the other hand, the reactive voltage drops will be somewhat, though slightly, changed by skin and proximity effects. This stems from the fact that the resistances of the conductors are changed by skin and proximity effects. Therefore the current distribution in the conductors, and thus the resistive and reactive voltage drops in the conductors, changes with frequency. At 60-cycles and for bus and conductor geometry commonly encountered in practice it commonly suffices to calculate the a.c. resistances of the square tubular conductors by multiplying their d.c. resistance $R_{\text{d.c.}}$ by the known[7, 8, 16] skin-effect factor $K_s$.

Accurate calculation of $R_{\text{a.c.}}$ requires that the values of $K_sR_{\text{d.c.}}$ thus obtained be multiplied, in turn, by appropriate proximity effect factors $K_p$. Because of the intractable mathematics involved, it has not been possible to calculate rigorously these factors for single-phase or three-phase coaxial square tubular conductors. On the other hand, the simpler—though yet mathematically difficult—corresponding problem for coaxial circular tubular conductors has been solved. In view of the above discussion and analysis of the corresponding inductances of these two busses, and in view of their general geometric similarity, it is to be expected that values of $K_p$ for a bus comprised of circular tubular conductors would be substantially the same as values of $K_p$ for a bus comprised of square tubular conductors having sides and thicknesses identical with the diameters and thicknesses of the corresponding circular conductors.

Now Dwight[17] has published equations ((22), (23), and (29) of Reference 17) for the ratio of $R_{\text{a.c.}}/R_{\text{d.c.}}(\equiv K_sK_p)$ for each of the three conductors of a three-phase coaxial circular tubular bus and curves (Fig. 2 of Reference 17) for the particular case of balanced currents. Accordingly, if a value obtained from Dwight's equations or curves is divided by $K_s$ for the same *circular tubular conductor*, there is obtained a value of $K_p$ which is a good approximation to the $K_p$ of the corresponding square tubular conductor. (It is to be noted that the required value

---

[17] H. B. Dwight, "Reactance and skin effect of concentric tubular conductors," Trans. A.I.E.E. 61, 513–518, 976–977 (1942).

of $K_s$ can be obtained from Dwight's equations or curves: it is equal to the value of $K_sK_p \equiv K_s$ for the conductor when considered as the innermost conductor of a three-phase bus.) Commonly, however, the refinement stemming from use of the values of $K_p$ is not necessary in practice.

### IX. BUSSES COMPRISED OF STRUCTURAL TUBULAR CONDUCTOR

A conductor comprised of two slightly separated channels or angles, placed flange to flange, usually is not of a square cross section. If, however, the cross section does not differ too greatly from a square cross section, and commonly this is the case in practice, it is to be expected that a fairly good approximation to the actual inductance of the bus can be effected by judicious use of the equations for the square cross section. In an earlier paper[6] on single-phase coaxial busses the writers calculated that an equivalent square tubular bus with conductors having either the same external perimeters (rounded edges aside) or sides equal to the webs of the given structural conductors have inductances in good agreement with those of the structural tubular bus and showed that these analytic deductions were confirmed by experiment. It is to be inferred that selecting an equivalent three-phase bus on one or the other of the bases mentioned will yield approximate values of inductance within a few percent of the actual values, which is all that is required for most design purposes.

Skin-effect and proximity-effect factors for calculating the a.c. resistances of the conductors can be obtained in like manner.

### X. BALANCING CONDUCTOR CURRENTS IN THREE-PHASE COAXIAL BUSSES

Because of the unbalanced geometry of the three-phase coaxial bus the phase currents will, in general, not be balanced. In such case they must be calculated by the procedure detailed in chapter 2 of reference 13. For obvious reasons, however, balance is most desirable. Though a considerable degree of balance can be obtained by proper geometrical design (make, in so far as is feasible, the associated impedances identical), complete balance is not to be so obtained. The system can be balanced, however, by the use of suitably designed and suitably placed metal sleeves fitted around the conductors. Though account of this scheme has long been published,[6, 18] and satisfactory results have been obtained in practice,[19] it would appear that comparatively little use of it has been made to date.

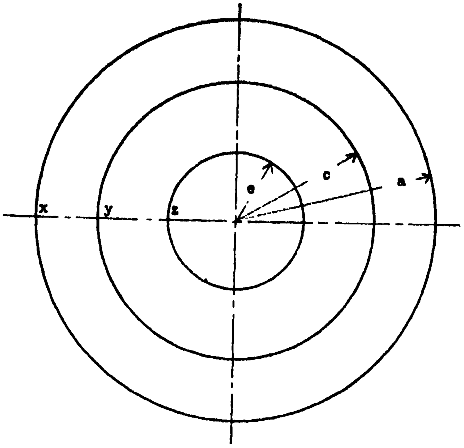

FIG. 4. Cross section of coaxial bus comprised of circular tubular line-segment conductors.

### APPENDIX I

The cross section $S_x \equiv S_1 - S_2$ of conductor $x$ of Fig. 1 can be considered as the symmetrical superposition of a positive square area $S_1$ of side $a$ and a negative square area $-S_1$ of side $b$. By well known theory[6, 12]

$$S_x^2 \log D_{xx} = S_1^2 \log D_{11} + S_2^2 \log D_{22} - 2S_1S_2 \log D_{12} \quad (34)$$

wherein as detailed in Appendix I of reference 6

$$S_1^2 \log D_{11} = -(25/12)S_1^2 - (1/6)[K(a, a) + K(0, 0) - 2K(a, 0)], \quad (35)$$

$$S_1S_2 \log D_{12} = -(25/12)S_1S_2 - (1/6)\{K[(a+b)/2, (a+b)/2] + K[(a-b)/2, (a-b)/2] - 2K[(a+b)/2, (a-b)/2]\} \quad (36)$$

and, generally,

$$K(A, B) = (A^4 - 6A^2B^2 + B^4) \log(A^2+B^2)^{\frac{1}{2}} - 4AB^3 \tan^{-1}(A/B) - 4A^3B \tan^{-1}B/A. \quad (37)$$

Substituting appropriately in Eq. 34, col-

[19] W. K. Boice, "Current-balancing reactors for turbine generators," Power Plant Eng. 48, October, 94, 120 (1944).

lecting corresponding terms, and solving for $\log D_{xx}$ yields Eq. (4).

In similar fashion, the cross section $S_y \equiv S_3 - S_4$ of conductor $y$ of Fig. 1 can be considered as the symmetrical superposition of a positive square area $S_3$ of side $c$ and a negative square area $-S_4$ of side $d$. By well-known theory

$$S_xS_y \log D_{xy} = S_1S_3 \log D_{13} - S_1S_4 \log D_{14} - S_2S_3 \log D_{23} + S_2S_4 \log D_{24}, \quad (38)$$

wherein the four terms on the right-hand side of Eq. 38 are analogous to those of Eq. (36).

Substituting appropriately in Eq. (38), collecting corresponding terms, and solving for $\log D_{xy}$ yields Eq. (5).

## APPENDIX II

The cross section $S_x$ of Fig. 2 is comprised of four identical line segments, $S_1$, $S_2$, $S_3$ and $S_4$. By well-known theory

$$S_x^2 \log D_{xx} = 4(S_{11}^2 \log D_{11} + 2S_1S_2 \log D_{12} + S_1S_3 \log D_{13}), \quad (39)$$

wherein as detailed in Appendix III of reference 6,

$$\log D_{11} = \log a - 3/2, \quad (40)$$

$$\log D_{12} = \log a + (1/2) \log 2 + \pi/4 - 3/2, \quad (41)$$

$$\log D_{13} = \log a + \pi/2 - 3/2. \quad (42)$$

Substituting appropriately in Eq. (39), collecting corresponding terms, and solving for $\log D_{xx}$ yields Eq. (9).

In similar fashion, the cross section $S_y$ of Fig. 2 is comprised of four identical line segments $S_5$, $S_6$, $S_7$, and $S_8$. By well known theory

$$S_xS_y \log D_{xy} = 4(S_1S_5 \log D_{15} + 2S_1S_6 \log D_{16} + S_1S_7 \log D_{17}), \quad (43)$$

wherein as detailed in appendix III of reference 6,

$$\log D_{15} = (1/2)\{\log(a^2+c^2) + [(a^2-c^2)/ac] \times \tan^{-1}[(a+c)/(a-c)] - \pi(a-c)^2/4ac - \log 2 - 3\}, \quad (44)$$

$$\log D_{16} = (1/4)\{[(a+c)^2/ac] \log(a+c) - [(a-c)^2/ac] \log(a-c) - 2 \log 2 + \pi - 6\}, \quad (45)$$

$$\log D_{17} = (1/2)\{\log(a^2+c^2) - [(a^2-c^2)/ac] \tan^{-1}[(a-c)/(a+c) + \pi(a+c)^2/4ac - \log 2 - 3\}. \quad (46)$$

Substituting appropriately in Eq. 43, collecting corresponding terms and solving for $\log D_{xy}$ yields Eq. 10.

## APPENDIX III

The values of $K(r)$ in Table I are obtained by substituting the indicated values of $A$ and $r$ in Eq. (13), obtaining the values of the logarithmic and arctangentic terms from the Work Projects Administration Tables, and performing all computation on a 10-row electric calculating machine. To avoid cumulative errors all computation was effected to eight significant figures. For actual use, however, $K(r)$ need only to be known to the three or four significant figures given in Table I. For use in design, the designer may find it convenient to plot a curve of $K(r)$ *versus* $r$ from the values given.

TABLE I.

| $A$ | $r$ | $K(r)$ | $A$ | $r$ | $K(r)$ |
|---|---|---|---|---|---|
| 0 | 1 | −0.541 | 0.50 | 1/3 | −0.5611 |
| 0.10 | 9/11 | −0.553 | 0.55 | 7/31 | −0.5611 |
| 0.15 | 17/23 | −0.5560 | 0.60 | 1/4 | −0.5612 |
| 0.20 | 2/3 | −0.558 | 0.65 | 5/33 | −0.5612 |
| 0.25 | 3/5 | −0.5590 | 0.70 | 3/17 | −0.5612 |
| 0.30 | 7/13 | −0.5597 | 0.75 | 1/7 | −0.5612 |
| 0.35 | 13/27 | −0.5603 | 0.80 | 1/9 | −0.5612 |
| 0.40 | 3/7 | −0.5607 | 0.90 | 1/19 | −0.5612 |
| 0.45 | 11/29 | −0.5608 | 1.0 | 0 | −0.5612 |

## APPENDIX IV

The self geometric mean distance of a circular annulus is[18]

$$\log D_s = \log r_1 - [4(r_1^2 - r_2^2)^2]^{-1}[r_1^4 - 4r_1^2r_2^2 + r_2^4(3 + 4 \log r_1/r_2)], \quad (47)$$

wherein $r_1$ and $r_2$ are, respectively, the external and internal radii of the annulus.

The mutual geometric mean distance of a circular annulus and an area of arbitrary area within it is

$$\log D_m = (r_1^2 - r_2^2)^{-1}(r_1^2 \log r_1 - r_2^2 \log r_2) - 1/2. \quad (48)$$

Substituting appropriately in Eqs. (47) and (48) yields the self and mutual geometric mean distances of Fig. 3:

$$\log D_{xx} = 1.0764, \quad \log D_{xy} = 1.0649,$$
$$\log D_{yy} = 0.7739, \quad \log D_{xs} = 1.0649,$$
$$\log D_{ss} = 0.2174, \quad \log D_{ys} = 0.7543.$$

Substituting these values and those of the currents in Eqs. (1)–(3) and (26)–(28) yields the values of example 4. Confirmatively the values of reactive voltage drop on conductors $y$ and $z$ are in agreement with the values obtained by Dwight[17] who utilized the same bus to illustrate his paper. The value for $I_x$ is considerably smaller than Dwight's value. As, however, this small value stems from the algebraic summation of several large values, the difference in the two values is not surprising if (as the writers understand) Dwight's values were obtained by slide rule whereas the writers' were obtained by use of an electric calculating machine, all numerical values being held to eight decimal places during computation.

The self-geometric mean distance of a circle and the mutual geometric mean distance of the circle to any arbitrary area within it are identical:

$$\log D_s = \log D_m = \log r_1,$$

where $r_1$ is the radius of the circle.

Substituting appropriately in Eq. (49) yields the self- and mutual geometric mean distances of Fig. 4:

$$\begin{aligned} \log D_{xx} &= 1.0986, & \log D_{xy} &= 1.0986, \\ \log D_{yy} &= 0.8109, & \log D_{xz} &= 1.0986, \\ \log D_{zz} &= 0.4055, & \log D_{yz} &= 0.8109. \end{aligned}$$

Substituting these values and those of the currents in Eqs. (1)–(3) and (26)–(28) yields the values of example 5.

# Mechanical Behavior of High Damping Metals*

CLARENCE ZENER
*Institute for the Study of Metals, The University of Chicago, Chicago, Illinois*

(Received July 16, 1947)

The relation between the various measures of internal friction are independent of the precise mechanism of the dissipation of energy when the internal friction is small, but not when it is large. In this paper the relation between the two measures most commonly used, logarithmic decrement and tangent of the angle with which strain lags behind stress, is deduced for all levels of internal friction in the important case in which the dissipation of energy is due to a relaxation process having a single time of relaxation. The conditions are further derived under which a specimen of such a metal will not vibrate, but returns aperiodically to its equilibrium configuration.

## I. INTRODUCTION

SEVERAL measures of internal friction are in common use. Engineers frequently report the specific damping capacity, $\Delta E/E$, defined as the ratio of the energy dissipated per cycle over the average energy of vibration. The measure generally used in physics varies according to the method used in its determination. When the method of free decay is employed, the logarithmic decrement $\delta$ is used. On the other hand, when the method of forced oscillation is employed, the angle $\alpha$ by which strain lags behind stress is usually measured, and the internal friction is reported in terms of $\tan\alpha$. At low values of internal friction all these various measures are related by simple conversion factors. Thus[1]

$$\Delta E/E = 2\delta = 2\pi \tan\alpha. \qquad (1)$$

Recent measurements[2] in this laboratory have indicated that polycrystalline metals have, under appropriate conditions, a $\tan\alpha$ as large as 0.1. Under these conditions the term specific damping capacity becomes inappropriate since the very concept of energy of vibration is ambiguous. Under these conditions the relation between $\delta$ and $\tan\alpha$ in Eq. (1) begins to become inaccurate size in its derivation $\tan\alpha$ was assumed to be a small order quantity. The precise relation between $\delta$ and $\tan\alpha$ is dependent upon the mechanism of the dissipation of energy. One important mechanism of energy dissipation in metals arises from the relaxation of an internal parameter which is disturbed from its equilibrium value by a change in strain.[3-6] This parameter could refer, for example, to the stress induced difference in chemical potential of solute atoms in two types of interstitial positions. Frequently this internal parameter, which will be denoted by $A$, obeys a simple relaxation equation of the type

$$dA/dt = -\tau_\epsilon^{-1}A - \gamma\dot{x}, \qquad (2)$$

where $x$ denotes the deformation and $\tau_\epsilon$ denotes the time of relaxation at constant strain. In such cases the relation between stress and strain is completely specified, and hence one may deduce, the precise relation between $\delta$ and $\tan\alpha$ obtained from free-oscillation and forced-oscillation experiments, respectively. This relation is obtained in section II. In section III the conditions are derived under which the material behaves in an aperiodic manner, that is, under which the material is self-overdamped.

## II. RELATION BETWEEN $\delta$ AND TAN$\alpha$

In the most appropriate method of investigating highly damping material one employs an auxiliary-inertia member so that the inertia of the specimen itself is of no consequence. One thereby avoids all uncertainty as to the precise manner in which strain is distributed throughout the specimen. The strain is everywhere specified

[6] C. Zener, Phys. Rev. 71, 34 (1947).

by a single-deformation parameter $x$ which describes the overall deformation, e.g., angle of twist in a torsion experiment. We shall denote by $f$ the force conjugate to $x$, e.g., the torque acting upon specimen in a torsion experiment.

The deformation $x$ is a linear function of $f$ and the internal parameter $A$. Thus

$$x = M_R^{-1}f + \lambda A. \tag{3}$$

Here $M_R$ refers to the elastic modulus under conditions of complete relaxation, and is called the relaxed elastic modulus. We shall find it convenient to also introduce the unrelaxed modulus $M_U$, which refers to the elastic modulus measured under conditions in which no relaxation takes place. Upon using Eqs. (2) and (3) we see that

$$M_U/M_R = 1 + \gamma\lambda. \tag{4}$$

We shall also find it convenient to introduce the time of relaxation of $A$ under conditions of constant stress, $\tau_\sigma$. Again comparing Eqs. (2) and (3) we find

$$\tau_\sigma/\tau_\epsilon = 1 + \gamma\lambda. \tag{5}$$

Making use of these definitions we find that elimination of $A$ between Eqs. (2) and (3) leads to

$$dx/dt + \tau_\sigma^{-1}x = M_U^{-1}(df/dt + \tau_\epsilon^{-1}f). \tag{6}$$

The angle $\alpha$ by which strain lags behind stress in a forced oscillation experiment may now be found by substituting

$$f = f_0 e^{i\omega t}$$

into Eq. (6). We find

$$\tan\alpha = \frac{M_U - M_R}{(M_U \cdot M_R)^{\frac{1}{2}}} \cdot \frac{\omega(\tau_\epsilon\tau_\sigma)^{\frac{1}{2}}}{1 + \omega^2 \cdot \tau_\epsilon\tau_\sigma}. \tag{7}$$

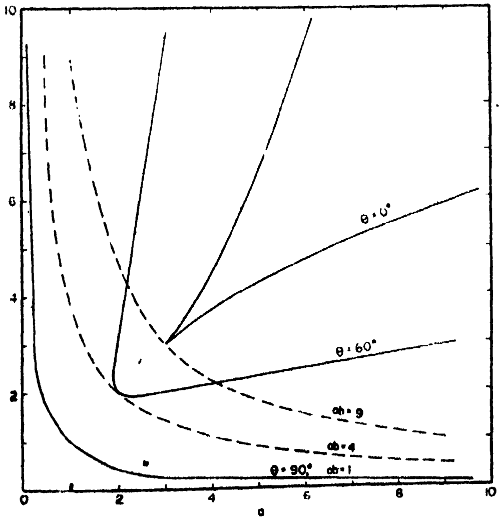

**Fig. 1.** Diagram for determination of conditions for $\delta_m$. Logarithmic decrement is constant along lines of constant $\theta$. Variation of frequency of vibration corresponds to motion along a line of constant $ab$.

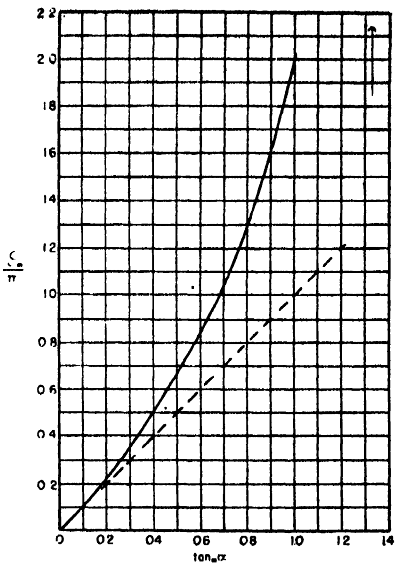

**Fig. 2.** Relation between maxima values of $\delta$ and of $\tan\alpha$ in a plot *vs.* frequency of vibration. Solid line gives exact relation. Dashed line gives extrapolation of relation valid at small values of internal friction.

In the case of a free oscillation experiment, the force $f$ in Eq. (6) is the negative of the force which acts upon the inertia member. Thus if we denote by $I$ the inertia,

$$Id^2x/dt^2 = -f. \tag{8}$$

An equation containing $x$ alone is now obtained by eliminating $f$ between Eqs. (6) and (8). We thus find

$$d^3x/dt^3 + \tau_\epsilon^{-1}d^2x/dt^2 + \omega_U^2(dx/dt + \tau_\sigma^{-1}x) = 0. \tag{9}$$

Here we have introduced the "unrelaxed" angular frequency

$$\omega_U = (M_U/I)^{\frac{1}{2}}. \tag{10}$$

We shall later find it convenient to introduce the "relaxed" angular frequency

$$\omega_R = (M_R/I)^{\frac{1}{2}}. \tag{11}$$

The logarithmic decrement is now found by sub-

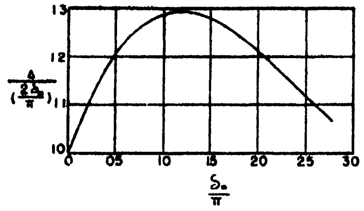

FIG. 3. Relation between relaxation strength and $\delta_m/\pi$.

stituting

$$x=x_0e^{-\xi t} \tag{12}$$

into Eq. (9). According as $\xi$ is expressed as

$$\xi=\xi_0e^{i\theta} \tag{13}$$

or as

$$\xi=\mu+i\eta \tag{14}$$

the logarithmic decrement is given by

$$\delta/\pi=2\cot\theta \tag{15}$$

or

$$\delta/\pi=2\mu/\eta. \tag{16}$$

Upon using the substitutions

$$E^3=\omega_U{}^2\tau_\sigma{}^{-1},\quad a=(\tau_\epsilon E)^{-1},\quad b=\omega_U{}^2E^{-2},\quad U=E^{-1}\xi,$$

we transform this cubic equation into the standard form studied by Jahnke and Emde,[7] namely

$$U^3-aU^2+bU-1=0. \tag{17}$$

As a clue as how to proceed to evaluate the logarithmic decrement from this cubic equation we note that

$$ab=M_U/M_R=1+\gamma\lambda, \tag{18}$$

and

$$b/a=(\omega_U\omega_R\tau_\epsilon\tau_\sigma)^{\frac{1}{2}}. \tag{19}$$

In experiments upon a given material at a given temperature, the product $ab$ therefore remains fixed. On the other hand the ratio $b/a$ varies as we vary the frequencies $\omega_U$, $\omega_R$, either by changes in dimensions of the specimen or through changes in the inertia $I$. Upon comparing the manner with which the angle $\theta$, and hence $\delta$, varies in $(a, b)$ space as shown in Fig. 1 taken from Jahnke and Emde,[7] with how the product $ab$ varies, we see that for a given product $ab$ the logarithmic decrement is a maximum when the ratio $b/a$ is unity. Our problem is therefore considerably simplified if we restrict ourselves to finding the maximum value $\delta_m$ of the logarithmic decrement in a plot of $\delta$ *vs.* frequency of oscillation. In practice this maximum value may also be obtained by a variation of temperature over a range so small that the ratio $M_U/M_R$ remains essentially constant, but sufficiently large so that $\tau_\sigma$ and $\tau_\epsilon$ vary by a large factor. This restriction allows us to replace $b$ by $a$ in Eq. (17). We now note that this simplified cubic equation may be factorized as follows,

$$(U-1)\{U^2+(1-a)U+1\}=0. \tag{20}$$

The first root of Eq. (20) corresponds to an aperiodic motion. Upon solving for the two roots in the second factor, and upon noting the relations in Eqs. (14) and (16), we obtain

$$\delta_m/\pi=2(a-1)\{4-(a-1)^2\}^{-\frac{1}{2}}. \tag{21}$$

We shall now compare $\delta_m$ with the maximum value of $\tan\alpha$, $\tan_m\alpha$, obtained in a plot of $\tan\alpha$ *vs.* $\omega$. Upon observing that the parameter $a$ in Eq. (21) is given by

$$a^2=M_U/M_R, \tag{22}$$

we obtain from Eq. (7)

$$\tan_m\alpha=(1/2)(a-a^{-1}). \tag{23}$$

A plot may now be made of $\delta_m/\pi$ *vs.* $\tan_m\alpha$ through the two parametric equations (21) and (23). Such a plot is presented as Fig. 2. It is to be observed that $\delta_m$ becomes infinite when $a$ is 3, and hence when $\tan_m\alpha$ is 4/3, or when $\alpha$ is 53°. An analytic relation may be found between $\delta_m/\pi$ and $\tan_m\alpha$ when the internal friction is

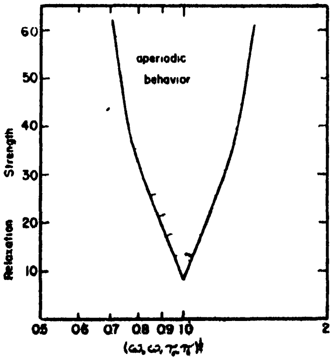

FIG. 4. Conditions for aperiodic behavior.

---

[7] E. Jahnke and F. Emde, *Funktionentafeln* (Teubner, Leipzig, 1938), second edition, addenda, pp. 20–23.

small. Towards this end we introduce the quantity

$$y = a - 1,$$

and expand $\delta_m/\pi$ and $\tan_m\alpha$ in a power series in $y$. We obtain

$$\delta_m/\pi = y(1 + y^2/8 + \quad).$$
$$\tan_m\alpha = y(1 - y/2 + \quad)$$

and hence

$$\tan_m\alpha = (\delta_m/\pi)\{1 - \delta_m/2\pi + \quad\}.$$

The quantity

$$\Delta = (M_U - M_R)/M_R$$

is known as the relaxation strength, and is of theoretical significance since it is directly related to the constants of the material. Thus from Eq. (4)

$$\Delta = \gamma\lambda.$$

In terms of the parameter $a$ the relaxation strength may be written as

$$\Delta = a^2 - 1. \tag{24}$$

The parametric Eqs. (21) and (24) may now be used to obtain a plot of $\Delta$ *vs.* $\delta_m/\pi$. Such a plot is presented as Fig. 3. The analytic relation at small values of $\Delta$ is readily seen to be

$$\Delta = 2(\delta_m/\pi)\{1 + \delta_m/2\pi + \quad\}.$$

### III. CONDITIONS FOR APERIODIC BEHAVIOR

A specimen will not vibrate freely if all three roots of Eq. (17) are real. The boundary of the region in $(a,b)$ space for which all three roots are real may be found by the method outlined by Jahnke and Emde.[7] This boundary is labeled $\theta = 0$ in Fig. 1. A more useful plot is obtained when this boundary is expressed in terms of the two variables

$$\Delta = ab - 1$$

and

$$(\omega_U\omega_R\tau_\epsilon\tau_\sigma)^2 = (b/a)^{\frac{1}{2}}.$$

Such a plot has been deduced by graphical methods from an enlarged plot of the aperiodic boundary in $(a,b)$ space, and is presented as Fig. 4.

---

# The Field of a Microwave Dipole Antenna in the Vicinity of the Horizon. II*

C. L. Pekeris**

*Columbia University Mathematical Physics Group, Columbia University, New York, New York*

(Received July 20, 1947)

In this paper the results of a previous investigation are extended to include cases where the elevation of the transmitter $z_1$, or of the receiver $z$, is less than about 1 when expressed in natural units of height. When $z_1 < 1$ and $z > 1$ the electromagnetic potential $\Psi$ in the vicinity of the horizon is given, in the case of strong absorption $(\beta \gg 1)$, by

$$|\Psi| = [(\tfrac{3}{2})^{\frac{1}{2}}/\pi(r\bar{r})^{\frac{1}{2}}]\,|(1+\beta z_1)G(p)/\beta|, \tag{a}$$

where

$$\beta_v = i(k_0/q)^{\frac{1}{3}}(\epsilon_1 - 1)^{\frac{1}{2}}/\epsilon_1;\quad \beta_h = \beta_v\epsilon_1, \tag{b}$$

and the notation of $I$ is used. Expression (a) equals expression $(B)$ or $(C)$ of $I$ multiplied by the factor $|(1+\beta z_1)|$.

When both $z_1$ and $z$ are less than about unity the potential is given by

$$|\Psi| = (L/r^2)\,|(1+\beta z_1)(1+\beta z)g(p')/\beta^2|, \tag{c}$$

where $L$ is the natural unit of horizontal distance. Expression (c) is equal to the expression for the surface wave given in $(D)$ of $I$ multiplied by the factor $|(1+\beta z_1)(1+\beta z)|$.

In I[1] closed expressions were obtained for the field in the vicinity of the horizon in the three cases: (1) $z_1 > 1$, $z > 1$; (2) $z_1 = 0$, $z > 1$; and (3) $z_1 = 0$, $z = 0$. The purpose of this investigation is to extend the analysis to cover the cases (4) $z_1 < 1$, $z > 1$ and (5) $z_1 < 1$, $z < 1$. It was shown in Eqs. (16) and (17) of I that the Hertzian potential $\Psi$ of a dipole situated at elevation $z_1$ in an atmosphere of standard refraction is given by

$$\Psi_1 = (-i\pi/3)e^{i\omega t}(qk_0^2)^{-\frac{1}{3}}\int_0^\infty J_0(kr)kdkN(u)$$
$$\times[M(u_1) + (B/A)N(u_1)],\quad z > z_1, \tag{1}$$

---

* This paper is based on work done for the Naval Research Laboratory under contract N6ori-110, task order No. 3, with the Navy's Office of Research and Inventions. Publication assisted by the Ernest Kempton Adams Fund for Physical Research of Columbia University.

** On leave of absence from Massachusetts Institute of Technology.

[1] C. L. Pekeris, J. App. Phys. 18, July, 1947. This paper will be referred to as I.

$$\Psi_2=(-i\pi/3)e^{i\omega t}(qk_0^2)^{-\frac{1}{3}}\int_0^\infty J_0(kr)kdkN(u_1)$$
$$\times[M(u)+(B/A)N(u)],\quad 0<z<z_1,\quad (2)$$

where

$$u(z)=u_0+z;\ u_0=(k_0^2-k^2)/H^2;\ k_0=2\pi/\lambda,\quad (3)$$
$$M(u)=u^{\frac{1}{2}}H_{1/3}^{(1)}[(2/3)u^{\frac{3}{2}}],$$
$$N(u)=u^{\frac{1}{2}}H_{1/3}^{(2)}[(2/3)u^{\frac{3}{2}}],\quad (4)$$
$$B/A=-[\beta M(u_0)-\dot{M}(u_0)]/Q(u_0);$$
$$Q(u_0)=\beta N(u_0)-\dot{N}(u_0).\quad (5)$$

In order to evaluate (1) for small values of $z_1$ we expand the integrand into a power series in $z_1$ as follows:

$$\begin{aligned}Q(u_0)&[M(u_1)+(B/A)N(u_1)]\\ &=\beta[M(u_1)N(u_0)-N(u_1)M(u_0)]\\ &\quad-[M(u_1)\dot{N}(u_0)-N(u_1)\dot{M}(u_0)]\\ &=(6i/\pi)[(1+\beta z_1)-u_0z_1^2(\beta z_1+3)/6\\ &\qquad-z_1^3(\beta z_1+2)/12+\cdots],\end{aligned}\quad (6)$$

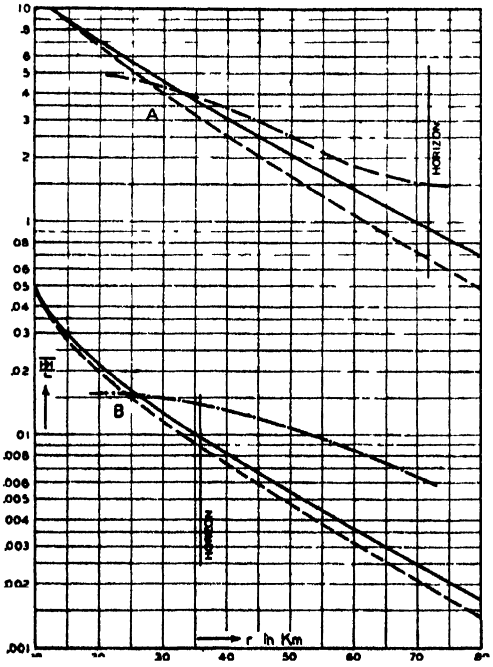

FIG. 1. Comparison of our results with those of B. van d. Pol and H. Bremmer.[2] $\lambda=700$ cm; A: $z_1=0.63$, $z=0.63$; B: $z_1=0$, $z=0.63$.

——— Exact values from normal-mode theory.
— — — — Eq. (20).
— · — · — Eqs. (A) and (B) of reference 1, valid when $z$ is large.

where use was made of the relations

$$N(x)\dot{M}(x)-M(x)\dot{N}(x)=(6i/\pi),$$
$$\frac{d^2N}{dx^2}+xN=0,\quad \frac{d^2M}{dx^2}+xM=0.\quad (7)$$

Since for the field in the vicinity of the horizon the principal contribution to the integrals in (1) and (2) arises from a small range of integration in the neighborhood of $k=k_0$, we may consider $\beta(=iv_0^{\frac{1}{3}}\epsilon_1^{-\frac{1}{2}})$ in (6) as a constant (to within $\beta_h^{-2}<10^{-5}$). Hence, on disregarding powers of $z_1$ above the first, we have

$$\Psi_1(z_1,z)\simeq(1+\beta z_1)\Psi(0,z),\quad (8)$$
$$\Psi(0,z)=2e^{i\omega t}(qk_0^2)^{-\frac{1}{3}}$$
$$\times\int_0^\infty J_0(kr)kdkN(u)/Q(u_0).\quad (9)$$

Expression (9), which is exact, has been evaluated in I for the case of strong absorption ($\beta\gg1$) and in the neighborhood of the horizon:

$$\Psi(0,z)\simeq[(3/2)^{\frac{1}{2}}/\pi(r\bar{r})^{\frac{1}{2}}]|G(p)/\beta|,$$
$$p=(3/2)^{\frac{1}{3}}(r-\bar{r})/L.\quad (10)$$

It can be shown that if the other terms in (6) are included, $G(p)$ in (10) must be replaced by

$$G(p)+i(3/2)^{\frac{1}{3}}z_1^2[(\beta z_1+3)/6(1+\beta z_1)]\frac{dG}{dp}$$
$$-z_1^3[(\beta z_1+2)/(1+\beta z_1)12]G(p)+\cdots.\quad (11)$$

Relation (8) agrees with a similar result arrived at by v. d. Pol and Bremmer[2] on the basis of the normal mode theory. Burrows and Gray[3] have also computed a function

$$F(L)=(3^{\frac{1}{2}}/2\pi)|G[(8/9)^{\frac{1}{3}}p]|,$$

using the normal-mode theory.

Turning now to the case where both $z_1$ and $z$ are small, we have to evaluate (9) for small $z$.

---

[2] B. v. d. Pol and H. Bremmer, Phil. Mag. 27, Eq. (10), 265 (1939).

[3] C. R. Burrows and M. C. Gray, Proc. I.R.E. 29, 14 (1941).

Hence we write

$$\frac{N(u)}{Q(u_0)}=\frac{N(u_0)}{Q(u_0)}\cdot\frac{N(u)}{N(u_0)}=[(qk_0^2)^{\frac{1}{2}}/T]$$

$$\times\{-i+[(u_0)^{\frac{1}{2}}N(u_0)-i\dot{N}(u_0)]/Q(u_0)\}$$

$$\cdot\left[1+\frac{z\dot{N}(u_0)}{N(u_0)}+\cdots\right], \quad (12)$$

$$T\equiv[(k_0^2-k^2)^{\frac{1}{2}}+\gamma(k_1^2-k^2)^{\frac{1}{2}}],$$

$$\Psi(0, z)=\phi+\psi+z\phi', \quad (13)$$

$$\phi=-2ie^{i\omega t}\int_0^\infty J_0(kr)kdk/T,$$

$$\psi=2e^{i\omega t}\int_0^\infty J_0(kr)kdk$$

$$\times[(u_0)^{\frac{1}{2}}N(u_0)-i\dot{N}(u_0)]/Q(u_0)T, \quad (14)$$

$$\phi'\simeq-2ie^{i\omega t}\int_0^\infty J_0(kr)kdk\dot{N}(u_0)/N(u_0)T. \quad (15)$$

In (15) we have not included the contribution from the second term in the braces of (12) because it is of the order of $1/\beta$ relative to the contribution from the first term. The integral in (15) is to be understood as the limit approached as $h\rightarrow 0$ when a factor $\exp[-ih(k_0^2-k^2)^{\frac{1}{2}}]$ is inserted in the integrand. Since for large $\beta$, $Q\simeq\beta N(u_0)$ we have

$$\psi=(\Lambda+\phi')/\beta,$$

$$\Lambda\equiv2e^{i\omega t}\int_0^\infty J_0(kr)kdk(u_0)^{\frac{1}{2}}/T. \quad (16)$$

It can be shown that for large $\beta$

$$\Lambda\rightarrow-Le^{i\theta}/(\beta r^2)=-\beta\phi,$$

$$\theta=(\pi/2)+\omega t-k_0r. \quad (17)$$

Hence

$$\phi'=\beta(\phi+\psi)=\beta\Psi(0, 0);$$
$$\Psi(0, z)=(1+\beta z)\Psi(0, 0), \quad (18)$$

where $\Psi(0, 0)$, the surface wave on a spherical earth, is given by

$$\Psi(0, 0)=(e^{i\theta}L/\beta^2r^2)g(p'). \quad (19)$$

Combining (18) with (8) we arrive at an expression for the field in terms of the surface wave when both $z_1$ and $z$ are small:

$$\Psi(z_1, z)=(1+\beta z_1)(1+\beta z)\Psi(0, 0). \quad (20)$$

In Fig. 1 a comparison is shown between the field obtained by van d. Pol and Bremmer[2] and values computed from Eqs. (20) and (19). Here $z_1$ or $z$ is not more than 0.63, so that Eqs. (A) and (B) of I, which are valid only for $z>1$, are inadequate.

# Letters to the Editor

## Grain Growth in Alpha-Brass

J. E. Burke
*Institute for the Study of Metals, University of Chicago, Chicago, Illinois*
June 30, 1947

An extensive series of data on isothermal grain growth in alpha-brass has recently been published by Walker.[1] Plotting from these data log$D$ (grain diameter in mm), *vs.* log time, one obtains a series of isothermal curves. An example for 42.4 percent deformation prior to recrystallization is shown in Fig. 1. One should like to know whether time and temperature for this process are related by a heat of activation $Q$. If so, times at temperature $T_1$ should be related to times at temperature $T_2$ by the equation:

$$\ln(t_1/t_2) = (Q/R)(T_2^{-1} - T_1^{-1}).$$

This equation can be solved to give values of $t_1/t_2$ to convert times at a given temperature to times at any reference temperature. By taking $Q$ as 60,000 cal. per mole it is found that the data taken at all temperatures can be plotted on a smooth curve at a single reference temperature, with only a reasonable experimental scatter. Figure 2 shows this for the curves of Fig. 1, at a reference temperature of 500°C. It thus seems proper to assign a heat of activation to the process. This curve is not a straight line.

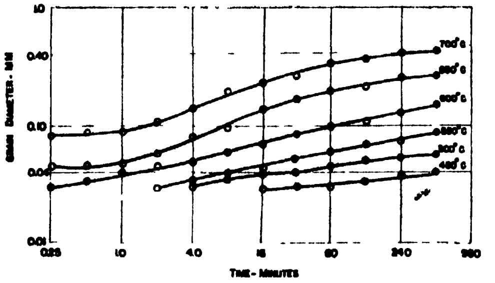

FIG. 1. Isothermal grain growth at various temperatures in alpha-brass.

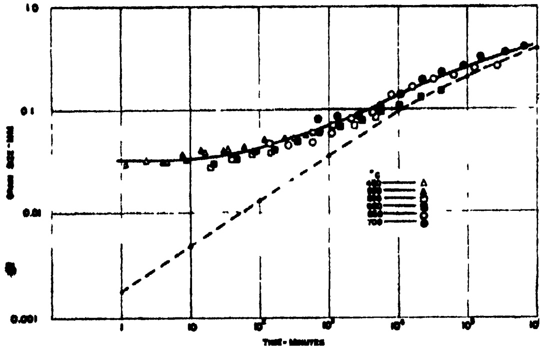

FIG. 2. Solid line: composite grain-growth curve at 500°C reference temperature; Dashed line: composite curve corrected by subtracting 0.03 mm.

Beck, Kremer, and Demer[2] report that their data for grain growth in high purity aluminum follows the relationship:

$$D = kt^n,$$

where $k$ is a constant and the exponent $n$ increases linearly with temperature. Obviously this relationship cannot hold for short times, for, at $t=0$, $D$ has a finite value, $D_0$.

The present data are expressed reasonably well by the relationship:

$$D - D_0 = k_1 t^n,$$

where $D_0$ is the grain size at the time of recrystallization, $k$ is a temperature-dependent constant, and the exponent $n$ has the value 0.425 until late in the growth process. The dotted line in Fig. 2 was obtained by subtracting the recrystallized grain size reported by Walker for this series (0.03 mm) from the solid curve through the experimental points. It can be seen that it is a straight line until the late stages of growth, but that the slope definitely falls off then. Similar results are obtained from other series of data in Walker's work.

This work was supported by the Office of Research and Inventions, U. S. N. (Contract No. N6ori-20-IV).

## Comments on "Grain Growth in Alpha-Brass"

Paul A. Beck
*University of Notre Dame, Notre Dame, Indiana*
September 12, 1947

In the above note J. E. Burke calculated a heat of activation value from grain-growth data on brass obtained by H. L. Walker.[1] Considering the scatter of the data, his value of 60 kcal./g of atom is in reasonable agreement with the heat of activation value of 73.5 kcal./g atom previously calculated for brass by Beck, Kremer, and Demer,[2] by an essentially identical method, from other published grain-growth data. Thus, Burke's result tends to confirm Beck, Kremer, and Demer's conclusions with regard to the heat of activation value from grain-growth data on brass.

Burke states that the relationship,

$$D = k \cdot t^n, \tag{1}$$

found by Beck, Kermer, and Demer for isothermal grain growth in high purity aluminum cannot hold for short times, for at $t=0$, $D$ has a finite value, $D_r$, the grain size as recrystallized. Obviously, Burke uses $t$ to denote the time for grain growth. The zero point of his time scale is at the moment when recrystallization is just complete. However, in the nomenclature used by Beck, Kremer, and Demer $t$ denotes the total time of annealing, which includes the time for recrystallization.* Clearly, Burke's objection is based on a misunderstanding of the nomenclature.

Since most of the annealing periods used by Beck, Kremer, and Demer are very long in comparison with the time for recrystallization, the error committed by using "grain-growth time" instead of "total time," as a result of the above misunderstanding, is negligible, except for the shortest annealing periods at the lowest annealing temperatures. Consequently, the whole matter would be lacking in significance were it not for another mistake in Burke's note. He uses the time data from Walker's paper as if these meant "time for grain growth" in the above sense. Actually, Walker, like Beck, Kremer, and Demer, uses the "total time" of annealing. As some of the times of recrystallization in Walker's work are relatively long (such as 16 min. at 450°C), the error resulting from this misinterpretation is significant.

The dotted line in Burke's Fig. 2 gives $\log(D-D_r)$ as a function of $\log t$, where $t$ is supposed to be the time for grain growth, but it is actually the total time of annealing of Walker's specimens, as explained above. Although the initial portion of this line was so selected across the "reasonable scatter" of the transposed experimental points that it is straight, Burke admits that deviation from the straight line definitely occurs at longer annealing periods. Nevertheless, he considers that the data are reasonably well expressed by the relationship:

$$D-D_r=k_1t^n. \tag{2}$$

A comparison of relationships (1) and (2), by using Beck, Kremer, and Demer's grain-growth data on high purity aluminum at 400°C, is given in Fig. 1. It is clear that the plot of $\log D$ *vs.* $\log t$ closely approximates a straight line. Plotting the same data as $D-D_r$ *vs.* $t_g$ ($t_g$ is used here to designate "grain-growth time" in order to avoid confusion) results in a curve which asymptotically approaches the above straight line at very large $t_g$ values. Similar curves are obtained for other annealing temperatures. Obviously, relation (2) does not fit the grain-growth data for high purity aluminum, but formula (1) does.

It can be easily shown that the initial portion of the curve in the figure approaches a slope of $n=1$. If $t_g$ approaches zero, $D/D_r$ approaches 1, that is $D/D_r=1+d$, where $d$ is a very small number, and

$$D-D_r=d\cdot D_r. \tag{3}$$

In Eq. (1) the constant $k$ can be eliminated if one puts $D=D_r$ for $t=R$, where $R$ is the time for just complete recrystallization. The following formula is then obtained:

$$D/D_r=(t/R)^n$$

or, substituting $t_g=t-R$,

$$D/D_r=(1+t_g/R)^n. \tag{4}$$

From (4), with the above relations,

$$1+d=(1+t_g/R)^n,$$

and from this, for a small value of $t_g$,

$$d=(n/R)t_g. \tag{5}$$

By substituting (5) into (3) one obtains

$$D-D_r=n(D_r/R)t_g. \tag{6}$$

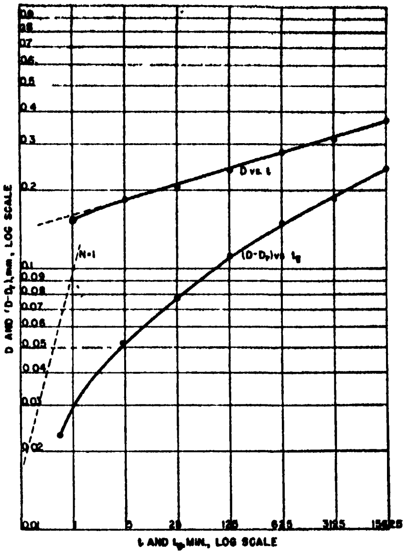

Fig. 1.

Formula (6) shows that for small values of $t_g$ the relationship between $D-D_r$ and $t_g$ is linear. This means that at very short times in the logarithmic plot the curves for all temperatures approach the slope of $n=1$. At long annealing times they approach the $D=k\cdot t^n$ straight lines, where the slope, $n$, increases with the temperature.*

* A fuller discussion of these questions is included in a detailed paper by Beck, Kremer, Demer, and Holzworth to be published in Metals Technology, September, 1947.

## Electron Microscope and Electron-Diffraction Study of Slip in Metal Crystals

R. D. Heidenreich and W. Shockley
*Bell Telephone Laboratories, Inc., Murray Hill, New Jersey*

August 20, 1947

The process of plastic deformation in metal crystals has been the subject of many investigations, both experimental and theoretical, over a long period of years. The new experimental results to be described briefly in this letter have been presented orally before two different groups* but have not appeared in print. A fuller account of the methods and results will appear in a British publication.

The current experiments concerning the structure of slip bands were carried out using 99.99 percent aluminum cast in the form of small single crystals (20×6×2 mm). The as-cast crystals were mechanically polished through 4/0 French emery to produce a flat, 6×20 mm surface and then electropolished to remove the heavily worked layer. The samples were then annealed 3–4 hours above 600°C, electropolished again, and then etched and rinsed[1] to produce a clean, dry surface exhibiting etch pits indicating the orientation of the crystal. Electron-diffraction reflection patterns from the crystals prepared in this manner were Kikuchi line patterns: taken as a criterion for a reasonably perfect crystal.

The electron micrographs were obtained from anodic-oxide replicas of the crystals produced by anodizing in a 2.5 percent boric acid solution neutralized with ammonium hydroxide. These replicas are capable of a resolution of real structure down to at least 50A.

Plastic deformation was accomplished either by pulling the crystals in tension or by compression along the long axis of the crystal after the final surface was prepared. Examination of the surfaces with a light microscope at 50–100× indicated the orientation of the slip lines and their relative density and distribution for various amounts of plastic deformation.

The following conclusions were arrived at from combined electron microscope and electron-diffraction results on numerous aluminum crystals with various amounts of deformation.

(*A*) *Electron Microscope*—The electron micrographs clearly show that the slip bands observed in a light microscope are actually laminar regions (see Fig. 1). Observations of slip bands at various orientations to the prepared surface and their traces through etch pits indicate that the laminae are about 200A thick and of rather indefinite extent. From micrographs taken of crystals with various amounts of plastic deformation, the development of slip bands is proposed to be as shown in Fig. 2. The initial slip occurs in a single (111) plane (in the slip direction) until a displacement of about 2000A is experienced. This particular plane apparently then offers sufficient resistance to further motion that slip begins anew on another (111) plane about 200A removed from the original. The process repeats and results in a laminar slip region. In the case of two adjacent slip regions, the laminae finally merge at high deformations to produce a large field of laminae as shown in the final stage in Fig. 2.

(*B*) *Electron Diffraction*—As mentioned, electron-diffraction patterns from the newly prepared crystal are Kikuchi line patterns.

Patterns taken with the electron beam parallel to and normal to the slip traces observed on the prepared surface, at various deformations, indicated that the material between visible slip bands is relatively unaffected at small deformations. That is, the Kikuchi lines persist until the spacing of the slip bands is reduced to about 5$\mu$ or somewhat less (about 5 percent elongation). At about 5 percent elongation the Kikuchi lines disappear, leaving only a spot pattern, and at still higher deformations the spots begin to split up, indicating rotation of various parts of the crystal. Slip on a second set of planes is usually observed at elongations in excess of about 5 percent.

Patterns taken normal to the slip traces generally do not exhibit Kikuchi lines but show, instead, multiple Laue spots. As the deformation increases more spots appear, and their total angular spread increases to as much as 8–10° at 10 percent elongation.

The electron microscope and electron-diffraction results are consistent in the conclusion that practically all the distortion occurs in the slip bands and very little in the remainder of the crystal.** The laminae in a slip region experience not only a translation in the slip direction, but also slight rotation relative to one another as indicated by the electron-diffraction patterns taken normal to the traces. This rotation is probably a result of constraints imposed during deformation. It is suggested that the rotation of

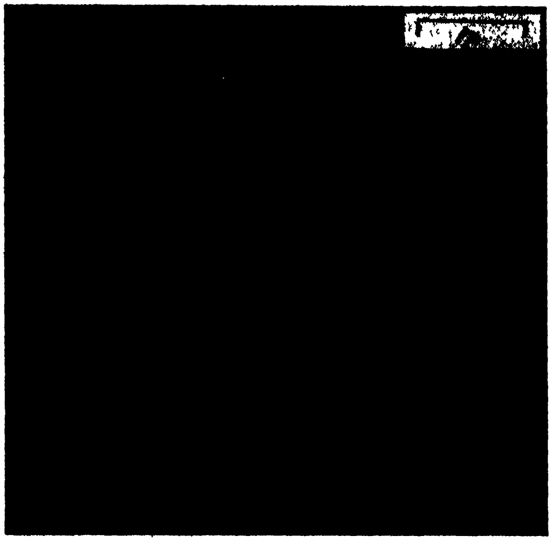

**Fig. 1. Intersecting slip bands at surface of electropolished and etched aluminum crystal showing laminar nature of slip region.**

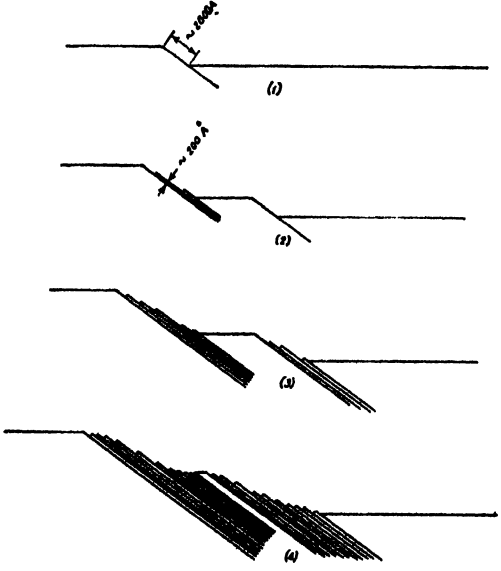

**Fig. 2. Progressive formation of laminar slip region with increasing deformation. Adjacent slip regions merge to produce large field of laminae at high deformation.**

the laminae is responsible for asterism in x-ray Laue photographs of deformed metals.

The laminar nature of the slip bands in aluminum suggests similar studies of other metals. First results show that nickel exhibits similar phenomena. In a private discussion, Mr. R. Maddin of Yale University has indicated that the results he has obtained with brass crystals are quite similar to those with aluminum.

# New Books

## Helium

By W. H. Keesom. Pp. 494, Figs. 258, 25×17 cm. Elsevier Publishing Company, Inc., New York, 1942. Price $10.00.

Professor Keesom has used the war years in Holland to good advantage for the world of science by writing an excellent book about the helium atom in its gaseous, liquid, and solid states. There is, in addition, a review of work on the helium nucleus and on subjects related to the outer electrons. By compiling the experimental work on liquid helium and by inserting his keen criticism of the work, Professor Keesom has rendered in this section alone a valuable contribution to research workers in the field of low temperatures. From experience this reviewer has found that *Helium* is an active and authoritative text used by low temperature research laboratories.

The manuscript had been completed by Keesom in 1941, and for this reason the very important researches on liquid helium by P. Kapitza and by L. Landau got into the text through the supplementary notes at the end of the book. Since the publication of *Helium* in 1942, there have been published experimental and theoretical papers (again mostly by the Russians: Kapitza, Peshkov, Andronikashvilli, Lifshitz, and Landau) which would amply warrant another monograph on the subject of liquid helium by some recognized authority. Keesom has done a good job of summarizing F. London's theory about He *II* being a condensation in momentum space and the theoretical research by the Dutch workers Bijl, DeBeer, and Michels very properly receives attention. The experiments on flow of liquid helium in phase *II* are sometimes confusing, and the reader would do well to mentally sort out these as problems to be tackled by a theory after the first-order physical properties are understood. The x-ray evidence for spatial order in He *II* by Keesom and Taconis, and the subsequent theory involving holes in the lattice, is not too convincing.

Professor Keesom's book serves as an excellent source of information concerning the temperature scale, and sharply brings to attention the confusion which exists about the vapor pressure *vs.* temperature for liquid helium below 2°K. It would seem that the Leiden and Oxford laboratories have their respective viewpoints about the temperature scale below 2°K clearly stated in Keesom's book and that the eighth International Conference of Weights and Measures would render a service to the now numerous low temperature laboratories by asking its own Advisory Committee for Thermometry to use Keesom's book as a report and to recommend one temperature scale to be used by all laboratories until such time as another scale shall be warrented. The problem of an international temperature scale below −190°C will undoubtedly be taken up by the Advisory Committee for Thermometry, and in this respect Keesom's book gives prominence to the Leiden helium thermometer and the virial coefficients or gas-law correction terms used at Leiden. The Berlin helium thermometer and gas-law correction terms used by Henning have been presented by Keesom without criticism; the Berlin scale is not in precise accord with the Leiden scale.

Keesom's book is two things: (a) it is a complete source book for information about helium in its gaseous, liquid, and solid state, and (b) it is a monument to the lifetime research of Kamerlingh Onnes, of W. H. Keesom, and of their many collaborators. There are many excellent diagrams of apparatus, but space did not permit the book to reveal the intricate low temperature techniques which have made Leiden the great laboratory in this field of science.

## Introduction to Aerodynamics of a Compressible Fluid

By Hans Wolfgang Liepmann and Allen E. Puckett. Pp. 262, 6×9½ in. John Wiley and Sons, Inc., New York, and Chapman and Hall, Limited, London, 1947. Price $4.00.

This book is a compilation in a systematic manner of most non-classified material on this extremely important phase of aerodynamics. It has been presented by two well-known authorities in this field as an introduction to the subject rather than as a standard classroom textbook, no problems and few practical examples being presented.

The book, one of the Galcit Aeronautical Series, is divided into two phases. Part I furnishes the reader a background of fundamentals, including basic thermodynamics, one-dimensional equations of motion, isentropic channel flow and applications, shock waves, and optical methods of flow observation. The chapter on optical methods is extremely descriptive, being quite brief in its mathematical discussions, although the essential introductory material is presented. The lack of illustrated examples, illustrations of flow phenomena, and comparison with experimental data, primarily caused by wartime restrictions, is a great handicap in the clarification of this section.

Part II is an introduction to the more mathematical literature on the subject and deals with two- and three-dimensional motions of a compressible fluid. This comprises an introduction to practically all present day methods of solution of compressibility problems, covering specifically the method of small perturbations, the method of development of the potential function into a power series in the thickness parameter or in the Mach number, the hodograph methods, the method of characteristics, and certain exact solutions. A very brief discussion of viscosity effects and experimental data is included, the latter being necessarily brief because of the small amount of unclassified material available in this field. Again much is lost in the lack of practical examples, comparison with experiment, and the lack of pictorial illustrations of flow phenomena. This is greatly offset by the clarity of mathematical presentation.

The book is primarily aimed for graduate consumption, requiring a good working knowledge of differential and integral calculus as well as a knowledge of advanced calculus.

A brief table of references is also included.

## Antennae, an Introduction to Their Theory

By J. Aharoni. Pp. 265, 6¼×9¾ in., Figs. 149. Oxford University Press, London, 1947. Price $8.50.

The study of antennae is peculiarly difficult both theoretically and experimentally. While much progress has been made during the past decade, many interesting and important problems remain unsolved. Accordingly, all who are engaged in research in this field, and especially those who teach courses in it in graduate schools, will welcome J. Aharoni's systematic and comprehensive introduction to its mathematical theory. Because of the advanced nature of the subject, the book is, in effect, an integrated presentation of a special branch of mathematical physics. It is carefully planned, well organized, and its principal contents are delineated in sufficient detail to permit analytical sequences to be followed readily by a reader adequately prepared in the methods of classical theoretical physics and in electromagnetic theory.

The book begins with an illuminating introduction which summarizes and describes briefly the three general methods which have been used by various investigators in the theoretical analysis of antennae. Appropriately, the author uses these methods as the subjects of his three chapters: I. "Antennae and Boundary-Value Problems" (86 pages); II. "Antennae and Integral Equations" (149 pages); III. "Antennae as Wave Guides" (29 pages). The presentation of antenna theory in this manner is an important feature of the book since it emphasizes a unity of subject and of purpose in a diversity of method.

In Chapter I the introduction is followed by an excellent, concise review of electromagnetic theory. The main part of the chapter discusses with exceptional clarity typical boundary-value problems involving planes, spheres, cylinders, and cones. A study of free and forced oscillations of spheres and spheroids following the work of Stratton and Chu and of Ryder concludes the chapter.

Chapter II opens with a derivation of ordinary electric-circuit theory from general electromagnetic principles beginning with the power equation expressed in terms of the scalar and vector potentials and the densities of charge and current. This is an important and well-written section. It serves to correlate in a fundamental manner the circuit aspects of antenna theory with conventional electric-circuit analysis. This correlation is effectively pursued and developed in subsequent analyses of the magnetic dipole (or small loop) and the electric dipole. From these, the argument continues logically to thin-wire antennae for which the integral equation is derived in quite general form. The study of the center-driven antenna and of the receiving antenna follows closely the original work of Hallén and its extension by King and Blake and King and Harrison. The chapter continues with the derivation of the electromagnetic field following the conventional procedure of assuming a sinusoidal current distribution; it concludes with a section on the effect of the earth on the field, and a section on direction finding.

Chapter III is devoted to a concise but clear presentation of the theory of the bi-conical antenna of small angle and to the relationship between antenna theory and transmission-line theory as developed by Schelkunoff.

Taken as a whole, *Antennae, an Introduction to their Theory* is an authoritative and valuable book which skillfully delineates and summarizes major phases of antenna theory as published up through the year 1945. It should prove to be an excellent text and reference book for advanced students and research workers in the field of antennae and applied electromagnetism.

## Technological and Physical Investigations on Natural and Synthetic Rubbers

By A. J. Wildschut. Pp. 173+xi, Figs. 72, Tables 17, 14.5×20.5 cm. Elsevier Publishing Company, Inc., New York, 1946. Price $3.00.

This monograph is one of a series describing research in Holland in the five years of German occupation (1939 to 1944), during which period regular journal publication was interrupted. Although not intended as exhaustive, the investigations described provide a surprisingly comprehensive coverage of the field. The material is presented in the orderly manner associated with a compilatory book without neglecting those descriptions of experimental details expected in an original contribution. The monograph will be carefully studied by all scientific workers concerned with the properties of elastomers. They will find experimental results and concepts which are new, as well as those which are confirmatory of, or occasionally at variance with, material previously published elsewhere. As an example of the former, measurements of the tensile strength of unelongated and elongated rubbers at the temperature of liquid hydrogen are reported for the first time, to the reviewer's knowledge. The latter is illustrated by the results and conclusions of J. M. Goppel on the degree of crystallization as a function of elongation, measured by means of x-rays, which differ from those obtained in America by J. E. Field. It is regrettable that outside contemporary literature, particularly American and British, was for the most part unavailable during the period of preparation, precluding its integration with the work presented. However, the desirability of prompt publication, in the reviewer's judgment, outweighed any possible gain to be derived from the inspection of all published material.

Part I of the monograph is concerned primarily with technological investigations. In Chapter 1, a survey of the various rubbers and rubber-like materials investigated, their classification and formulation, is followed by data, with discussion, of a comprehensive list of mechanical properties. Then aging, electrical and standard physical properties, and resistance to chemicals are presented. Chapter 2 includes measurements on the plasticity of unvulcanized rubbers, a discussion of aging tests and the mechanism of aging, and mathematical interpretations of the stress-strain curve. Studies of the vulcanization process are given in Chapter 3, with emphasis on the use of synthetic resins as vulcanizing agents.

Part II is devoted to more fundamental physical studies. It is prefaced, in Chapter 4, by a discussion of physical methods in structural research. Plastic and elastic properties, with which Chapter 5 is concerned, are suggested as the most important. The thermodynamics of vulcanized rubbers, the plastic flow, the elasticity and permanent set, and the internal friction are each analyzed in considerable detail. Experimental techniques are described. The effects of very low (−253°C) and high temperatures and of swelling on the mechanical properties, particularly tensile tensile strength, are shown in Chapter 6. The x-ray investigations previously mentioned are set forth in Chapter 7. Several investigations on the electrical properties of rubber are treated briefly in Chapter 8. Finally, in Chapter 9, general conclusions of the entire work, emphasizing the uses and limitations of the various rubbers and the advances in knowledge of fundamental properties bearing on the theory of structure, are summarized.

# New Booklets

The Gaertner Scientific Corporation, 1201 Wrightwood Avenue, Chicago 14, Illinois, announces the publication of *Bulletin 151–74, Large Two-Lens Quartz Spectrograph.* 8 pages, free on request.

Leeds and Northrup Company, 4902 Stenton Avenue, Philadelphia 44, Pennsylvania, publishes a quarterly newspaper-style bulletin entitled *Modern Precision.* 8 pages, many photographs.

Burrell Technical Supply Company, 1936 Fifth Avenue, Pittsburgh 19, Pennsylvania, has published a 4-page bulletin describing its "unit-package" tube furnaces for temperatures up to 2650°F.

Dow Corning Corporation, Midland, Michigan, announces an issue of silicone notes entitled *DC 710 Silicone Oils.* 8 pages, free on request.

Sound Products Section of Radio Corporation of America has published a comprehensive new manual on the engineering and installation of sound systems. It is designed for use by architects, building engineers, and the construction industry generally, and covers all types of buildings. 288 pages, bound in simulated black leather, fully illustrated and indexed. Available at $5 from RCA sound systems distributors or direct from the RCA Sound Products Section, Camden, New Jersey.

# Here and There

### New Appointments

David A. Katcher has been appointed editor of a new semipopular magazine on physics to be published early next year by the American Institute of Physics. The new magazine is planned to fill some of the gap which now exists between specialized technical journals and popular science magazines. Katcher comes to the Institute from the Naval Ordnance Laboratory in Washington, D. C.

Isaac L. Auerbach, Albert Auerbach, Gerald Smoliar, and Joseph D. Chapline, Jr. were recently added to the staff of the Electronic Control Company, Philadelphia, Pennsylvania.

Cyril J. Staud has been named Director of Kodak Research Laboratory, and John A. Leermakers is the new Assistant Director and head of the Photographic Theory Department.

Walter Ramberg has been appointed Chief of the Mechanics Division of the National Bureau of Standards, succeeding Hugh L. Dryden, who is leaving the Bureau to become Director of Research for the National Advisory Committee for Aeronautics. The appointment of Grote Reber, radio physicist and engineer, to the staff of the Bureau was also announced recently.

R. C. Mason has been named Manager of the Electro-Physics Department of the Westinghouse Research Laboratories, succeeding Gaylord W. Penney, who was recently appointed Westinghouse Professor of Electrical Engineering at the Carnegie Institute of Technology.

### Princeton Professor Drowned

Assistant Professor Shuichi Kusaka, a member of the Department of Physics at Princeton University and an authority on cosmic-ray theoretical research, was drowned on August 31 while swimming at Beach Haven, New Jersey.

### RCA Fellowship Award

An RCA Fellowship was established in January 1947 for the purpose of encouraging RCA engineers to obtain advanced degrees and to help in the recruiting of young engineers for research and development. First RCA Victor employee to be awarded the fellowship was Harry J. Woll, engineer at the company's Camden plant. He will study for the Ph.D. degree at the University of Pennsylvania, and during this period will be on leave of absence from the company.

### Acta Crystallographica

A new journal of crystallography, Acta Crystallographica, sponsored by the recently formed International Union of Crystallography, will start publication in January 1948. (See Journal of Applied Physics, April 1947.) It will be published by the Cambridge University Press under the editorship of Professor P. P. Ewald, a former editor of the Zeitschrift für Kristallographie, and a panel of regional co-editors. The annual subscription will be $10 for six issues and, by courtesy of the American Institute of Physics, arrangements have been made for subscribers in the U.S.A., its possessions, and Canada to subscribe through that body. Subscribers in other countries should subscribe directly through the Cambridge University Press, Bentley House, Euston Road, London, N.W. 1, England. Articles for publication will be accepted in English, French, German, or Russian, and authors in the U.S.A. are invited to submit manuscripts to Professor I. Fankuchen, Brooklyn Polytechnic Institute, 85 Livington Street, Brooklyn 2, New York.

### Westinghouse Scientist Honored

Arpad L. Nadai, Consulting Engineer of the Westinghouse Research Laboratories, has been awarded the Worcester Reed Warner Medal by the American Society of Mechanical Engineers, honoring noteworthy contributions to the permanent literature of engineering. Earlier this year Dr. Nadai delivered the James Clayton Lecture before the British Institution of Mechanical Engineers in London and Manchester.

### British American Research, Limited

National Research Corporation, Cambridge, Massachusetts, announces the formation of British American Research, Limited, which has recently been incorporated in Scotland as a joint venture with Daniel Varney, Limited. The latter company was engaged during the war in the manufacture of scientific research instruments and laboratory apparatus. The new company will undertake the manufacture and sale of high vacuum equipment.

# A Preliminary Study of a Physical Basis of Bird Navigation

HENRY L. YEAGLEY
*Department of Physics, The Pennsylvania State College, State College, Pennsylvania*

(Received June 26, 1947)

## Foreword

F. C. WHITMORE
*Dean of the School of Chemistry and Physics, The Pennsylvania State College*

The theory presented was formulated in 1942 at the Pennsylvania State College by Dr. H. L. Yeagley, Associate Professor of Physics. Its only public presentation is in a preliminary non-technical article in the October 1943 issue of The Penn State Engineer, a local student publication. The training of birds for the first experiments was begun in May 1943. The first actual field test was made November 7, 1943 with homing pigeons trained to navigate to Paoli, Pennsylvania. This experiment was witnessed by officers of the U. S. Army Signal Corps, including Major Otto Meyer, in charge of the Army Pigeon Service Agency of the U. S. Army Signal Corps. Because of the positive nature of the results and their importance to communication in the war, all subsequent work was reported only to the Army Service Forces:

Report on Bird Navigation, "Theory and confirming evidence" Decemder 12, 1944.
Report on Bird Navigation, "Hamlet experiment," April 24, 1945.
Report on Bird Navigation, "A continuation of experiments started at the Pennsylvania State College in December, 1942," January 4, 1946.
Report on Bird Navigation, "East-West experiment," June 30, 1946.

The bird navigation theory as presented implies an organ or organs in the bird's physiology which are sensitive to the effect of its motion through the vertical component of the earth's magnetic field and to the effort exerted to overcome the coriolis force, due to the earth's rotation. Both these influences involve a set of lines which together form a navigational gridwork. By correlating its instantaneous land speed with the two above effects, a bird can fly to its home which is a unique point in this gridwork, or to related companion points existing in the gridwork at positions other than its home. Experimentation with homing pigeons between the home and spurious home points (conjugate or companion points) has yielded data which supports the theory.

PROBABLY no natural phenomenon has intrigued man and held his interest more than the ability of the homing pigeon to fly long distances from a strange locality and across unfamiliar territory to its home loft. Many leading ornithologists believe that this same ability guides wild birds in their long migratory flights over land and water areas. Invariably, references made to this remarkable accomplishment in the bird world are in terms of "instinct," which is a way of saying "we don't know."

The over-all problem of bird navigation involves at least the following five factors:

1. A desire on the part of the homing pigeon

to go to the home loft or, in the case of wild birds, to go to their summer feeding and breeding grounds, or their warmer wintering areas during migratory periods.

2. The physical strength and endurance to fly the required distance.

3. A knowledge of familiar landmarks, within a minimum radius, for piloting to the exact spot. (This radius distance for homing pigeons is known to be about twenty-five miles.)

4. The ability to navigate. This implies the possession and use of an organ or organs as navigating instruments.

5. Considerable navigating experience in flying in and about the "home" region. With homing pigeons this experience is artificially built up by sending the birds to gradually increasing distances.

It is well known that many birds of the migratory species return to their breeding and nesting grounds after being trapped and sent hundreds of miles into strange territory. Many such flights have been arranged so that the birds must orient themselves and fly hundreds of miles over water routes out of sight of land. One species, the Golden Plover,[1] performs the remarkable feat of navigating 3000 miles from Alaska to the Hawaiian Islands with no landmarks over the broad expanses of the Pacific Ocean. Hundreds of individuals of the albatross family roam over thousands of square miles of the Southern Pacific area. Members of each species finally return to their own tiny island to breed and raise young. Hood Island[2] of the Galapagos Archipelago group, is headquarters for one species of these birds. Since there are no "sign posts" of any kind over the ocean wastes, the flights must involve true navigation until the home island comes into view. Other types of birds, including noddy and sooty terns, swallows, herring gulls, numerous varieties of ducks, hawks, storks, starlings, chimney swifts, have the homing or navigating ability developed to a high degree.

Thus, while man has been slowly and laboriously learning to navigate during the past six centuries, birds have been using a system of their own for perhaps millions of years.

Hundreds of papers have been written suggesting possible fragmentary explanations of the mystery of bird orientation. The more scientifically possible of these explanations involve sensitivity of the bird to one or more of the following:

1. The effect of motion through the earth's magnetic field.[3]

2. Gravitational differences due to variations in the earth's radius.

3. The Coriolis effect due to the earth's rotation.[4]

In order to set up a working system of bird navigation or, indeed, of any navigation, a combination of two or more overlapping fields of influence is necessary. Each of these must possess definite gradients. Possible grid patterns might represent repetitive, displaced fields of a single kind, or combinations of two or more of the following:

1. Light beams—limited, by horizon extinction, to comparatively small areas, and useful only in piloting.

2. Sound beams—too limited for long distances, conceivably available only for piloting.

3. Electric fields—extremely limited by small intensity factor, variable magnitudes, lack of permanence.

4. Electromagnetic radiations—network of radio or radar beams such as are used in the radio-range network system of navigation or, more properly, piloting.

5. Magnetic fields—the earth's natural magnetic field, a somewhat irregular function of distance from the magnetic poles.

6. Force fields, such as:

   a. Coriolis force,
   b. Gravitational force,
   c. Centrifugal force.

[4] Dr. W. H. Thorpe and D. H. Wilkinson, "Ising's theory of bird orientation," Nature, December 21 (1946). Also, G. Ising, "The physical possibility of a biological sense of orientation based on the rotation of the earth," Ark. Math. Astrophys. 32A, No. 4 (1946).

Appended is a bibliography of the fragmentary suggestions that have previously been made in explanation of bird navigation. Special attention is called to Dr. D. R. Griffin's paper,* "The sensory basis of bird navigation," and to W. M. Levi's book, *The Pigeon*,† for an excellent general coverage of the subject.

In setting up the present theory of bird navigation the following well-known facts pertaining to the flying and use of homing pigeons were considered:

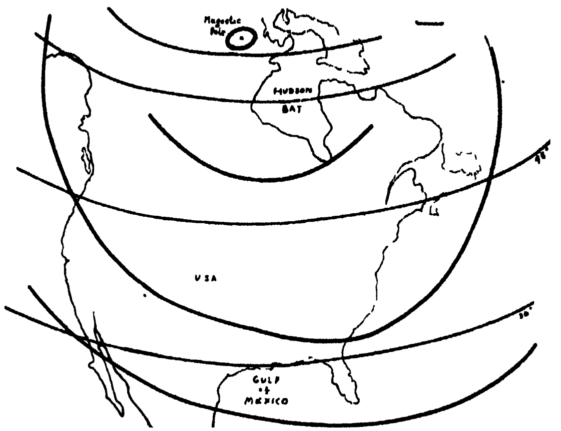
1. When released at unfamiliar and distant points, they usually fly in large circles for a matter of minutes before moving off in a straight line. When training flights have been experienced once or twice daily for weeks, and pigeons are released individually from new locations around the compass, they often sense the correct direction, after having flown only one or a fraction of a complete circle.

2. Homing pigeons are unable to navigate in a thick haze or fog or in complete darkness. Blinded or hooded birds fly first in a large circle and then in a decreasing spiral, gradually decending until about six feet above ground level, after which a "crash" landing is made.

3. Pigeons are unable to navigate successfully in winds much over thirty-five miles per hour.

4. After reaching four or five weeks of age, homing pigeons can be trained "around the compass" for six or eight weeks at increasing distances of one, two, four, eight, sixteen, thirty-two miles (repeating each distance one or two times before increasing), after which they are easily capable of navigating flights of distances up to seventy miles and more. With a few more weeks of training, flights of one to two hundred miles, or even more, are readily accomplished. A year later, with some additional short training flights added to their experience, they can readily navigate home from four hundred miles, without previous experience of any kind in the new territory.

5. Written reports by the Army and Navy Communications[5] as well as numerous oral reports by representatives of flying-clubs and individuals, indicate that pigeons are confused and are unable to orient themselves when released from points near powerful radio and radar broadcasting stations. There are some indications that the audiofrequencies rather than the carrier-frequencies are the disturbing factor.



MAP I. North American section of earth-globe showing lines of equal magnetic vertical-Coriolis gridwork. South magnetic pole displacement from north terrestrial pole is roughly about 20° or 1400 miles.

The following theory is presented as the first complete working hypothesis to explain homing-pigeon navigation.

Three major factors are involved:

1. Sensitivity of birds to the effect of flying through a magnetic field.

2. Sensitivity to the forces, produced by the earth's rotation, acting on masses moving over its surface in a straight line (part of the well-known Coriolis effect which is a function of latitude).

3. Visual sensitivity to velocity over the earth's surface (land speed).

By correlating the results of the first and last of these sensitivities the bird can detect his "magnetic latitude." This differs from his true latitude because the magnetic poles are grossly and asymmetrically displaced from the earth's poles (Map 1). By similar correlation of the second and last sensitivities it is possible to detect the true latitude.

The effective result of these two correlations is that the bird can recognize his home locality at the intersection of a characteristic line in the

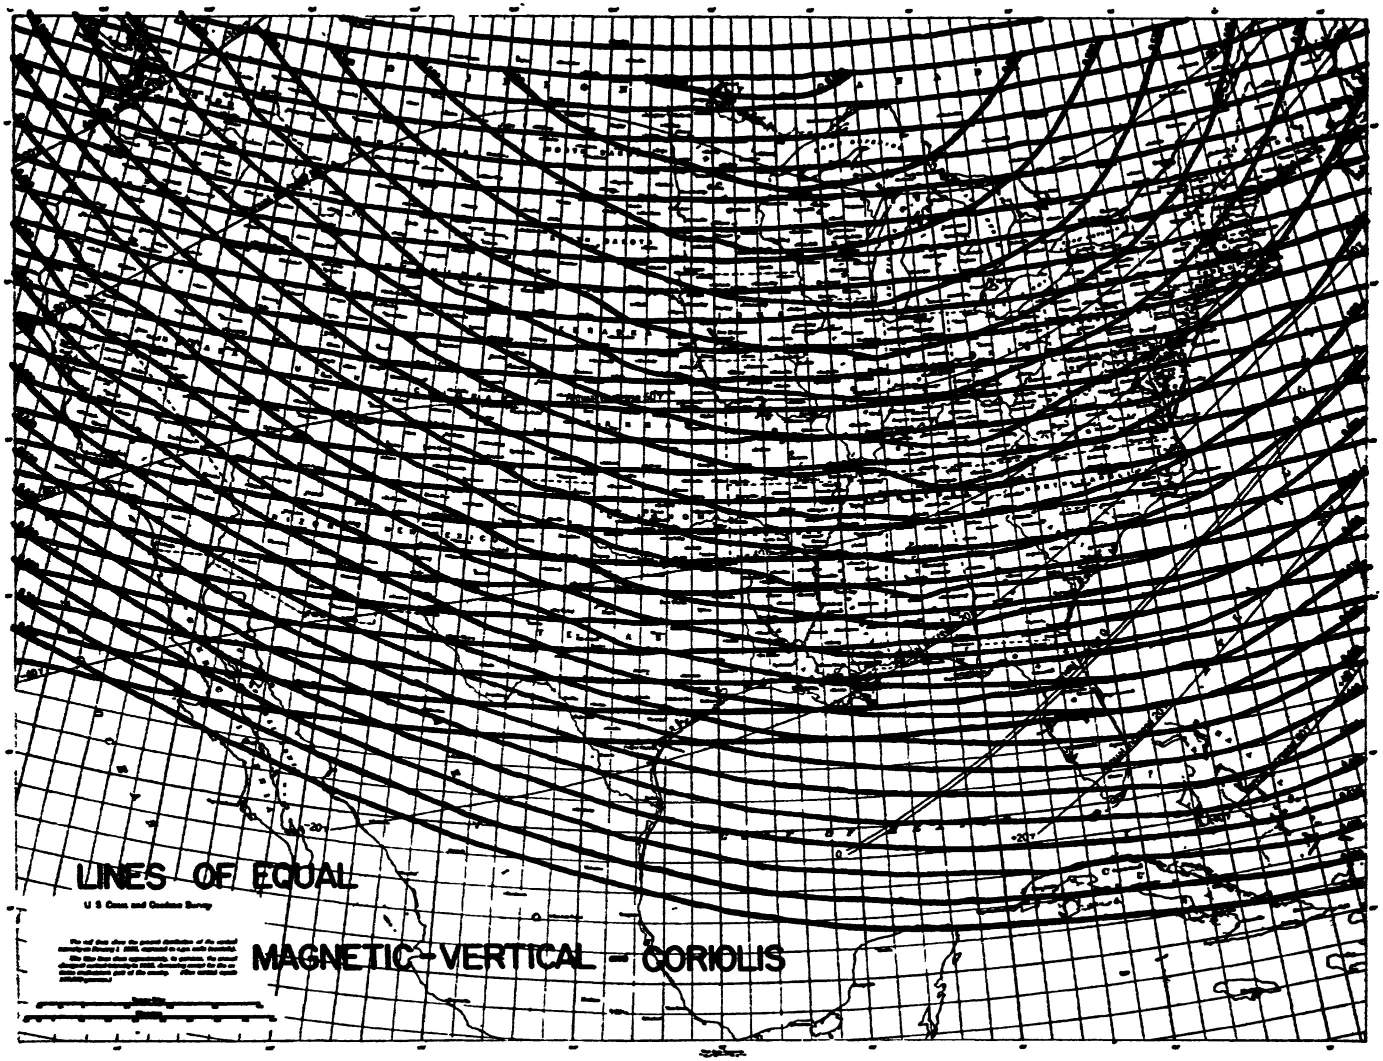
† W. M. Levi, *The Pigeon* (R. L. Bryan Company, Columbia, South Carolina, 1944).

[5] *Experiments With Homing Pigeons' Sensitivity to Radio Frequency Waves*, conducted by 285th Signal Pigeon Company, March 1945.



Map II. Lines of equal magnetic vertical-Coriolis gridwork for the United States and bordering areas.

earth's magnetic vertical field with a characteristic line of latitude.

Thus it appears that the secret of bird navigation depends on the displacement of the magnetic poles from the rotational poles of the earth with the subsequent intersection of the lines of equal magnetic-vertical intensity with latitude lines (Maps I and II).

The fact is that it was a study of Map II in relation to the failure of homing pigeons near Indianapolis, Indiana,[6] which gave the first clue to the present theory. As will be noted, in that area the two sets of curves are essentially parallel. Thus in that section, the two sets of correlations guide the birds to a line many miles long instead of to an approximate point. It should be added that the study of maps involving lines of equal magnetic declination, equal magnetic dip, equal magnetic horizontal intensity, equal total magnetic intensity, or any combination of these failed to show such parallelism in southern Indiana.

In operation, the navigation may be as follows:

1. A bird is sensitive by virtue of some organ or organs to the magnitude of the effect of its motion in flight through the vertical component of the earth's magnetic field.[7] This effect which must be correlated with its land speed, is a direct function of the bird's horizontal velocity, and the distance from the magnetic poles. It is a maximum at the poles and decreases somewhat irregularly from each pole toward a line approximately half-way between. By this means, a bird, if flying in a location of magnetic vertical field intensity different from its home, can consciously fly in a direction which will bring its land-speed magnetic vertical-field effect[8] back to that to which it is accustomed during its normal flight around home territory. Since the lines of equal vertical magnetic-field intensity are irregular closed curves centering around the magnetic poles, it is evident that they represent one set of lines involving a velocity-magnetic vertical-field-gradient pattern which is part of our proposed navigational grid system.

2. A bird is sensitive by virtue of some organ or organs to the magnitude of the Coriolis effect. This latter results from a natural relationship between the earth's rotational velocity and motion of a body over the earth. The forces involved are a direct function of the earth's rotational speed, the speed of a body moving over the earth's surface, and the latitude of the moving body. As in the case of the electromagnetic effect, the bird must correlate its land speed with the magnitude of this force in order to use it as a guide. The lines of equal Coriolis force are true circles coincident with parallels of latitude. Hence, if a bird, usually subject to the Coriolis effect of normal flying around home territory, is displaced north or south, he need only fly in a direction which will bring the "feel" of the Coriolis land-speed relation back to normal and he will be back on his own latitude circle. These circles represent a second set of lines which in bird orientation involves a force land-speed-gradient pattern which is a part of our postulated navigational grid system.

Map I illustrates the existence on the earth of a gridwork of two distinct sets of curves, representing the land speed *vs.* electromagnetic effect and the land speed *vs.* Coriolis effect. For any horizontally moving body over the earth's surface these intersecting curves give rise to a system of unique pairs of conjugate points.

This conception offered an opportunity for the experimental testing of the theory. If a bird locates its home by navigating to the intersection of the proper magnetic vertical and the proper latitude, he should as readily navigate to the conjugate point as to his home, if released nearer the former. As can be seen on Map II the conjugate point of State College, Pennsylvania is in central Nebraska. A location near Kearney, Nebraska, has been used for checking the theory, as will be described below.

## EFFECT OF MOTION THROUGH THE MAGNETIC FIELD

It is a well-known fact that whenever a continuous ring or circle of some material medium is rotated in a magnetic field, so that the lines of flux are cut, an e.m.f. is induced. This is said to result from a change of flux linkage and its magnitude is given by:

---

[6] F. J. Sauerteig, "Indianapolis," Am. Racing Pigeon News, Nov. 1942, p. 1.

[7] See reports to the U. S. Army Signal Corps listed in the Foreword.

[8] This effect may be the same phenomenon as the so-called "electromagnetic effect," it will subsequently be referred to as such for the sake of brevity.

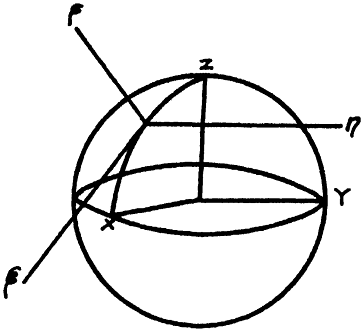


FIG. 1.

e.m.f. $= d\psi/10^8 dt$ (e.m.f. = induced voltage);

$d\psi/dt$ = rate cutting of flux in number of lines cut per second;

$10^8$ = factor needed to give result in volts or joules per coulomb.

Although it is quite customary in physics texts to give problems in which it is required to find the voltage induced when a straight wire of given length cuts a magnetic field of given strength and orientation at a given velocity, no known experiment has ever shown conclusively that an e.m.f. is induced under these latter conditions. Nevertheless, in dealing with bird navigational flight in this theory the assumption is made that the bird in some way senses the effect of flying normally through the vertical component of the earth's magnetic field, and the laws obeyed are the same or analogous to the electromagnetic effect. Whether or not it is the latter, as is ordinarily meant in the physical sense, or a phenomenon for which man has not yet conceived a picture, does not alter its general application to the theory involved. For if a bird navigates according to a pattern which fits exactly into the vertical, magnetic-field Coriolis gridwork, illustrated in Map II, some mechanism relating it to bird navigation exists, even though man does not yet comprehend its full import. A flying bird or any object moving at right angles to a magnetic field or its component would constitute a system comparable to a moving straight wire mentioned above rather than a rotating ring.

Should the sensitivity of the bird involve the ordinary laws of electromagnetism, the magnitude of the induced voltage for a bird flying forty miles per hour at State College, Pennsylvania, where the vertical component of magnetic field intensity is .556 oersted,[9] would be:

$$\text{e.m.f.} = \frac{d\psi}{10^8 dt} \quad \frac{H \cdot L\, ds}{10^8\ dt} \quad \frac{.556 \times 1 \times 1798}{10^8}$$

$10^{-5}$ or 10 microvolts per cm of length.

$d\psi$ = lines of flux cut, $H$ = field intensity, $L$ = length of conductor, 40 mi./hr. = 59 ft./sec. or 1798 cm/sec. This voltage might make itself felt either across the nerves in the wings and other gross parts of the bird or across the eye, the ear, or any organ or parts of organs.

Not only sensitivity to the absolute value but also reaction to its variation is necessary to guide the bird in the compensatory direction. For this reason the increments of magnetic vertical-field intensity should be examined.

Average values of the vertical component of magnetic-field intensity are 0.60 oersted at a distance of 15° from the south magnetic pole in the Hudson Bay region, and 0.68 oersted at a distance of approximately 5 to 8 degrees from the South Magnetic Pole in the general region south of New Zealand. These values diminish to zero at points along great circles, approximately midway between. In equatorial regions the variation of the vertical intensity in a general north-south direction is about .01 oersted per degree. In the United States the corresponding variation is roughly .007 oersted per degree. Since all experimental work involved in this report has been done in this country the latter value will be considered for illustrative purposes.

$$\frac{d(\text{e.m.f.})}{d\varphi} = \frac{L}{10^8}\,\frac{ds}{dt}\,\frac{dH}{d\varphi} = \frac{1.798 \times 10 \times 7 \times 10^{-3}}{10^8}$$

$$= \frac{1 \times 1798 \times .007}{10^8} = \frac{1 \times 1.798 \times 7}{10^8} = 12.6 \times 10^{-8}$$

= .13 microvolt change for approximately each degree or seventy miles of flight (a change of 1.3 percent per degree).

$d\varphi$ = increment of "magnetic latitude"

---

[9] World values of $H$ may be obtained from map No. 1702, "The vertical intensity of the earth's magnetic force," published by the Hydrographic Office, Washington, D. C. Values for the United States of America from Booklet and Serial number 602, as previously indicated.

## EFFECT OF MOTION THROUGH THE CORIOLIS FIELD

The following equations represent the Coriolis acceleration or force per unit mass and were obtained from A. G. Webster's *Dynamics* (G. E. Stechert and Company, New York), p. 320–322.

$$d^2\xi/dt^2=2\Omega\sin\varphi(d\eta/dt),\quad \text{(see Fig. 1)} \tag{1}$$

$$d^2\eta/dt^2=-2\Omega\{(d\xi/dt)\sin\varphi+(d\zeta/dt)\cos\varphi\}, \tag{2}$$

$$d^2\zeta/dt^2=-g+2\Omega\cos\varphi(d\eta/dt). \tag{3}$$

$\varphi$ = latitude of place, $\Omega$ = angular rotational speed of the earth, $-g$ = acceleration of gravity, $\pm\eta$ = distance moved east or west on the earth surface, $\pm\zeta$ = distance moved north or south on the earth surface, $\pm\xi$ = distance moved toward zenith or nadir, $t$ = time.

According to these equations, it is apparent that a bird might conceivably make use of Coriolis forces due to its motion in any direction (i.e., horizontal, vertical, or their resultant directions) as part of its system of navigation. Only horizontal motions are considered as part of this theory but if vertical motions were also included, no basic changes would be involved in the discussion, since in any case the magnitude of the resulting Coriolis forces will still be a function only of $\Omega$, $\sin\varphi$ and $ds/dt$. Since the bird's continuous and normal motion in homing is horizontal, only the latter will be considered. Hence the following modified equation is obtained by combining (1) and (2):

$$\begin{aligned} a&=[(d^2\xi/dt^2)^2+(d^2\eta/dt^2)^2]^{\frac{1}{2}}\\ &=2\Omega\sin\varphi[(d\eta/dt)^2+(d\xi/dt)^2]^{\frac{1}{2}}. \qquad (4)\\ &=2\Omega\sin\varphi(ds/dt) \end{aligned}$$

In (2) the term $(d\zeta/dt)\cos\varphi$ is zero since motion in the $\zeta$ (vertical) direction is considered zero. Equation (3) denotes that there will be a vertical force of Coriolis resulting whenever there is a component of horizontal velocity eastward or westward. When the motion is in the $+\eta$ (eastward) direction it is downward, and *vice versa*. The value of $d^2\zeta/dt^2$ (insofar as the bird is concerned) varies above or below $-g$ when it flies in any horizontal direction having a component of velocity either east or west. This vertical force could also be part of the bird's orienting mechanism and might operate to help maintain migrating birds on a true north or south course. In the bird's home territory where it recognizes local landmarks and awareness of direction is a factor, as in piloting operations, this vertical force may again operate in guiding him. As previously stated, even though this vertical force, or the term $(d\zeta/dt)\cos\varphi$ (in Eq. (2)), actually enters the picture, it in no way changes the over-all concept of the Coriolis land-speed relation to bird navigation as set forth in the theory. As homing pigeons are known to fly at rates of twenty to sixty miles per hour, a value of forty miles per hour, or fifty-nine feet per second, will again be used for making an illustrative calculation. A median value of 45° latitude will also be chosen arbitrarily to go with this arbitrary speed value. Substituting in Eq. (4):

$$a=2\times\frac{2\pi}{86{,}400}\times.707\times59$$

$$=\frac{4\times3.14\times7.07\times5.9}{8.64\times10^4}=\frac{524}{8.64\times10^4}=61\times10^{-4}$$

$$=.0061 \text{ feet per second per second.}$$

The direction of this Coriolis acceleration on the northern hemisphere is to the right and on the southern hemisphere to the left of the line of flight. This latter is commonly known to produce the counter-clockwise and clockwise whirlpools of moving fluids on the northern and southern hemispheres of the earth.

As a result of this accleration, the force per unit mass would be $F=\text{ma}=1\times.0061$ or .0061 poundal per pound at 45° latitude, and a speed of forty miles per hour. Or in terms of rate change of Coriolis effect with respect to time:

$$\frac{da}{dt}=2\Omega\frac{ds}{dt}\cos\varphi\frac{d\phi}{dt}\cdot$$

But

$$\frac{d\phi}{dt}=\frac{1}{r}\cdot\frac{ds}{dt},$$

$$\therefore\frac{da}{dt}=\frac{2\Omega\cos\varphi(ds/dt)^2}{r}=\frac{2\times2\pi\times.707\times59\times59}{86400\times3955\times5280}$$

$$=\frac{4\times3.14\times7.07\times5.9\times5.9\times10^1}{8.64\times3.96\times5.28\times10^{10}}$$

$$=1.72\times10^{-8} \text{ ft./sec./sec. each second,}$$

or about

$$10.8\times10^{-5}=.000108\frac{\text{ft./sec./sec.}}{\text{degree}}.$$

This 1.7 percent change of force per unit mass therefore occurs in flying one degree normal to the parallel circles of equal Coriolis effect at 45° latitude. The absolute value of Coriolis acceleration varies from maximum $1.00/.707\times.0060=.0085$ ft./sec./sec. at forty mi./hr. at the poles to zero at the equator.

Judging by these tiny increments of Coriolis force and magnetic effect which the bird would have to correlate with land speed for navigational guidance,[4] the tendency is to reject its validity.

Also it is certain that there is a physical basis for this ability to navigate which pigeons constantly demonstrate. It seems fair to assert that if the directives involved were of a gross magnitude, with modern scientific tools and mathematical means of investigation they would have been uncovered before now.

Examination of Maps I and II reveals that in the equal magnetic-vertical intensity Coriolis-force gridwork each pair of intersecting lines cross each other at least twice. In addition, about midway between the pairs of conjugate intersections, approximate parallelism often exists over a considerable portion of their lengths. These conditions also differ from a perfect pattern because large segregated surface deposits of magnetic materials on the earth prevent the equal magnetic-vertical lines from more than simulating the form of a true circle. On the United States Map II it can be seen that this condition of parallelism obtains over a fairly wide band of land area, including parts of Wisconsin, Illinois, Indiana, Kentucky, Tennessee, etc.

The above-mentioned relationships suggest that birds trained to navigate to one point of intersection of two lines toward the east, should, if released nearer to their conjugate point, fly preferentially toward the latter. Likewise, the region of parallelism or tangency should be one of confusion for navigating birds. If trained within this region their home would not contain a unique point with reference to the theory, or, if trained outside but released within this region, they would be in the dilemma of being apparently able to fly toward their home in either of two directions, approximately 180° apart. This suggests the experiments of training homing pigeons to navigate to one location and releasing them near the conjugate point of the location, or at points in between the two conjugates to see if they react to the home or conjugate positions.

TABLE I.

| Nov. | Day | Two copper plates | Two magnets | Lost one magnet | Lost two magnets |
|---|---|---|---|---|---|
| 7 | 1st | 5 | – | 1 | – |
| 8 | 2nd | 3 | – | – | |
| 9 | 3rd | – | – | – | - |
| 10 | 4th | – | 1 | 2 | 2 |

Another suggested experiment arises from the idea that if birds are guided by the effect of flight through the vertical component of the earth's magnetic field, they should become confused if a sufficiently strong superimposed magnetic field moves upward and downward across their bodies simultaneously. These and the previously mentioned considerations led to the following set of experiments which will be described in chronological order.

## EXPERIMENT I

### The Magnetic Wing Experiment, November 7, 1943

The first experimental test of the theory was made by superimposing on homing pigeons while in navigational flight, a magnetic field moved up and down by their wing motion. This was accomplished by attaching hyflux-chrome magnets on the under side of the wings, between the first and second joints.

The normal magnetic effect would be the one due to the somewhat pulsating forward motion at right angles through the vertical component of the earth's magnetic field. If a number of homing pigeons with the superimposed moving experimental field were unable to home normally and a like number with identical training but with attached copper plates of the same approximate mass and size should home from the same release point in the normal fashion, it would be an indication that the earth's magnetic field plays a part in bird navigational guidance.

The birds used in this experiment were raised and trained for it by Mr. Lowell Gable of Paoli, Pennsylvania. Because he is an educated man with a scientific mind and one of the foremost in the field of homing pigeon racing, it was felt the experiment would be more significant than under other circumstances. Mr. Gable carefully trained twenty of his best young birds to pilot and navigate to his loft from distances up to one-hundred miles. The training flights were always from stations to the west, northwest, and north of Paoli so that the birds would not become familiar with land areas to the south and southwest over which the final experimental flights would be run. They were singly released many times at fifty to one-hundred airline miles or more to insure individual navigating skill and eliminate those that simply followed their loft-mates home. Between 10.05 A.M. and 12:04 P.M. on the morning of November 7, 1943, the twenty trained birds were released at a point eight miles southeast of Bellaire, Maryland. The airline distance to the loft at Paoli was about sixty-five miles. To the wings of each bird in turn was attached either a pair of magnetic or copper plates before it was set free. None was released until the previous one had been out of sight for five minutes. Its general direction of travel at time of disappearance was carefully noted. All even-numbered birds carried hyflux-chrome magnets, whereas the odd-numbered ones had copper plates attached to their wings. Both magnets and copper plates used were 1″×.218″×.025″ and weighed approximately .8 gram. Attachments were made on the under side of the manus portions of the wings. Since any attachment involving the wing feathers or feather follicles would have caused rapid and serious irritations, a plan had been devised by which thin silk strands were threaded through the flesh between the third and fourth metacarpal bones. Previous and later tests showed that no soreness or injury resulted from long attachment or from hundreds of miles of flying with the plates remaining in position.

The record of their returns as supplied by Mr. Lowell Gable is shown in Table I.

The magnets on the wings of the birds were separated about 12″ between centers when in a horizontal, full-spread position. They were of such strength as to produce a horizontal intensity, half-way between them, about equal to that of the earth's magnetic horizontal component in the region of State College. This value is approximately .172 oersted.

TABLE II.

3 with copper plates deviated less than 10° from a direct line toward the home loft, sixty-five airline miles to the northeast.
4 with copper were less than 50° off from this line toward the north.
3 others with copper were less than 30° off from this line toward the east.
4 with magnets were about 45° off from this line.
2 with magnets were more than 90° from this line.
3 with magnets were approximately 130° off from this line.
1 with magnets flew in the exactly opposite direction from the home loft.

By assuming that the magnets move up and down with approximately simple harmonic motion and estimating the wing beats at 180 per second and their amplitude at ⅛ foot, a value of .12 microvolt per centimeter was computed for the maximum induced e.m.f. per centimeter on the bird's anatomy.

This value of .12 microvolt per centimeter, as can be seen, is of the same order of magnitude as the change of e.m.f. involved in flying eighty miles toward or away from the normal magnetic-vertical line previously considered at 45° latitude. Both its magnitude and its pulsating character, i.e., changing three-hundred and sixty times per minute, from zero to .12 microvolt per centimeter and back to zero, might conceivably serve to confuse the bird and upset his navigating prowess during its occurrence.

The following important points should be noted:

1. Eight of ten birds with copper plates returned home during the first two days.

2. Of those returning, having originally had two magnets each and subsequently losing either one or both, only one with one magnet got home before the fourth day.

3. Only one bird with two magnets got home at all and it arrived on the fourth day.

4. None of the other birds, at this writing, has ever returned.

The final results of the experiment were well presaged by the directions in which the birds left the release point. Each was carefully watched out of sight before another was released. Table II

indicates the general direction at which the birds went out of sight from the release point.

Since these birds were well trained and outstanding homing pigeons, Mr. Gable and others expert in the field of flying and racing homing pigeons expected at least two or possibly three of those with two magnets to home, just on the basis of their intelligence and ability to "hunt" their way home. On the basis of probability and chance a similar prediction would obtain.

## EXPERIMENT II

## The First Nebraska Experiment

With the positive though limited data for the electromagnetic phase of the theory secured, the groundwork was laid for testing the theory as a whole. Examination of the U. S. Coast and Geodetic Survey Map I revealed that the conjugate point of State College, Pennsylvania, (corrected for 1944) i.e., another position having

identical values of magnetic vertical intensity and Coriolis force, lies in about the south-central portion of Nebraska (ten miles north of Kearney). A plan was worked out whereby a group of one hundred or more carefully selected homing pigeons would be settled[10] and trained at State College, after which the birds and lofts would be transferred to the above conjugate point. Tests would then be made to determine if they would fly from the surrounding regions toward that point instead of heading for State College, Pennsylvania.

With this plan in view, training flights up to fifty miles around State College were decided upon and the birds were housed in a conspicuously designed and painted loft so it could be seen from as great a distance as possible. In addition, it was moved[11] each day so that the occupants, returning from training flights, would become accustomed to looking for the loft and not for familiar landmarks nearby. A five-foot observation balloon was raised each day about one-hundred and fifty feet above the loft as an additional beacon or guide. All these plans were executed carefully. The loft had a peak resembling a church spire and the whole was painted a brilliant yellow. It was moved two hundred feet each day and during the training period traveled a distance, by tractor power, of about three miles in a zigzag path over and across the college farms. The birds were given initial

---

[10] Having been in full flight around loft, the bird returns and enters it. During his first free flight outdoors even though raised on the spot, it is easily frightened off in a panic, and may fail to take visual account of its surroundings. On a second release it is practically certain to return.

[11] Its location was shifted 200 feet each day for training flights of the birds, and never returned to a previous location.

piloting training flights[12] of one, two, four, eight, and sixteen miles in several directions around the compass. From then on for a period of three months they had practice flights twice daily up to fifty and more miles. There was seldom a half-day during which they were not released at some new point around the compass. Care was used to prevent repetitional flights which might either aid or hinder them in the Nebraska experiment. It is known that repeated training during the same part of the day and over the same terrain causes homing pigeons to fly habitually by the sun's direction. Near the end of the training period they were released from time to time in singles, doubles, and sets of five at twenty-five-mile airline distances.

On the day set for the start of the trip to Nebraska the birds were transported to Altoona by truck in one of the homing lofts. The shipment from there on was by express so the loft had been carefully designed to make it as large as possible and yet have it go inside the express car. During the entire 1100-mile trip the nests with eggs and young were cared for by the parent birds. On arrival in Kearney the loft was set on the fair grounds until magnetic measurements were made to check the values obtained from the U. S. Department of Commerce. Also a second loft had been built and previously shipped, to double the chance of the birds' finding one in case they navigated from the release points to the predicted conjugate point. Askania magnetometer measurements showed that the magnetic vertical-field intensity ten miles north of Kearney was the same as State College. Unfortunately, however, the field intensity gradually increased to about three times its normal value fifteen miles east and returned to its normal value ten miles beyond the anomaly. This condition meant that there were actually two conjugate points twenty-five miles apart, which called for a choice of placing the two lofts about 10 miles apart on either side of the point as planned according to the U. S. averages, or putting one at the normal conjugate point and the other twenty-five miles to the east at the anomalous conjugate point. The limited personnel and transportation facilities made the twenty-five mile separation impractical. In addition, magnetic anomalies exert most of their influence fairly near the ground surface and for all these reasons the former strategy was used. The lofts were carefully placed five miles east and west of the calculated position on as high ground as could be found in that flat country. The birds were allowed to rest one day to acclimate themselves to the immediate surroundings.

Beginning with June 28, groups of birds were taken out to release points around the compass forty and more airline miles away. Each bird carried an army-message capsule with the words.

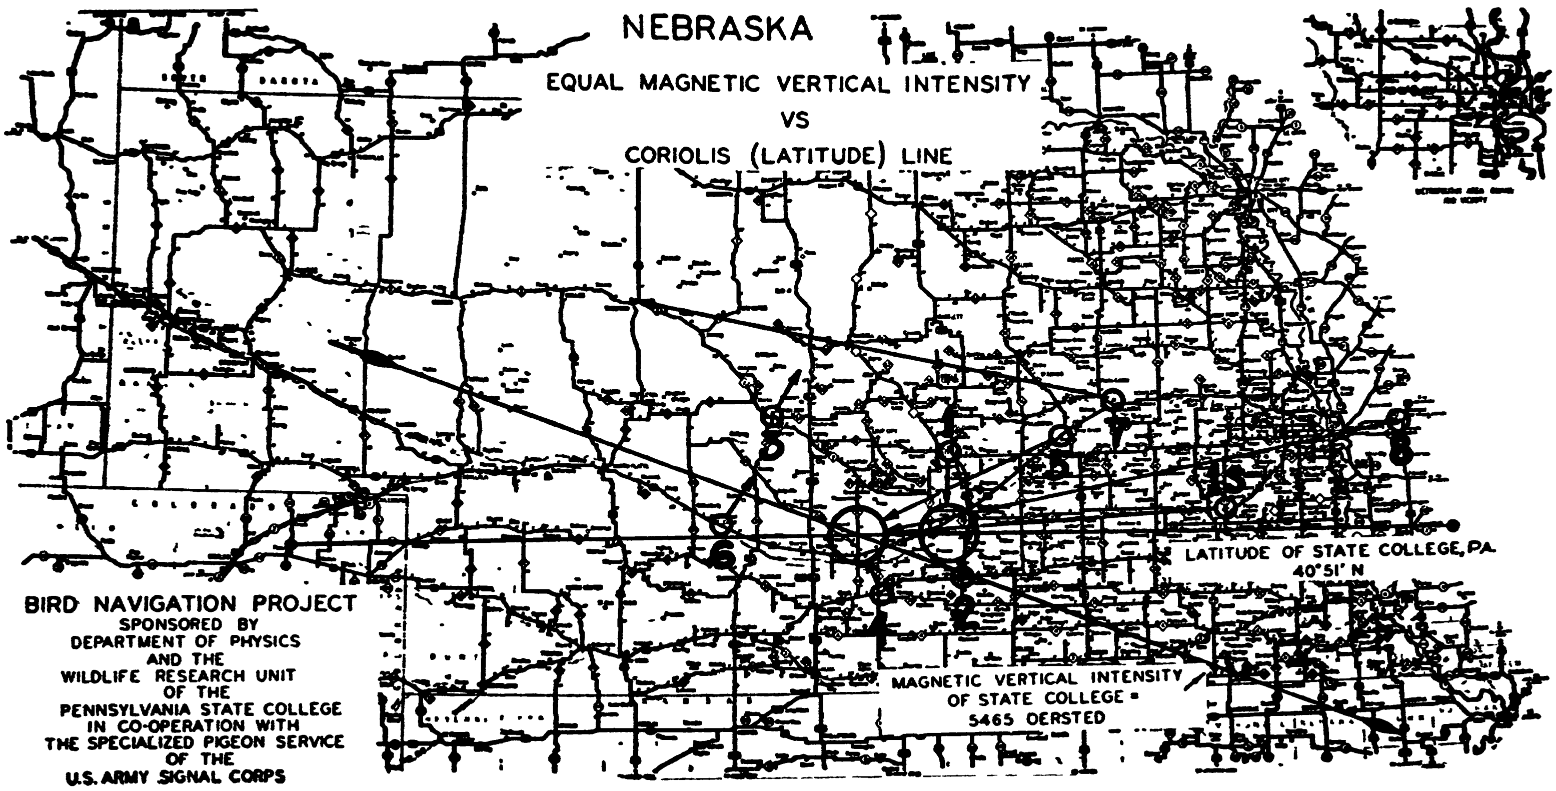
The data obtained from these experiments are set forth in Table III. Releases No. 1 through No. 8 show the direct result of the experiment proper carried out between June 29 and July 8. Releases labeled Specials No. 1 and No. 2 were performed before, and Special No. 3 after the main experiment and will be discussed later in the report. Map III, showing the state of Nebraska, contains a representation of the data shown on Table III except for that designated Special release No. 2 and No. 3. Each vector on the map represents graphically the sum total of the results for a given day or release number, the latter being in one-to-one correspondence on the map and table.

The flights of all birds reported were plotted as vectors on a preliminary work map and their vector sum obtained. The length of the latter was divided by the number of flights involved and the resultant vector represents the average result of all the recorded flights of that day. In referring to these in this report the term "total flight vector" will be used. A brief inspection of the total flight vectors for the eight days shows that numbers one, two, four, five, and eight not only point in the right direction but actually

---

[12] Short distance flights in which guidance could always be had by means of familiar landmarks.



MAP III. Flight vectors showing average flights of the various groups of pigeons released according to data on Table III.

terminate within ten miles of one or the other of the two predicted points (the normal and anomalous ones). In fact, four, five, and eight, and Special No. 1 terminate with good precision. It is a notable fact that one bird, a blue bar female, WB28, of flight number five, flew the seventy miles, and found and entered the loft, despite hot, twenty-seven-mile per hour winds at right angles to its line of flight. Another unusually significant flight was that of the light blue check female, band number IF43B1014, the only bird flown that day, and the only one released outside of Nebraska. Its flight started at 3:30 P.M. about twenty miles east of Council Bluffs, Iowa. Not only did it fly the one hundred eighty-five airline miles across hot winds averaging twenty miles per hour but, as with the seventy-mile flight described above, it flew in the opposite direction from its home in State College to find and enter its 4×4×5 foot loft displaced one thousand miles west of its home to the middle of a Nebraska grain field.

Total flight No. 6, representing nine reported birds, shows one of two anomalous results; these birds flew in an average direction 60° off the theoretical course. One possible explanation is that there was a violent thunder storm between the release and loft positions that come up swiftly just after the last bird had been released. An important fact about this flight (true for all releases), is that the birds did not fly toward State College nor in random directions. None of the nine flew in a direction as much as 90° off from the direction of the total flight vector. It is interesting to observe that, although the trend of this flight was not toward the home Coriolis line, it did follow almost the shortest route to the correct magnetic-vertical line of State College. Flight No. 3, also anomalous, has not the mitigating factor of an intervening electric storm, but it should be noted that the magnetic fields in the region involved are of the most distorted on record, according to Mr. James Affleck of The Gulf Research and Development Company. Release No. 7 is relatively unimportant since only one bird was reported of the two released. Actually, the flight direction is quite good, being only about 40° off theoretical, and the bird may have flown in and out of the twenty-five-mile error distance for homing pigeons. Further, the hot Nebraska wind that day varied from twenty-six to forty-eight miles per hour along the flight path, and the temperature averaged 94°F throughout.

Special release No. 1 represents an "advance guard" experiment in which twelve carefully trained homing pigeons were shipped to Lincoln, Nebraska, to be released by Professor P. A. Downs of the University of Nebraska. These birds, although not trained specifically for the experiment, had had several years of navigational and racing experience from points up to one hundred miles from State College, Pennsylvania. After they had been singly released and carefully watched out of sight, Dr. Downs later remarked that although they looked like good homers, unfortunately they went the wrong direction. Eight of the twelve had flown out of sight toward the west, exactly opposite from State College. Examination of the total flight vector for this group reveals that, for the five reported birds, making an average flight of one-hundred thirty miles, it ends practically on the predicted position.

On June 25, Dr. Downs again released twelve homing pigeons of excellent flying stock raised in State College, Pennsylvania, this time "prisoners" up to a year or more in age, and without flying experience except inside their home loft and fly-pen. In observing their behavior at the liberation, it was noted that they merely scattered in random directions. Of six subsequently reported by telegraph, four remained at Lincoln, two others went in directions neither toward State College nor its Nebraska conjugate. This serves to illustrate the fact that even good homing pigeons must have flying experience and training, in order to respond to the navigating influences.

Special release No. 3 was the outcome of a visit to Mr. J. A. Rendle of Cozad, Nebraska, an outstanding racing pigeon expert, whose name had been given us by Major Otto Meyer of the U. S. Army Signal Corps. Informed of our experiment, he straightway offered to train some of his best young birds for a reverse test of the theory. The conjugate point of Cozad is somewhat east of the middle of Pennsylvania, but the magnetic deposits in the mountains scatter it into several positions east and west along the

Coriolis line which is essentially the same (.04 of a degree north) as that of State College, Pennsylvania.

On September 15, we received from Mr. Rendle twelve young homing pigeons trained around the compass fifty miles from Cozad. The following day they were released in groups of three, at Berkeley Springs, Virginia. Inspection of Pennsylvania Map IV shows the total flight vector for the six reported: one stayed at or returned to Berkeley Springs but none followed a flight line more than 60° or so from the total flight vector, itself in a correct direction, and terminating within ten miles of the same Coriolis line through Cozad. This Cozad, Nebraska, to Pennsylvania result is a corroboration of the strongly indicative State College, Pennsylvania, Kearney, Nebraska, results.

Shortly before receiving these young Cozad birds Mr. Rendle shipped 10 old birds which had had 200 to 400 mile flights in their records. These were released at various places one hundred miles or more from the center of Pennsylvania. Closely paralleling Mr. Rendle's own predictions three of these birds homed across the 1400 or more miles to Cozad in from one to three weeks. Finally three of the remaining ones were reported found in the region of Michigan, western Pennsylvania, and eastern Ohio. A full discussion of these results requires more space than is available here and will appear in a later paper.

### *Salient Points of the First Nebraska Experimental Results*

1. Of one-hundred twenty-two birds trained in State College and released in Nebraska, only one was ever reported east of Indiana. This was telegraphed in eight months later from Phillipsburg, Pennsylvania.

2. Of the eight main Nebraska releases, six of the total flight vectors support the validity of the theory, in addition to the indicative results obtained with the Cozad, Nebraska birds flown from south of Pennsylvania.

3. The Askania magnetometer readings on a sixty-mile line indicate there are two rather than one magnetic vertical-Coriolis conjugates in the Kearney, Nebraska, region. Two groups of total flight vectors (Special No. 1 together with Nos. 4, 5, and 8) and (Nos. 1 and 2), also show this to be true.

4. Two birds, one from seventy, the other from one-hundred eighty miles, flew in directions almost exactly opposite to their home area in State College, Pennsylvania, and found their lofts at the predicted conjugate point. An additional bird was found within three miles of the west conjugate and three were reported within less than ten miles of the anomalous conjugate point. Considering the fact that a homing pigeon should be familiar with landmarks twenty-five miles out from its home loft in order to assure a successful flight termination, it is evident that six of the reported birds (see data on releases Nos. 1-2 and 3, 4–4, 5-1, 8–1, Special No. 1–1) performed the equivalent of "homing" at their conjugate points. It is probable that a high percent of those used in the experiment flew into the regions involved, but, not seeing the loft or familiar landmarks, flew out again in random directions.

5. The results were good in the face of many adverse factors acting against success, such as:

(a) The birds were trained in green mountainous country but the experimental flights were over flat, brown terrain.

(b) The limited supply of five-foot signal balloons used in piloting the birds at the home loft were quickly blown down and punctured on stones during the first few minutes in the air during the first two days in Nebraska so their use had to be abandoned.

(c) The experimental flights were executed in hot, dry winds of from sixteen to forty-eight miles per hour velocity which blew continuously during the day. Experienced racing-pigeon men fear any wind velocities above twelve miles per hour even at normal temperatures. This was in direct contrast to low velocity winds or complete absence of winds during the training period in Pennsylvania.

(d) The birds of necessity were always liberated after 1:00 P.M., because of inadequate help and transportation. This is late in the day for the most successful flying and navigating results.

(e) Experience has shown the longer experimental flight to be more successful. Over-caution, especially at the beginning of the undertaking,

### Glossary to Table IV

Bred (B)—includes mating of old birds, hatching and raising youngsters to flying stage (about four and one-half weeks or longer), but without any flying outside of the loft confines.

Settled (S)—involves letting birds fly outside of loft for the first time. Youngsters up to five or six weeks of age can be settled at a new loft, any distance whatever from the home cote, twenty-four hours after arrival.

Resettled (RS)—repeating operation (S) at a new loft or loft location. The Army was able to do this in seven or eight days by mobiling the birds at the initial settling station.

Flown (F)—this means that, in addition to regular daily exercise flights from the loft, the birds are each day released at progressively greater distances from the home location. Flights of under twenty-five miles are for the purpose of giving them knowledge of local landmarks for piloting to the exact loft locations, plus knowledge of magnitude and gradients of the directives for later use in navigating over unfamiliar territory.

Mobiled (M)—after settling to a portable loft, the latter is moved each day so birds, in their local flying and short training flights, search for it rather than for a particular spot on the land. In military mobiling operations the loft transfers are along a straight line. In the training operations of these experiments the successive locations were always on a circuitous route.

Remobiled (RM)—after settling and mobiling in a given region the birds are resettled, with the same or similar appearing portable lofts, at any desired distance from the last location. In the war, birds were mobiled in this country and remobiled in the European and Pacific war theatres.

caused us to keep the release distances on the short side.

At the completion of the first tests of the bird navigation theory just described, the data obtained were examined critically by the statistical group at the Iowa State College. These men, under Dr. George W. Snedecor, recommended that, in view of the indicative results, work should be continued and more data should be obtained. With this object in view plans with newly suggested procedures were carried out which resulted in the following experiments.

### EXPERIMENT III

### Hamlet Experiment, September 1944

The writer has talked to many persons, with much experience in racing homing pigeons, who contend that birds have a mysterious power to retrace a path over which they have been carried, even in darkness or in a drugged condition. Some tests of this contention[13] have been made and negative results obtained. There are also many experienced pigeon-racing men who claim that homing pigeons possess the remarkable ability to return to a loft from a distance, merely by virtue of their having lived in it. In the experiment of June, 1944, already recorded, the birds used in "Special release No. 2," had neither flying experience around their home loft at State College, Pennsylvania, nor navigational training. Although the data are far too limited to be conclusive, they do indicate an inability of such birds to make any effective attempt whatever at homing.

At the close of the first full-scale experiment in Nebraska it was found possible to secure, from mobile lofts of the Army Signal Corps at Fort Monmouth, New Jersey, three hundred pigeons, which (with one exception, as later learned) had had no training in navigation, although some had had limited "pilotage" experience from being settled and flown from short distances at the lofts where they were bred. These birds were bred and shipped from Fort Sam Houston, Texas, Camp Crowder, Missouri, and other stations indicated in Table IV and had been given only "mobile" training at Fort Monmouth. Upon arrival at the experimental headquarters at Hamlet, Nebraska, on September 29, 1944, they were placed in Army mobile lofts and permitted a twenty-four-hour rest before being transferred to the various release points. In order to take care of the slight possibility that they might be able to navigate even with the various types of training indicated, the releases were arranged from locations within a hundred and fifty miles radius of Hamlet, Nebraska. The latter is practically on the conjugate point for Fort Monmouth, New Jersey, and according to the theory and the Kearney, Nebraska, results, the point toward which the birds would fly, should their limited Fort Monmouth mobile training be adequate. On September 30, 1944, two hundred and fifty of these birds were re-

(Towns in Nebraska unless otherwise specified)

leased in four groups near Goodland, Kansas, Miller, Nebraska, Alma, Nebraska, and Quinter, Kansas, respectively. Small groups of twos, threes, fours, and fives were released, ten minutes apart, beginning at dawn. The weather was cool and clear with gusty winds of about fifteen miles per hour blowing during the day. Of two hundred and fifty birds released, fifty-four were reported on or before October 30, by telegrams.[14]

---

[14] Of the remaining fifty of the original three hundred, half were youngsters, the others yearlings. The twenty-five yearlings were released at Culbertson in a group most of

The performance of the birds released, as indicated by the telegrams reporting the flight terminals, seems to divide them into three natural groups (Table V) each of which will be dealt with separately.

### *Results*

*Group No. 1.* These forty-eight birds flew in short random flights ranging from zero to sixty miles from the points of release. The arithmetical average of the forty-eight flights is about twenty miles. Of these, twenty were reported within a mile of the release point. An even more significant indication about the flight of these birds is that the average of the vector sum of their flight vectors (previously referred to as the "total flight vector") is less than ten miles. Since these flights, including distance and directions, are vector quantities, the vector sum and its average is the only one which has real meaning in this connection.

*Group No. 2.* This 110-mile flight seems significant in that this bird flew in a direct line for Hamlet, Nebraska, which is the conjugate point of Fort Monmouth, New Jersey, and stopped just thirty miles beyond. Of the fifty-two birds reported, it is the only one which had had the proper training in navigating to do this. It was later learned that it had been used in communications at Fort Monmouth, New Jersey, and inadvertently was shipped with the less experienced birds.

*Group No. 3.* These five birds are distinguished from the rest in that they made long flights averaging one hundred and fifteen miles in length, in addition to flying in directions quite accurately toward their original homes which are as follows:

| Bird No. | Place bred |
|---|---|
| 31 | Camp Clairborne, Louisiana |
| 36 | Camp Crowder, Missouri |
| 41 | Camp Crowder, Missouri |
| 50 | Fort Benning, Georgia |
| 51 | Camp Clairborne, Louisiana |

A check made with the head of the Army Pigeon Service revealed that they had been settled and had had considerable flying experience around their home loft before being shipped to Fort Monmouth, New Jersey, which may account not only for the length but also the direction of their flights.

It should be noted that any one of the fifty reported birds, having been bred from some of the world's finest homing pigeons, had the inherited qualities and the mental and physical make-up to fly a like distance toward Fort Monmouth or its conjugate point had they also possessed the means of so doing, brought about by the required type of navigational training. If the "retracement" contention had credence, they should have flown back along the path over which they had been transported by train two days before, or retraced the paths over which they had been taken by car from Hamlet to the various release points, during the hours previous to their release. In the latter case they should have flown toward Hamlet first and then started eastward to Fort Monmouth instead of the short random flights in forty-seven of fifty-four reported cases.

It is a well established fact that homing pigeons settled and trained to navigate at any point, will, in most cases, if physically able, return to it when released moderate distances away, such as one to three hundred miles. This experiment indicates, however, that just settling[15] and mobiling will not replace the training in navigation which they must have to home successfully from a distance. It therefore seems evident, whereas they may inherit the ability to navigate, that they must first have specialized and adequate training in order to accomplish it.

The results of the Hamlet experiment and Special No. 2 and all other tests of these experiments, indicate that homing pigeons do not retrace paths over which they have just been transported unless these latter happen to be directly in line from the home (or its conjugate point) to which they have been trained to pilot and to navigate.

---

which took up residence on the spot. The twenty-five youngsters were retained for "navigation" training at State College, Pennsylvania, for later experimentation.

[15] See explanation in Glossary appended to Table IV. Explains training which they must have to home successfully from a distance. It therefore seems evident, whereas they may inherit the ability to navigate, that they must first have specialized and adequate training in order to accomplish it.

## EXPERIMENT IV

## The East-West Experiment, June 1945

As previously stated, the orientation of the magnetic-vertical lines with respect to the Coriolis lines produce regions where the gridwork character tapers off and a pattern of irregular parallelism or tangency occurs. Reference to Map II indicates this relationship over a fairly wide strip of land through the region which includes the states of Wisconsin, Illinois, Indiana, Kentucky and continuing in a south-south-east direction. An irregular line including all the points of tangency in this region will subsequently be referred to as "the line of tangency."

It seems evident that if birds are guided to a unique point (their home or conjugate point) by conditions requiring grid representations of the fields of influence, they would lack that guidance in a region where the indicating lines approximate a condition of parallelism. Such has been thought to be the case by racing pigeon men in the region just referred to.[16] The procedures of

this experiment were designed to test this phase of the theory.

On April 23, 1945, fifty five-week old youngsters were received from Fort Sam Houston, Texas. Pilotage and navigation training of these birds was started immediately. Their loft was not mobiled and training releases were made twice daily. These consisted of one, two, four, eight, sixteen, and twenty-five mile flights for pilotage experience, and many thirty-, fifty-, and seventy-mile flights, in several directions, for navigational training. On some of the longer flights they were liberated in twos, threes, and fives to make them more self-reliant and capable of independent navigational flights.

On June 10, 1945, when the experiment was to begin, there remained forty-two birds. The other eight were lost in the longer training flights, especially when released in small groups. They were transported by truck from State College to the points of liberation which were about equally spaced between State College, Pennsylvania, and Kearney, Nebraska. Table VI shows the time and place these birds were released as well as the time and place each was found and reported. Table VII shows the release and terminal points of all the birds whose flight terminals were determined. These include all reported by telegraph and in the case of the eastern releases, five which actually arrived at the home loft. In addition it classifies them as follows:

- Group 1 Those birds released east of the line of tangency (or region of confusion).
- Group 2—Those birds released west of the line of tangency.
- Group 3—Those birds which were released within a distance of one hundred miles east or west of the line of tangency and flew across it.

The column at the right on Table VII also shows the distances which each bird flew on a direct line toward the conjugate for the "western" releases and toward the home loft in the case of the "eastern" releases. The $Y$ column shows the perpendicular distances flown either (+) counter-clockwise or (−) clockwise from the direct line to conjugate or home point, respectively.

Table VIII shows the computation of results from the data on Table VII. The algebraic sums of the $X$ and $Y$ components of both groups were divided by the number of flights contributing to their totals. These values of ($\Sigma X$/No. flights) and ($\Sigma Y$/No. flights) were then added vectorily to determine the resultant "flight vector" for the group of birds involved.

As shown, the Eastern group (No. 1) on the average flew 1.8 miles in a counter-clockwise direction while averaging 71.4 miles toward the home (a deviation of approximately 1.0°) whereas the Western group (No. 2) deviated 5.8 miles in a clockwise direction while averaging 93.1 miles toward the conjugate point (a deviation of approximately 3.6°).

At the conjugate end of the experiment the birds, even without errors caused by large local magnetic anomalies, would be subject to errors of fifteen or twenty-five miles from the point, because of the natural errors of navigation to which they are subject. At the home end the pilotage training permits the bird, by means of local landmarks, to finish the last twenty-five or so miles of the journey to the loft. This probably accounts for the smaller angle of deviation for the eastern group.

Birds of group (No. 3) were deliberately liberated within the central two hundred-mile band, which should be a region of confusion insofar as the theory is concerned. It seems significant that the only birds to cross over the line of tangency were released in this band. More data will be obtained to check this indication.

## EXPERIMENT V

### Second Kearney Experiment, June 1945

This experiment deals with approximately two hundred homing pigeons trained at State College, Pennsylvania. In general, the preparations and procedures were the same as described in the previous experiment at Kearney, Nebraska. However, since the results of the previous tests had so thoroughly dovetailed with the requirements of magnetic-vertical Coriolis theory, at the suggestion of Major Otto Meyer and Lt. Arthur M. Lehman of the Army Signal Corps, it was decided to put a handicap in the way of these birds in order to give the theory the acid test. The plan involved training the birds by releasing them always north-west of State College, but when testing them for the conjugate point in the Kearney, Nebraska, region, making the releases well toward the north-east. In many of the pigeon races greater speed results from having the birds fly and refly over familiar territory and many believe the birds' ability to return depends on visual cues resulting from this careful training in the same direction.[17] Therefore, the significance of the above plane is self-evident.

During the first Kearney experiment in July 1944, five-foot meteorological balloons were used at State College and in Nebraska in an attempt to aid the birds in piloting the last ten or fifteen miles to the loft. The strong Nebraska winds, however, quickly blew them down and broke them so that their value was not determined. In this experiment eight-foot orange-colored box-kites were used for a similar purpose. The kites were flown during most of the training flights to the home loft at State College and during the two days the birds were released in Nebraska. Since no birds actually found the lofts this year, it is assumed that their effect was negligible.

TABLE VIII. Computations with diagrams of results.

Group (1)
Eastern releases

Distance traveled toward home loft $X_e = +908$ miles (11 birds)
Distance traveled away from home loft $-X_e = -\ 51$ miles (1 bird)
$\Sigma X_e\ \ +857$ miles (12 birds)
Deviation to left from the $X$ direction $Y_e = +\ 81$ (2 birds)
$-Y_e = -102$ (5 birds)
$Y_e = \ \ 0$ (5 birds)
$\Sigma Y_e = -\ 21$ (12 birds)

$$\frac{\Sigma X_e}{\text{No. birds}} = \frac{+857}{12} = 71\ 4 \text{ miles}; \quad \frac{\Sigma Y_e}{\text{No. birds}} = \frac{-21}{12} = -1.8 \text{ miles}$$

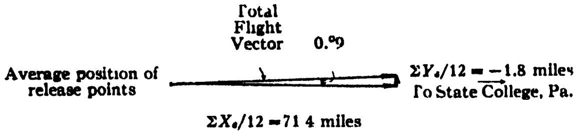

FIG. 2.

Group (2)
Western releases

Distance traveled toward conjugate point $+X_w = +1050$ miles (8 birds)
Distance traveled away from conjugate point $-X_w = -\ \ 26$ miles (3 birds)
$\Sigma X_w = +1024$ miles (11 birds)
Deviation to left from $X_w$ direction $Y_w = +\ 224$ miles (9 birds)
Deviation to right from $X_w$ direction $-Y_w = -\ 160$ miles (2 birds)
Net (to left) deviation from $X_w$ direction $\Sigma Y_w = +\ \ 64$ miles (11 birds)

$$\frac{\Sigma X_w}{\text{No birds}} = \frac{+1024}{11} = 93.1 \text{ miles}; \quad \frac{\Sigma Y_w}{\text{No. birds}} = \frac{+64}{11} = +5.8 \text{ miles}$$

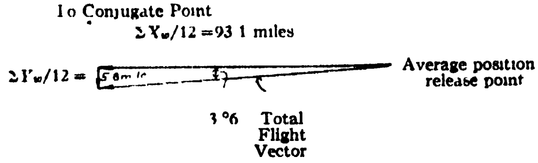

FIG. 3.

### Procurement and Training of Birds

Of the two hundred homing pigeons trained for this experiment one hundred fifty-nine were six-week old youngsters supplied by the Army Service Forces from the Army breeding lofts at Fort Sam Houston, Texas. The remainder were birds secured from various racing pigeon men a year previous and held over to be used as two-year-olds.

All the birds were housed in two mobile lofts having tall peaked roofs, six-foot ceilings, and six- by twelve-foot floor spaces. Each contained one hundred and twenty nest boxes with adequate avaries for sunning and bathing. The lofts were mounted on standard farm wagons having Timken high speed bearings, 6:00×16 automobile tires, and were painted a bright yellow. They were moved one hundred yards twice daily for receiving the birds from their training flights. The latter change in loft position was accomplished with a Fordson farm tractor.

Training flights were carried out morning and afternoon. After the initial short flights to the east, north, and west, to take care of their error in navigation, the birds were trained only from the north-west. Except for a few stormy days, training was continuous from the time the younger birds were received on April 14 until the day of departure for Kearney on June 10.

The navigation flights were extended to seventy miles airline. The birds flew the latter distance many times and on several occasions, when the wind velocity was practically zero, they homed in approximately seventy minutes.

## Table IX.

$X$ = distance bird flew toward conjugate point; $-X$ = away from point.
$Y$ = distance bird flew to left; $-Y$ to right of line drawn from liberation point to conjugate point. Released by: E-L = English-Lehman, H-B = Hendrickson-Brewer, H-R = Hendrickson-Rendle.

Training releases were made in groups of threes and fives a few times, but in most cases the birds were flown in groups of fifty.

On the morning of June 9th the birds were given a seven-mile exercise flight from the northwest. Immediately following, one of the lofts was transferred from its farm wagon base to a two-ton International Truck owned by the Agri-

cultural Engineering Department of the College. The second was coupled to the back of the truck. All feed, kites, and other needed equipment was put under a false floor built in the latter loft.

On June 10th at 7 A.M. the trip to Kearney, Nebraska, was started. The party consisted of Roy Johnson, in charge of trucks, Jack Nesbitt, in charge of kites, Donald Brewer, in charge of birds, Major Otto Meyer, Lt. A. M. Lehman, P. F. English, and H. L. Yeagley. The trip of more than twelve hundred miles was made in three days. Two men, including the driver, handled the truck, and drivers were changed every two hundred or so miles, while the remainder of the party rode in a car belonging to the Pennsylvania Cooperative Wildlife Research Unit of the Pennsylvania State College and driven by Dr. English. At Ames, Iowa, Dr. George Hendrickson joined the party with a car owned by the Iowa Cooperative Research Unit. Mr. J. A. Rendle of Cozad, Nebraska, also joined the party at Kearney and assisted in the experimental procedures.

Upon arrival at Kearney the lofts were placed one and twenty miles, respectively, north of the town. This spaced them about equally north and south of the western State College conjugate. After one day for resting the birds, they were taken in groups and released on an average of seventy-five miles to the N.N.E. and E.N.E., and N.E. of the loft locations.

On June 15th at ten P.M. reports from the United States Weather Bureau indicated that the next day would be clear with scattered clouds and that wind velocities would average ten miles an hour or lower. About four o'clock the next morning (June 16th) Dr. English and Lt. Lehman took one hundred eighteen birds for liberation at points averaging seventy-five miles to the north-east of the conjugate. The birds were all released during the morning groups of threes and fives in the regions around the

Nebraska towns of Clarks, Silver Creek, St. Edward, and Albion. Simultaneously Dr. Hendrickson and Donald Brewer released ten birds to the south-west (near McCook, Nebraska) for control purposes. As indicated by the weather reports, the day was unusually good for bird navigation.

The next morning, June 17th, with weather report and actual weather similar to that of the preceding day, Dr. Hendrickson and Mr. Rendle took the fifty-six remaining birds for liberation to regions around Stromsburg, York, and Hampton, Nebraska. The distance was about the same as the preceding day but the direction was more toward the east. Again the birds were released well before noon in groups of threes and fives. As in previous experiments the birds carried messages in Army message carriers asking the finder to report when and where the bird was found.

### *Results*

Table IX lists all birds which were reported (thirty-two percent of total released) up to the present writing. It lists the time and place of release, persons in charge of liberation, time and place they were found, and the distances flown along and at right angles to a line drawn through the conjugate point and the release point.

From racing-pigeon men it has been learned that birds which do not arrive home from one- and two-hundred-mile flights within a few days are likely not to arrive at all. This is taken as an indication that they become discouraged or fly at random after that time. For this reason all birds reported more than ten days after liberation were listed separately (Group B, Table IX) and this data used in a subsequent calculation to test its effect on the more reliable early data. A second separate listing consists of birds which never left, or perhaps returned to the release areas (Group C, Table IX). In any case, they were reported found within a ten-mile radius of the release point. The complete listing of the birds on Table IX is as follows:

Group A Birds reported within a nine- or ten-day period after liberation.

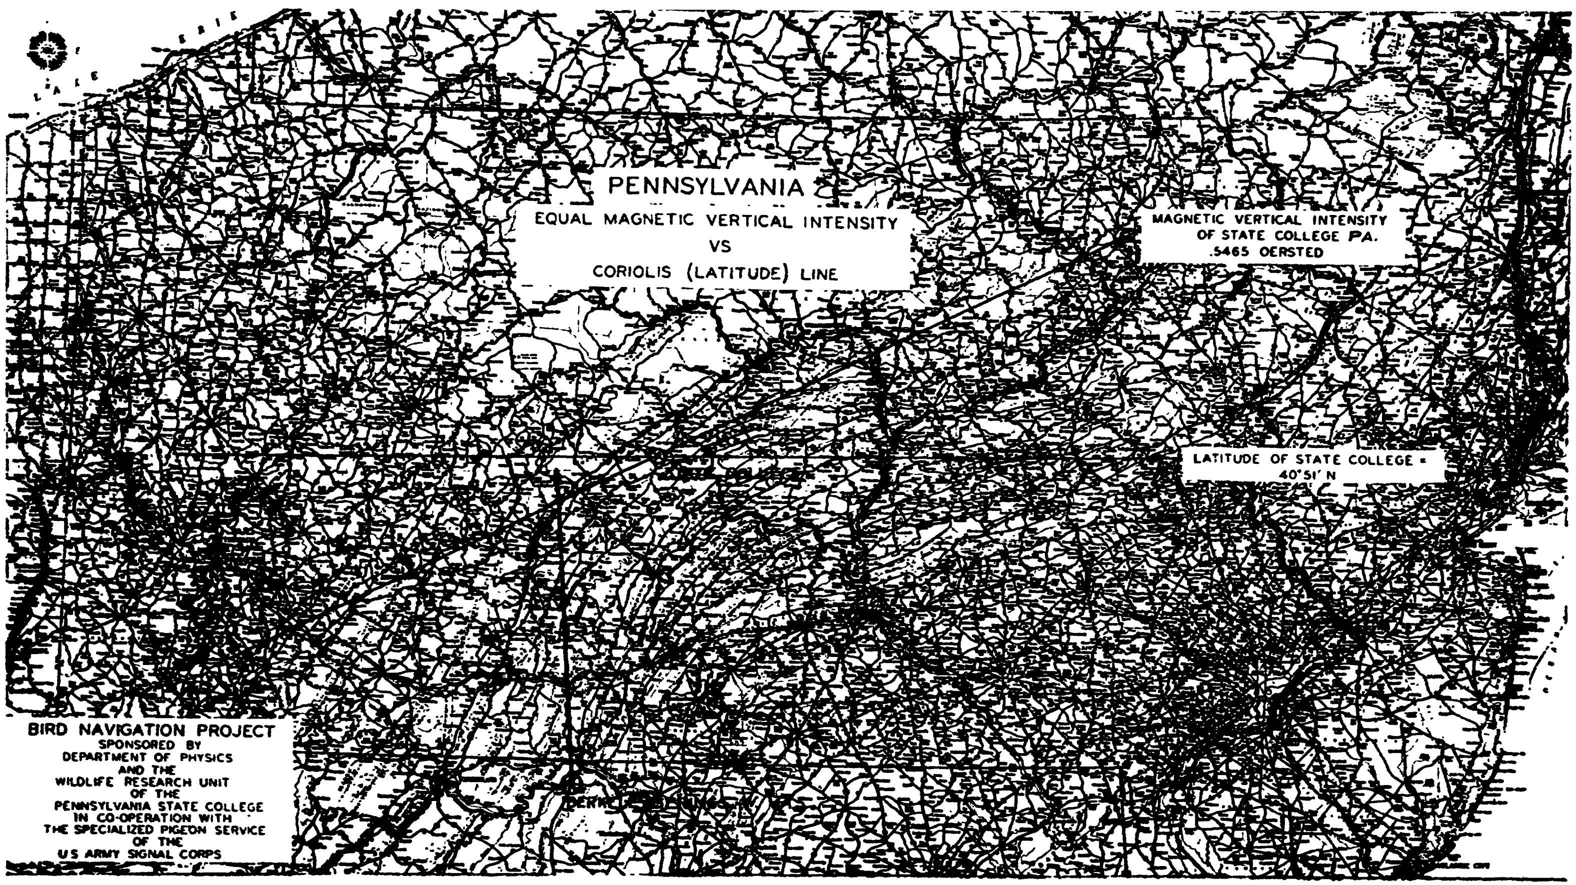
Group B Birds reported after June 26th.

Group C Birds which were reported less than ten miles from the release point.

In working out and interpreting the data of this experiment the same plan was followed as with the previous ones. The flight (release point to flight terminal) of each bird was plotted and a straight line drawn from the release point to the conjugate point. The algebraic sums $\Sigma X$ and $\Sigma Y$ of the components of all the flights toward and at right angles to the theoretically required direction line were divided by the number of birds and added vectorily to obtain the "total flight vector" for the groups.

On Table X is shown the average angle of deviation obtained from the flight data of the birds listed in Table IX. Those of Group A show a counter-clockwise deviation of 5.8°. When the data from those reported later (Group B) are used in the computations, the average deviation is seen to be +13.5 degrees.

As in the case of the 1944 Kearney experiments, the experimental birds seemed to behave



Map IV. Map of Pennsylvania with northern parts of Virginia and West Virginia. Arrow represents total flight vector for reported birds of Special release No. 3 on Table III.

according to the magnetic vertical-Coriolis theory by flying on the average, with only small deviation from a line toward the computed conjugate point. It is noteworthy that the angle of deviation for the birds reported within reasonable time limits is extremely small (5.8°), and this in spite of the fact the birds were trained in a manner devised to confuse them if possible. If the training flights around State College, Pennsylvania, had misled them into flying toward the sun or the south-eastern sky each day, then in the Nebraska liberations they would have flown toward the state of Missouri. This would have been roughly ninety degrees from both State College, Pennsylvania, and Kearney, Nebraska, directions.

During the study and computation of the data in this report it was noticed that the pigeons supplied by the Army Signal Corps, on the average, made more accurate flights in the direction of the conjugate point than those obtained from private sources. It therefore seemed desirable that a separate computation be made for these birds. The summation of their flight components ($\Sigma X, \Sigma Y$) and average components ($\Sigma X$/No. birds, $\Sigma Y$/No. birds) are:

Algebraic sum of distance flown in the direction of the conjugate by the twenty Army birds reported up to June 26, $\Sigma X = 2664$ miles.

Algebraic sum of distance flown at right angles to the above direction, $\Sigma Y = -45$ miles.

As indicated on Table XI, this represents an average flight of 133.2 miles in the $X$ direction and 2.2 miles in the $-Y$ direction or a deviation of only one degree from the average direct line to the conjugate point. This seems to indicate that the Army birds are superior navigators. The small angle of deviation also seems remarkable in view of the flatness of the Nebraska country as contrasted with the mountains in Pennsylvania where the birds were trained, and the anomalous set-up of the earth's magnetic field through which they had to fly in both regions.

## REMARKS

The fundamental importance of the foregoing explanation of the long mysterious bird navigation problem and the experimental data obtained is fourfold:

1. The results furnish an experimental indication that a bird moving across a magnetic field experiences an awareness to the effect.
2. The age-old mystery of bird migrations may be clarified by the results of this and already planned future experiments with wild birds. The ability of the Golden Plover[18] to navigate from Hawaii to Alaska, 3000 miles one way over ocean vastness, may possibly have an explanation in the homing pigeon's technique.
3. The biologists and psychologists can make use of its findings in studying the effect of a moving magnetic field on living nerves, an effect lacking demonstration up to now. Part of the ills occurring to pilots in super-speed planes and other high velocity craft, and attributed entirely to large values of acceleration, may conceivably be due to moving rapidly through the earth's magnetic field
4. There is evidence that wild birds and homing pigeons become confused when in the region of powerful broadcasting stations. Although there is much controversy on the subject, the evidence included in this report, both from the standpoint of the magnetic wing and the conjugate point experiments, indicates that the phenomenon could exist. Further evidence of this is also being sought with new experiments on homing pigeons now under way at The Pennsylvania State College.

## ACKNOWLEDGMENTS

The experimental work has been supported by: the Department of Physics and The Department of Zoology and Entomology of The Pennsylvania State College; the Pennsylvania Wildlife Research Group at The Pennsylvania State College and the Army Service Forces of the United States Army Signal Corps.

The men mainly responsible for carrying out the experimental procedures are: Dr. H. L. Yeagley, Department of Physics, and Professor Merrill Wood, Department of Zoology, both at The Pennsylvania State College; Dr. P. F. English and Dr. Logan Bennett, both of the Pennsylvania Wildlife Research Unit; Dr. George Hendrickson, Associate Professor of Wildlife Management, Iowa State College, and Major

# Inversion Applied to the Solution of 3-Dimensional Electromagnetic Problems*

A. Bloch
*Research Laboratories, The General Electric Company (Ltd.), Wembley, England*

(Received March 18, 1947)

This paper presents an extension of the method of inversion to certain electromagnetic problems and rectifies at the same time an error of long standing in the solution of an elementary problem which seems to have acted as a bar to just this extension.

If the image of a charge in a sphere is derived by the method of inversion, as is done in this paper, it becomes immediately obvious that the image of radially oriented dipole is another radial dipole plus a free charge proportional to the moment of the dipole. The potential caused by the free charge is not of negligible magnitude, and this indicates that the solution given by Sir J. Larmor and independently by S. P. Thompson and Miles Walker for the case of a magnetic dipole outside a sphere of infinite permittivity cannot be correct, for the image used therein consists of a simple dipole. However, it can be shown in addition that the latter image is not void of physical significance: the vector potential of such an image transforms in a simple manner and from this in turn follow simple laws of transformation for flux linked with loops and for mutual inductance between such loops.

This extension of the method of inversion is used in the second part of the paper to deal with a problem complementary to that of Larmor-Thompson, namely, with that of a spherical wall impermeable to magnetic flux. This problem is of practical importance as an idealization of an inductor used at radiofrequencies and placed inside a metal screen, and it has for this reason been dealt with by direct attack on several previous occasions. It is shown here that the action of such a screen on the field produced by the loop can be replaced by the introduction of a simple image loop. From this follows then a simple way of calculating the change in self and mutual inductance produced by such a screen, even in cases more general than considered heretofore. The losses caused by the screen can also be easily calculated by the use of H. A. Wheeler's concept of equivalent magnetic skin thickness.

## SYMBOLS

$O$ = center of inversion
$K$ = constant of inversion
$P$ = point at which a charge or current element is situated
$P'$ = inverse of $P$ $[OP \times OP' = K^2]$
$N$ = point at which the value of a potential is considered
$N'$ = point inverse to $N$
$l = PN$
$l' = P'N'$
$r, r'$ = a distance from $O$ and its inverse
$q, q'$ = an electric or magnetic charge and its inverse
$m, m'$ = a magnetic moment and its inverse
$I, I'$ = an electric current and its inverse
$V$ = an electric or magnetic potential
$\mathbf{A}$ = Vectorpotential
$\phi$ = magnetic flux
$L$ = self-inductance
$M, M_{12}$ = mutual inductance.

## INTRODUCTION

THE purpose of this paper is to present an extension of the method of inversion to the solution of certain electromagnetic problems and at the same time to rectify an error of long standing which seems to have acted as a bar to just this extension. In 1888 Sir J. Larmor considered[1] the magnetic field caused by a circular current loop in the presence of a cocentric soft iron sphere and concluded that for infinite permittivity of this sphere its action on the field outside its boundary could be replaced by that of an "image" of the original loop in the sphere. An identical solution was given independently by Silvanus Thompson and Miles Walker[2] and is still referred to in modern textbooks. It does not seem to have been noticed so far that an image of this kind does not solve the problem given.

If these images are introduced by the method of inversion—as will be done hereafter—such failure will be immediately evident. At the same time it is then not difficult to see that such an image obeys a simple law of transformation for its vector potential, from which follow in turn simple laws of transformation for magnetic flux through loops and mutual inductance between loops.

[2] S. P. Thompson and M. Walker, "Mirrors of magnetism," Phil. Mag. **34** (5th series) 213–224 (1895).

This extension is dealt with in the first part of the paper, to be followed in the second part by an application to a problem complementary to that of Larmor and Thompson and Walker, namely, to that of a sphere impermeable to magnetic flux. This case arises when we study the reaction of a screening can at radio frequencies on an enclosed loop, as has been done on several occasions. H. Kaden[3] considered a loop of very small dimensions situated at the center of a spherical screen. C. F. Davidson and J. C. Simmonds[4] have extended this solution to the case of a loop of finite dimensions. H. Buchholz[5] has given solutions for the self- and mutual-inductance of loops which are parallel to each other and coaxially situated in any position along the radius of the screening sphere. All these authors use a direct method of attack and require, therefore, a mathematical apparatus of some complexity.

The present papers show that the action of the screen can be represented as the action of a simple image loop and thus reduces all the problems mentioned to the well solved determination of the mutual inductance between two parallel and coaxial loops. Actually, the methods of the paper are capable of dealing with some slightly more general arrangement of the loops and with certain non-circular loops.

## I. THE METHOD OF INVERSION AND ITS EXTENSION TO MAGNETIC IMAGES

Let $O$ be a fixed point (the *center of inversion*) and $P$ a variable one; determine on $OP$ a point $P'$ so that the distances $OP$ and $OP'$ fulfil

$$OP \times OP' = K^2 \tag{1}$$

($K$ = *constant of inversion*).

Then if $P$ describes a line, or a surface, or a volume, $P'$ will describe a corresponding geometrical element (the *inverse* or the *image* of the original element).

The most important properties of this well-known geometrical transformation are recalled by Figs. 1 and 2. Figure 1 shows that the inverse of a circle contained in a plane through the center of inversion is another circle in the same plane. Hence the inverse of a sphere must be another sphere, that of a circle in a general position—defined by the intersection of 2 spheres—must again be a circle, and the inverse of a plane (sphere through the infinitely distant point) a sphere through the origin. Figure 2 illustrates the "conformal" property of the transformation: the angles of intersection between lines and surfaces remain unchanged in the transformation.

To apply this method to the solution of problems of the theory of potential we have to add to this a law for the transformation of charges, as follows: A point charge of magnitude, say $q$, situated at a point, say $P$, shall be represented by another point charge of magnitude $q'$ situated at the image $P'$ of $P$, whereby

$$\frac{q'}{q} = \pm\frac{K}{OP} = \pm\frac{OP'}{K} = \left(\frac{OP'}{OP}\right)^{\frac{1}{2}}. \tag{2}$$

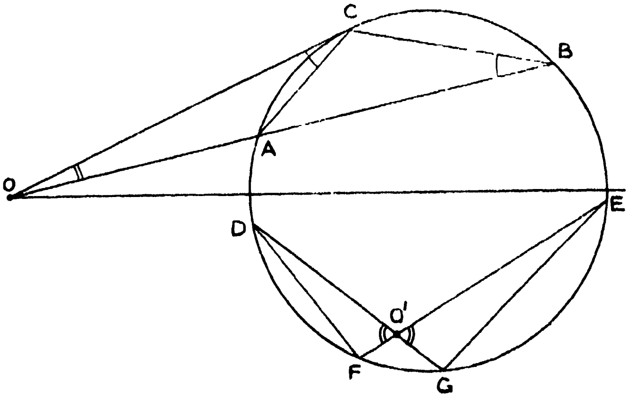

FIG. 1. The inverse of a circle is another circle. $\sphericalangle OCA = \sphericalangle CBA$ when $OC$ is tangent to circle; hence $\triangle OCA$ is similar to $\triangle OBC$, and $OA \times OB = OC^2$. If $K = OC$, this means that the circle inverts into itself; if $K$ is larger or smaller, the result of the inversion is correspondingly larger or smaller, but it will still be a circle. There is a similar proof if the center of inversion $O'$ is situated inside the circle: $\triangle FO'D$ is similar to $\triangle GO'E$ and $DO' \times O'G = FO' \times O'E =$ const.

[4] C. F. Davidson and J. C. Simmonds, W. Eng., **22**, 3 (1945).

[5] H. Buchholz, Archiv. f. Electrotechnik **28**, 556 (1934).

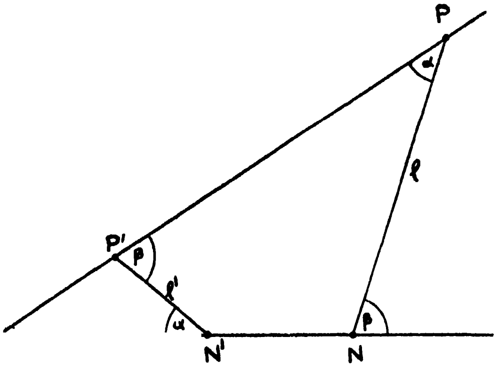

FIG. 2. If $OP\times OP'=ON\times ON'=K^2$, then $OP':ON'=ON:OP$, i.e., $\sphericalangle OP'N'=\sphericalangle ONP$. From this follows (a) if $l$ and $l'$ are infinitesimally small, the angles formed by these line elements with their radii vectorii are equal; (b) $l:l'=ON:OP'=OP:ON'=\left(\frac{ON\times OP}{ON'\times OP'}\right)^{\frac{1}{2}}=\frac{ON\times OP}{K^2}=\frac{K^2}{ON'\times OP'}$.

The reason for selecting this particular relation will become clear when we inquire into the potential $V$, caused by such a charge at some point $N$, and compare it with the potential $V'$ caused by the image charge at the image point $N'$ (see Fig. 2).

In this case $V=q/l$, and $V'=q'/l'$, hence

$$\frac{V'}{V}=\frac{q'}{l'}\cdot\frac{l}{q}=\pm\frac{K}{OP}\cdot\frac{OP}{ON'}$$

$$=\pm\frac{K}{ON'}=\pm\frac{ON}{K}=\pm\left(\frac{ON}{ON'}\right)^{\frac{1}{2}}. \quad (3)$$

The last equation shows that the transformed potential $V'$ can be calculated from the original potential without the need for inquiring into the position of the charge which "caused" the potential. Hence the potential will still transform accordingly to the same rule if it is due not to a single charge but to an assembly of charges.

These relations allow us to deduce the solution of a problem for the inverse space from the solution of the corresponding problem for the original space and *vice versa*. As an example we recall the case of a point charge $q$ in front of an infinite earthed plane. This problem is of course equivalent to that of the original charge, $q$, and of the mirror image, $q_m$, of this charge in this plane. By inversion from any point not coinciding with the plane the latter transforms into a sphere, with one charge $q'$ inside and the other one $q'_m$ outside its boundary. From Eq. (3) it is then seen that the potential of this sphere is again zero (for all points of the sphere not coinciding with the center of inversion the multiplier $K/ON'$ is finite; with a finite gradient of the field in the neighborhood of the center of inversion the potential of this point must then be zero too). Thus, the transformed arrangement solves the problem of a point charge inside or outside an earthed sphere. The "answers" for this case can be obtained either by appropriate translation from the results of the "plane" case, or, simpler still, by noting directly the fact that here too the total field is due to the combined action of the charge $q'$ and of the "image in the sphere" $q'_m$.

It is useful to note that we are led to this image charge also by a slightly different application of the method of inversion. If we invert the charge $q'$ and the sphere from the center of the sphere as inversion center in such a way that the sphere changes into itself (constant $K$ of inversion equal to the radius of the sphere) then $q'$ transforms into the image $q'_m$ previously found.*

From the fact that image and original charge are thus related by Eq. (2), it follows immediately, that in the case where we are given two charges of equal magnitude, forming a radially oriented dipole, the corresponding image charges cannot be equal. If the given charges are situated at, say $r$ and $r+dr$, the image charges are in this case situated at

$$r'=\frac{K^2}{r}, \text{ and } r'+dr'=\frac{K^2}{r+dr},$$

---

* That this is so—at least geometrically—is easily seen if we consider what happens to all those spheres which are common to the two charges $q$ and $q_m$ of the "plane" arrangement. These intersect normally with the plane, and they transformed therefor, in the first inversion into all those spheres which pass through the two charges $q'$ and $q'_m$ and intersect normally with the earthed sphere. In the second inversion—with the center of the sphere as inversion center—each of these spheres transforms into itself, i.e., their first common point must change into their second common point. (Their points of intersection with the earthed sphere remain fixed, and we know also that the angle of intersection must be again 90°.) Electrically the transformed arrangement could differ from the original arrangement then only by having both charges increased or decreased by the same factor. However, it is seen at once that this factor must be equal to unity as the electrical displacement at the surface of the sphere (charge per unit area) remained unchanged in this transformation (see Eq. 2)).

and they differ in magnitude by

$$\Delta q' = \frac{q \cdot K}{r^2} dr = \frac{m \cdot K}{r^2}, \tag{4}$$

where $m = qdr$ is the moment of the original dipole.

The case of an isolated sphere (with the given charges outside the sphere) differs from the case of an earthed sphere only insofar that a further charge at the center of the sphere is added so that the sum total of all the charges inside the sphere equals zero whilst the surface of the sphere still remains an equipotential surface.

The case of a magnetic dipole outside a shell of infinite permittivity is perfectly analogous to this latter case. From this follows immediately that a solution which takes the image of a radial dipole to be simply another dipole is not a case of ordinary inversion and is unlikely to follow the transformation law of Eq. (3) for the potential. (The potential produced at the surface of the sphere by the neglected free charge $\Delta q'$ is evidently of the same order as that produced by the dipole itself.)

This conclusion can be easily confirmed if we go to the trouble of writing down explicitly the expression for the magnetic potential of such a dipole. This expression, however, suggests further that it is now the magnetic vector potential of the dipole that follows the simple transformation law of Eq. (3). The magnetic vector potential of a radial dipole of moment $m$ situated at $P$ (Fig. 2) has at point $N$ the value

$$A = \frac{m}{l^2} \sin\alpha. \tag{5}$$

The direction of this vector is normal to the plane of the paper. The vector potential at $N'$ caused by the image dipole situated at $P'$ will be of magnitude

$$A' = \frac{m'}{l'^2} \sin\beta. \tag{6}$$

If we assume

$$\frac{m'}{m} = \frac{q' \cdot dr'}{q \cdot dr} = \frac{K}{OP} \cdot \frac{OP'}{OP} = \frac{K^3}{OP^3}, \tag{7}$$

we have

$$\frac{A'}{A} = \frac{m'}{m} \cdot \frac{l^2}{l'^2} \cdot \frac{\sin\beta}{\sin\alpha} = \frac{K^3}{OP^3} \cdot \frac{OP^2}{ON'^2} \cdot \frac{ON'}{OP'}$$

$$= \frac{K}{ON'} = \frac{ON}{K} = \left(\frac{ON}{ON'}\right)^{\frac{1}{2}}. \tag{8}$$

The foregoing finds an immediate application if we consider the fields produced by current loops. The magnetic effects of such a loop (not necessarily of circular shape), in which a current $I$ flows, is equivalent to that of a magnetic shell bounded by the loop, the strength of this shell (i.e., the magnetic moment per unit area) being equal to $I$.

Transformation of this shell produces as image another shell; if the original shell was spherical with center $O$, the image shell will also be spherical, and again of constant strength. Since corresponding elements of these two shells are related as to their surface areas as

$$\frac{S'}{S} = \left(\frac{r'}{r}\right)^2, \tag{9}$$

we have

$$\frac{I'}{I} = \frac{(m'/S')}{(m/S)} = \frac{K^3}{r^3} \cdot \frac{r^2}{r'^2} = \frac{K}{r'} = \frac{r}{K} = \left(\frac{r}{r'}\right)^{\frac{1}{2}}. \tag{10}$$

This means that we may replace this shell in turn by another current loop, the image of the original loop, the strength of the image current being given by Eq. (10).

The last equation may be used to show independently that the vector potential of such a loop transforms as stated in Eq. (8).

We have for the vector potential of the original loop

$$\mathbf{A} = \oint d\mathbf{A} = \oint \frac{I d\mathbf{s}}{l}, \tag{11}$$

and for that of the transformed loop

$$\mathbf{A}' = \oint dA' = \oint \frac{I' \cdot d\mathbf{s}'}{l'}. \tag{12}$$

The two contours over which these two line integrals are to be taken correspond to each other element $d\mathbf{s}$ for element $d\mathbf{s}'$, and the ratio

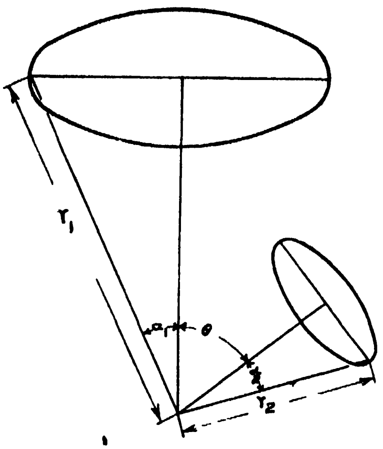

FIG. 3. The notation above $\gamma_2$ should read $\alpha_2$. The point at which the radii of the loops intersect should be labelled *O*.

of corresponding contributions $dA$ and $dA'$ is

$$\frac{d\mathbf{A}'}{d\mathbf{A}}=\frac{I'}{I}\cdot\frac{d\mathbf{s}'}{d\mathbf{s}}\cdot\frac{l}{l'}=\frac{K}{OP'}\cdot\frac{OP'}{OP}\cdot\frac{ON}{OP'}=\frac{ON}{K}. \qquad (13)$$

Hence the ratio of the two integrals themselves is given by the same constant.

From the transformation formula for the vector potential follows at once a simple formula relating the flux $\phi$ linked with a loop to the flux $\phi'$ linked with the image of this loop, provided each of the loops under consideration is again equidistant from the origin 0. The flux through such a loop can be calculated as $\phi=\oint\mathbf{A}d\mathbf{s}$, the integral being taken around the loop. The ratio of corresponding contributions to these integrals is (as $\mathbf{A}'\|\mathbf{A}$ and $d\mathbf{s}'\|d\mathbf{s}$)

$$\frac{\mathbf{A}'\cdot d\mathbf{s}'}{\mathbf{A}\cdot d\mathbf{s}}=\frac{ON}{K}\cdot\frac{ON'}{ON}=\frac{K}{ON}=\frac{\phi'}{\phi}. \qquad (14)$$

This is again a relation in which only the position of the "point of observation" enters, and not the position of the "causes."

If the flux through the loop (say, loop 1) is due to the fact that another loop (say, loop 2) carries a current $I_2$, we are led to a transformation formula for the mutual inductance $M_{12}$ between two such loops. It is

$$\phi_1=M_{12}\cdot I_2 \quad\text{and}\quad \phi_1'=M_{12}'\cdot I_2'. \qquad (15)$$

Hence

$$\frac{M_{12}'}{M_{12}}=\frac{\phi_1'/I_2'}{\phi_1/I_2}=\frac{K\cdot K}{r_1\cdot r_2}=\left(\frac{r_1'\cdot r_2'}{r_1\cdot r_2}\right)^{\frac{1}{2}}. \qquad (16)$$

The last formula is easily tested if we consider the mutual inductance between two circular loops, the axes of which intersect at an angle $\Theta$. (This angle can of course be zero, in which case we have two parallel, coaxial loops.) The value of this mutual inductance is given by Maxwell[6] by an expression of the form

$$M=r_2\cdot\Sigma_nC_n\left(\frac{r_2}{r_1}\right)^n=r_1\Sigma_nC_n\left(\frac{r_1}{r_2}\right)^n, \qquad (17)$$

where $r_1$ and $r_2$ denote the distances of the loops from the point 0 of intersection of the axes, and where the coefficients $C_n$ depend on the angle $\Theta$ and on the angles $\alpha_1$, and $\alpha_2$ which the radii of the loops subtend at *O* (see Fig. 3).

When this configuration is inverted, with 0 as center of inversion, we have

$$r_1'=K^2\ r_1, \quad r_2'=K^2/r_2$$

while $\alpha_1$, $\alpha_2$, and $\Theta$ remain unchanged. Hence

$$\frac{M'}{M}=\frac{r_2'\Sigma C_n\left(\dfrac{r_2'}{r_1'}\right)^n}{r_1\Sigma C_n\left(\dfrac{r_1}{r_2}\right)^n}=\frac{K^2}{r_1\cdot r_2}\,\frac{\Sigma C_n\left(\dfrac{r_1}{r_2}\right)^n}{\Sigma C_n\left(\dfrac{r_1}{r_2}\right)^n}=\frac{K^2}{r_1r_2} \qquad (18)$$

as required by Eq. (16).

If the loops are coaxial, any point on the common axis can be chosen as center of inversion. This can be used to transform the general case into various special cases. For instance, if we chose as center one of the points at which the common axis penetrates the sphere common to both loops, the two transformed loops will be co-planar. Another special case would be the transformation into loops of equal diameter, which is achieved by using as center of inversion the point at which the axis penetrates a sphere around the vertex of the cone common to both loops, the radius of this sphere being the geometrical mean of the distances of the two loops from this vertex (see the second method of apply-

---

[6] J. C. Maxwell, *A Treatise on Electricity and Magnetism*, Vol. 2, Chapter 14.

ing inversion to the problem discussed in the next section). It is, however, easily seen (by application of the formula given in the caption to Fig. 2) that in any such transformation the ratio of the shortest and the longest distance between these two loops remains invariant, which means (see below) that such transformation will not aid in evaluating the elliptic integral occurring in the formula for the mutual inductance.

## II. APPLICATIONS TO THE CASE OF A HIGH FREQUENCY SPHERICAL SCREEN

The theory developed in Section I can be usefully applied when we have to consider the screening effect of spherical metal "cans" at high frequencies. If the conductivity of such a screen is infinite, it is impermeable to magnetic flux at any frequency. Finite conductivity allows penetration of the field, though with the usual materials of construction such penetration is at radio frequencies limited to "skin depth." We may then either neglect this deviation from the ideal case altogether or take it into account by a simple approximation.

There are two ways in which the method of inversion can be applied to this problem, of which we shall consider first the more general one. Suppose that we are given a current loop—circular or otherwise—which is equidistant from the center of a hypothetical sphere, and further that we know the magnetic field produced by this loop. If we invert then from this center as center of inversion so that the sphere changes into itself, the loop will change into its image and we can predict from the theorems of Section I the field produced by this image. In particular, it follows from Eq. (14) that any test loop which we might draw on the surface of the sphere and that was linked with a certain amount, $\phi$, of the flux of the original loop will be linked with an identical amount, $\phi$, of flux produced by the image loop. Hence, if we take the correct sign for the current in the image loop, the sum total of the flux through the test loop will be zero. Thus the field produced by the combined action of original and image loop will have the property that none of its flux crosses the boundary of our hypothetical sphere, and we could introduce in its place an impermeable material screen without making any change to the field either inside or outside its boundary. Conversely, it follows that the effect of introducing such a screen on the field produced by the original loop could be simulated by the introduction of the image loop.

This allows us to calculate directly the change of self-inductance caused by the introduction of such a screen. We have, taking into account Eq. (10),

$$\Delta L = -M\cdot\frac{I'}{I} = -M\cdot\frac{r_0}{a}, \tag{19}$$

where $M$ is the mutual inductance between the image and the original loop and $r_0$ the distance of the latter from the center of the sphere of radius $a$.

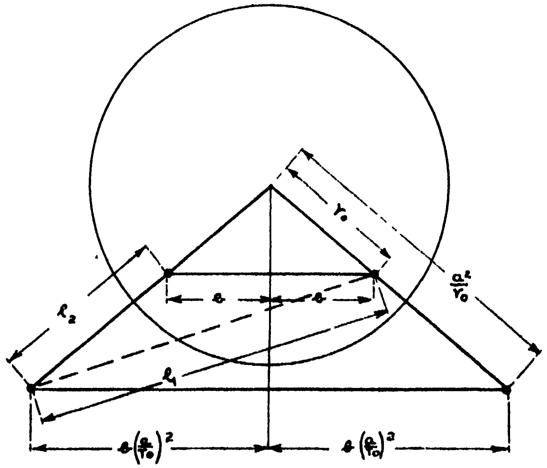
Similarly, the flux arising from the image loop causes a change in the mutual inductance between the original loop and any other loop (say, loop 2) inside the sphere of amount

$$\Delta M_{12} = -M_{12}'\cdot\frac{r_0}{a}, \tag{19a}$$

where $M_{12}'$ denotes the mutual inductance between the image loop and the second loop.

In the case of circular loops formula (19) is easily evaluated, for the two loops are then coaxial and parallel (Fig. 4), and their mutual inductance is given (references 6 and 7) by

$$M = 8\pi\left(\frac{bb'}{k}\right)^{\frac{1}{2}}(K-E), \tag{20}$$



$r_0$
$\frac{a^2}{r_0}$
$e$
$e$
$\ell_2$
$\ell_1$
$e\left(\frac{a}{r_0}\right)^2$
$e\left(\frac{a}{r_0}\right)^2$

FIG. 4.

---

[7] A. Russel, J. Inst. Elec. Eng. 67, 659 (1929).

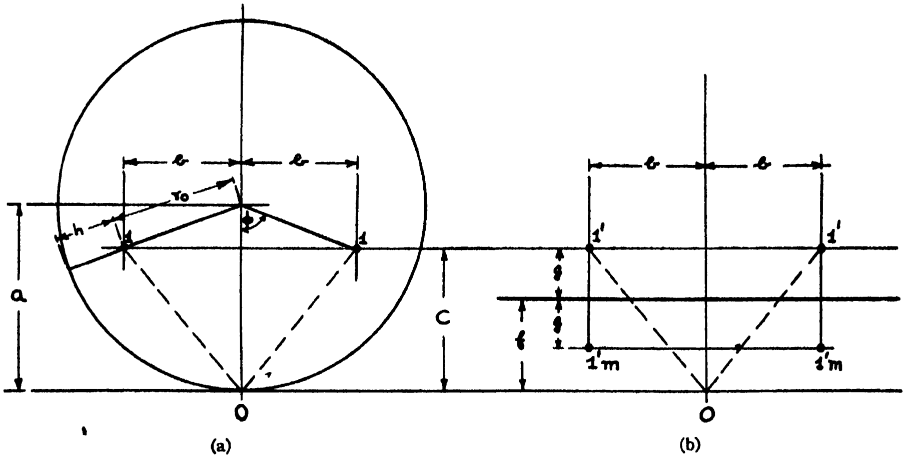


FIG. 5. Constant of inversion $K^2 = b^2 + c^2 = b^2 + (a - r_0 \cos\phi)^2$
$f = \frac{b^2+c^2}{2a}$ and $g = c - f = \frac{a^2 - r_0^2}{2a} \approx h$ for $h \ll a$.

where $b$ and $b'$ are the radii of the two loops and $K$ and $E$ are the complete elliptic integrals of the first and second kind to modulus $k$. This modulus itself is given by

$$k = \frac{l_1 - l_2}{l_1 + l_2} = \frac{\lambda - 1}{\lambda + 1} \left(\lambda = \frac{l_1}{l_2}\right), \tag{21}$$

where $l_1$ and $l_2$ denote the largest and the smallest distance between the elements of the two loops. In the present case $b' = ba^2/r_0^2$, and therefore

$$\Delta L = -\frac{8\pi b}{(k)^{\frac{1}{2}}}(K - E). \tag{22}$$

For the same reason we have, with $\alpha = a/r_0$, $\beta = b/r_0$ and $\nu = \alpha - 1/\alpha$

$$\lambda = \left(1 + \left(\frac{2\beta}{\nu}\right)^2\right)^{\frac{1}{2}}. \tag{23}$$

Evaluation of Eq. (20) is facilitated by extensive tabulation (references 6, 8, 9). There exists also a truly embarrassing number of approximations, (reference 9) so that it is perhaps useful to quote two which are simple but sufficient for slide-rule accuracy, (reference 7).

If $k < 0.9$, that is $\lambda < 20$ (that is in our case for loops which are not too close to the wall of the screen $P$) we have with an error of less than 6/10 of a percent

$$K - E = \frac{\pi k^2}{1 + 3(1 - k^2)^{\frac{1}{2}}}. \tag{24}$$

If $k$ is larger than 0.9 we have, with an error of less than ½ percent,

$$K - E = \tfrac{1}{2}(k)^{\frac{1}{2}}\left[\log_e 4 \cdot \frac{1+k}{1-k} - 2\right]. \tag{25}$$

The case of a very small loop can of course be dealt with in an elementary way. If the loop should be in the center of the sphere (Kaden's problem) we have the specially simple case that the image loop is infinitely distant, producing an image field that is homogeneous. The strength of this field can be found directly from the condition that the combined flux across the sphere must be zero everywhere. As the loop creates there a field strength (for unit current) equal to $2b^2\pi/a^3$ at those places where the sphere is penetrated by the axis of the loop, this too must be the strength of the image field. The image field sends then

$$\phi = b^2\pi \cdot 2b^2\pi/a^3 \tag{26}$$

---

[8] Circular C74 of the Nat. Bur. Stand. Washington (1924), reprinted 1937. A similar table is contained in Terman's *Handbook for Radio Engineers*. Further and more extensive tables are given by F. W. Grover, "Tables for the calculation of the mutual inductance of circuits with circular symmetry about a common axis," Sci. Pap. Bur. Stand. 20, (1926) and F. W. Grover *Inductance-Calculation* (D. Van Nostrand Company, Inc., New York, 1946).

[9] See the survey given by F. W. Grover in "Methods for the derivation and expansion for formulas for the mutual inductance of coaxial circles and of the inductance of single layer solenoids," Bur. Stand. J. Research 1, 487 (1928).

flux lines through the original loop, i.e.,

$$\Delta L = -2\pi^2 b\left(\frac{b}{a}\right)^3. \tag{27}$$

If the loop is placed eccentrically (distance $r_0$ from the center of the sphere) it follows similarly from Eq. (7) that

$$\Delta L = -2\pi^2 b\left(\frac{b}{a}\right)^3\left(\frac{\alpha^2}{\alpha^2-1}\right)^3. \tag{28}$$

The limiting case at the other end of the range is a loop that has from the screen only the very small clearance distance $h$. It can be shown that then the effect of the screen is identical with that of an impermeable plane that is parallel to the loop at a distance $h$. This particular case gives us an opportunity to illustrate shortly the second method of applying inversion which we mentioned at the beginning. Here we take as the center of inversion one of the points at which the axis of the loop penetrates the sphere. The sphere transforms then into a plane impermeable to flux. Without restricting the generality of the treatment we can select the constant $K$ of inversion so as to have the original loop transform into itself. With this particular choice of $K$ the current through the transformed loop will be of the same magnitude as in the original loop. The transformation is illustrated in Figs. 5a and 5b; this figure shows too how the transformed arrangement can be solved by the introduction of the mirror image $l_m'$ of the transformed loop $l'$.

If the walls of the spherical screen are not of infinite conductivity, the high frequency field penetrates to skin thickness and causes losses. These losses are calculated by Davidson and Simmonds for the case of the centrally situated loop. They can be calculated in a more general way if we make use of Wheeler's concept of the equivalent magnetic skin thickness ($=\frac{1}{2}$ conducting skin thickness). If the walls of the container of infinite conductivity are receded by the equivalent magnetic skin thickness, the magnetic energy of the field is increased (for constant input current) by just the same amount as if the field had penetrated into the walls of finite conductivity. (This is the definition of equivalent magnetic skin thickness.) The increase in loop reactance caused by this increase in field energy can easily be calculated, and, as the phase angle of such surface dissipation is always 45 degrees, this increase in reactance is numerically equal to the ohmic impedance component caused by the field penetration (reference 10).

In the present case, if the radius of the screen $a$ is increased by $\delta a$, the (negative) inductance increment $\Delta L$ previously found is varied by

$$\delta L = \left(\frac{\partial L}{\partial a}\right)\delta a. \tag{29}$$

Hence,

$$\delta R = 2\pi f\left(\frac{\partial L}{\partial a}\right)t_m, \tag{30}$$

where $f$ frequency of the field and $t_m = t/2$ equivalent magnetic skin thickness. The latter can be expressed in terms of the surface resistivity $R_s$ of the wall material. We have for the conducting skin thickness $t = 1/2\pi(\rho/f)^{\frac{1}{2}}$[$\rho$ = volume resistivity], and

$$t_m = \frac{t}{2} = \frac{R_s}{8\pi^2 f}$$

hence

$$t^2 = \frac{1}{4\pi^2}\frac{\rho}{f} = \frac{1}{4\pi^2}\cdot R_s\cdot t. \tag{31}$$

Equation (30) allows us to write down immediately Kaden's result for the resistance component. By differentiation of Eq. (27) we obtain

$$\delta R = \tfrac{3}{2}\pi\cdot\left(\frac{b}{a}\right)^4\cdot R_s.$$

There is no difficulty involved in evaluating Eq. (30) in a more general case, and, for instance, Davidson and Simmonds' result for $\delta R$ can be obtained from their series for $\delta L$ by term differentiation. Differentiation of the general expression given in Eq. (22) leads to a rather laborious expression which is therefore not given, as for all practical purposes it is sufficient to replace the differential quotient by a difference quotient, the latter being easily obtained by direct numerical calculation.

# Non-Linear Viscous Elasticity and the Eyring Shear Model*

GEORGE HALSEY**

(Received April 17, 1947)

Attempts to analyze stress-strain-time relationships observed in experiments with textile fibers have been reported in a series of papers. This work has led to some general conclusions: First, the simplest three element model (spring in parallel with another spring and a dashpot in series) is adequate for the approximate explanation of a wide range of the data obtained. Second, the viscous element (dashpot) almost always appears to be non-Newtonian while the springs less frequently are non-Hookean. Third, the most striking deviations from simple behavior indicate, not a more complex model consisting of many simple elements, but that the assumed laws governing the viscous, or less frequently, elastic elements are themselves too simple.

Frequently a more complex law or laws will restore the three-element model to approximate agreement with the experimental facts. Finally, any system so far investigated can be made to show the presence of a number or a distribution of relaxation times by prolonging the experiment over a period of time, or more positively, by going to a point of no instantaneous relaxation, and waiting for the inevitable long period of relaxation to appear. Procedures to deal with the general situation described here are presented.

The paper begins with a condensed but essentially self-contained summary of the theoretical portions of the series of papers that preceded it. The original presentation has been clarified and recast in a form more in harmony with the present work. For experimental evidence, and supplementary information, the reader is referred to the original series.

The paper continues with a discussion of the various aspects of non-linear viscous elasticity, including the topics: Six rules for analyzing stress-strain curves (presented at the meeting of the Division of High-Polymer Physics of the American Physical Society, January 31, 1947); the thixotropic viscous element, where for convenience, complex situations, in which the populations of various states enter into a time-variable viscosity, have been gathered under the name "thixotropy"; constant force springs, where a particularly non-Hookean behavior is described.

## INTRODUCTION

TO make a beginning in understanding the stress-strain behavior of a material[1] like a textile fiber or a plastic, a simple mechanical analogy has much to recommend it. The stress-strain relationship of most materials is not independent of time; thus, a simple elastic element (a spring) does not suffice to duplicate the behavior. Since immediate elongation is generally observed upon increasing the load, however, a spring effect initially unrestrained by viscous forces at the rate of loading in question is required. The existence of hysteresis, which is almost never absent, indicates that a viscous element (dashpot) must be incorporated in the model. The viscous element is restrained from free motion, by a spring, because in a majority of cases, the flow at constant load does not continue at a constant rate, showing that the force initially concentrated on the viscous element ultimately shifts to a spring.

The arrangement of elements indicated by this qualitative analysis is shown in Fig. 1. The two arrangements are almost equivalent, and, when Hooke's law is written for both springs, they are represented by identical equations. When a model of this kind is elongated at a constant rate, the stress-strain curve will begin at a steep slope, and then bend over as the yield force of the dashpot is reached. In terms of the first arrangement of the three elements (Fig. 1*a*), the stress-strain curve is made up of a line of slope equivalent to the sum of the stiffnesses of both springs being elongated together, followed by a transition region, leading to a line of slope corresponding to

the stiffness of the spring in parallel with the dashpot (Fig. 2).

These relationships will be expressed mathematically. If the total force on the model is $F$, and its elongation (change in length/original length) is $l$, the condition of experiment is $l=\rho t$, where $t$ is the time and $\rho$ is the rate of elongation. The problem is to find $F$ as a function of $t$. If $f$ is the force on the dashpot, and $l_1$ its elongation, $F-f$ is the force on the spring in parallel, and $l-l_1$ is the elongation of the spring in series. Hooke's law will be assumed to hold for the springs, and Newton's law of viscosity will be written for the dashpot. Thus the problem being solved is the linear three-element model operating at a constant rate of elongation. The equations governing these elements are

$$F-f=k_2l, \qquad (1)$$

$$f=k_1(l-l_1) \qquad (2)$$

for the two springs, and

$$dl_1/dt=f/\eta \qquad (3)$$

for the dashpot, and

$$dl/dt=\rho, \qquad (4)$$

the condition of experiment.

At this point, it is to be noted that the force $F$ on the whole system can be separated into two parts easily recognizable on the stress-strain curve, shown in Fig. 2. The broken line in this figure represents a line parallel to the ultimate slope, and starting at the origin. This line gives the force, $F-f$, on the spring in parallel with the dashpot as a function of strain. $F-f$ is a very simple function of elongation alone, and attention can now be directed to the residue of the force on the system, the difference between the ordinates of this line and those of the stress-strain curve itself. This difference, of course, is $f$, the force on the dashpot and spring in series, making up a Maxwell element. This function of $f$ *versus* $t$ is referred to as the "working curve." Eliminating $l$ and $l_1$ from Eqs. 2–4 gives

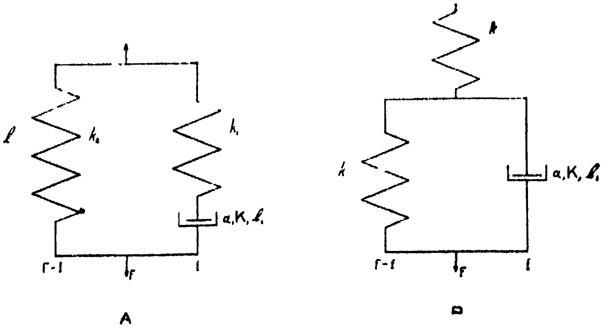

FIG. 1. Three-element model.

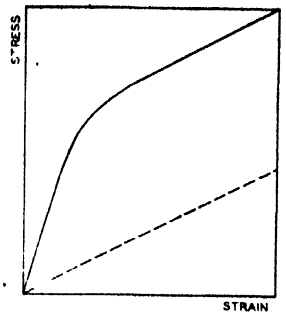

FIG. 2. A typical stress-strain curve.

$$(1/k_1\rho)(df/dt)=1-(f/\eta\rho). \qquad (5)$$

Writing

$$f/\eta\rho=\phi \qquad (6)$$

and

$$tk_1/\eta=\tau \qquad (7)$$

to absorb constants gives the dimensionless equation

$$d\phi/d\tau=1-\phi \qquad (8)$$

which can be integrated to

$$1-\phi=\text{const.}e^{-\tau}.$$

If $\phi=0$ when $\tau=0$ the constant becomes unity, and

$$\phi=1-e^{-\tau}. \qquad (9)$$

Now at this time it becomes desirable to introduce the idea of reduced variables. Equation (9) can be written in the form

$$af=1-e^{-bt}, \qquad (10)$$

where $a$ and $b$ are constants that must be adjusted to whatever units are selected for $f$ and $t$. If some natural unit of the curve is selected as the unit of measurement, what is called a reduced variable is defined. A procedure of this kind is often adopted when working with equations of state and it will be used here. Thus, the ultimate value of $f$ will be called unity, and $t$ will be called unity when $f=\frac{1}{2}$, in the reduced units. The constants $a$ and $b$ can then be com-

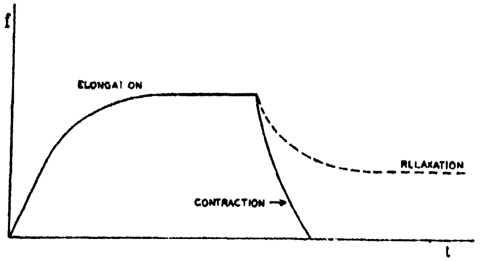

FIG. 3. Force on the dashpot as a function of time for elongation, contraction, and relaxation

puted when

$$t=\infty, \quad f=1, \qquad (11)$$
$$f=\tfrac{1}{2}, \quad t=1.$$

Therefore, from (10), $a=1$ and $\frac{1}{2}=1-e^{-b}$, so

$$b=\log_e 2=\ln 2$$

In reduced units, then,

$$f=1-e^{-t\ln 2}. \qquad (12)$$

The general nature of the curve is that of an exponential curve asymptotic to $f=1$, and for future reference, it should be noted that the force at the point $t=2$

$$f_2=1-\tfrac{1}{4}=0.75.$$

When the linear three-element model is relaxing at constant length, the problem is a very simple one, because $F-f$, the force on the parallel spring, is constant. Solving Eqs. (2) and (3) with $l$ constant gives

$$(1/k_1)(df/dt)=-f/\eta \qquad (13)$$

which yields a simple unimolecular decay law

The situation grows somewhat more complex when the usual repeated cycle stress-strain curve is considered. The separation of $F$ into $F-f$ and $f$ now has great utility. The force on the parallel spring is simply a function of elongation, and attention can be focused on the behavior of the dashpot and spring in series. Consider the working curve (Fig. 3) taken at a constant rate of elongation. If suddenly the elongation be halted, the relaxation curve begins, following Eq. (13). If the working curve be quite near its ultimate value, the dashpot is flowing at a rate equal to $\rho$, the over-all rate of elongation and the spring has ceased to elongate. This is shown by the constant value of the force. Therefore, when the elongation ceases, the dashpot will be flowing on at a rate equal to the over-all rate, and the force on the series spring will decay at exactly the same instantaneous rate as the initial slope near $t=0$ when the spring was being loaded at the over-all rate, $\rho$.

Now, if instead of stopping for relaxation the rate of elongation is reversed, at the ultimate value of $f$, then the force will be decaying for two reasons. The dashpot is still elongating at an instantaneous rate $\rho$, and the series spring is being shortened by another $\rho$. The total rate of decay is $2\rho$, and so, the instantaneous slope upon reversal when $f_{\text{reduced}}=1$ is twice the initial slope. As the contraction at rate $\rho$ proceeds, the slope decreases, for obviously, when $f=0$ the slope must be the initial slope, because the dashpot is no longer moving at all. As further contraction into the region of negative tension occurs, the situation is the same as in the initial elongation except that the sign of $f$ becomes negative.

The equation for this region is still the familiar (12). Then, because the region of steep slope occurs without an intervening reversal at a time preceding the familiar region, it becomes apparent that the equation for this region is also (12), but in the region of negative time. The slope at any value of $\phi$ is obtained from (8), and it is seen that at $\phi=-1$, the slope is twice that of $\phi=0$.

The working curve for positive and negative values of time is shown in Fig. 4. Using this curve, the stress-strain curve for many cycles of elongation and contraction is easily constructed with a pair of dividers and a ruler. The sawtooth pattern of the force on the spring in parallel is first marked out, putting in a horizontal sec-

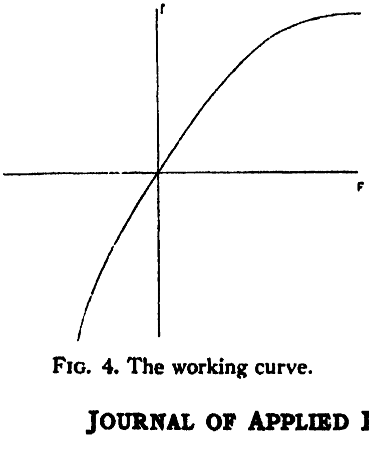

FIG. 4. The working curve.

tion for every relaxation. Then, starting at any point when $f$ is known to be zero, the curve is laid out measuring the $f$ value from the working curve. Whenever the direction of elongation reverses, the force value is measured from the other branch of the working curve, that is, where the value of $f$ is the same except for sign. Now it is quite clear that if the shape of the working curve is known, this process of calculation of a complex curve can be generalized. None of the laws has to be linear. The only restriction, at the moment, is that the viscous drag at a given rate be the same for moving the dashpot forward as for moving it backward. Actually, to calculate the working curve depends on the ability to integrate the equation, but this integration can always be found by numerical means.

With this generality available, the question arises "when is the three-element arrangement itself permissible?" The answer to this question lies in a study of the points where $f=0$, that is, when the stress-strain curve crosses the line ($F-f$ *vs.* $l$) representing the force on the spring in parallel. At this point, there will be no relaxation. On either side of it, relaxation will occur in opposite directions, tending toward it. These "points of no relaxation" lie on a line that is a function of elongation alone. By a study of experimental points of no relaxation, it can be ascertained that they are a function of elongation, alone. If they are, their totality of points forms the line representing $F-f$, the force on the parallel spring, which for convenience is referred to as the "spring line."

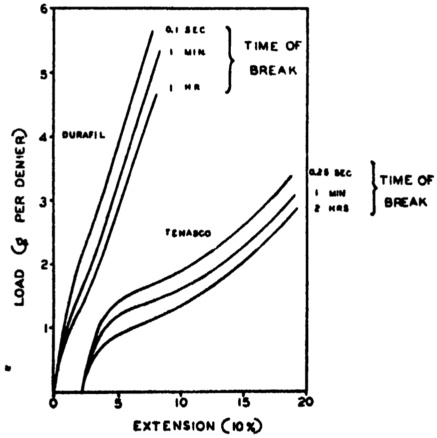

FIG. 5. Effect of rate of loading on load-elongation properties of regenerated cellulose rayons at 20°C and 65 percent R.H.

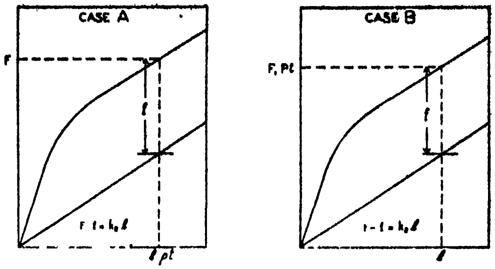

FIG. 6. The manner in which the various quantities are determined from the stress-strain curve; *A*, at constant rate of elongation, and *B*, at constant rate of loading.

A change in rate of experiment produces quite striking results. On the assumption of the Newtonian viscous element the force at a given elongation should be a linear function of the rate of elongation. Contrary to this, the function is found to be more nearly logarithmic. For example, D. Entwistle, in the third John Mercer Lecture,[2] publishes a curve (Fig. 5) showing the rate of elongation changed over a factor of 28,800 with the curves arranged in such a manner that he states: "Over a considerable range there is an approximately linear relationship between breaking load and the logarithm of the time of break." Because the breaking elongation is relatively independent of rate, this is equivalent to stating that the logarithmic law holds at any given elongation, since the curves parallel one another. This situation is entirely incompatible with any linear model, but harmonizes very well with the Eyring viscous element, or for that matter, any exponential law of flow.

In 1936 Eyring[3] proposed his law for viscosity in shear:

$$\text{rate of shear} = 2(V_h/V_m)(kT/h)e^{-\Delta F\ddagger/kT} \sinh f V_h/2kT, \quad (14)$$

where $V_h$ is the volume of the flow "hole," $V_m$ is the volume of the molecule, $k$ is Boltzmann's constant, $T$ is temperature, $h$ is Planck's constant, $\Delta F\ddagger$ is the free energy of activation for flow, and $f$ is the shear stress. This can be written for the present as

$$dl_1/dt = K \sinh \alpha f. \quad (15)$$

---

[2] D. Entwistle, J. Soc. Dyers and Colourists 62, 261 (1946).

[3] Henry Eyring, J. Chem. Phys. 4, 263 (1936).

The problem of the three-element model incorporating this viscous element will now be solved. It is a quite general law, and it includes the Newtonian law as a special case. The equations governing the model are:

$$F-f=k_2l,$$
$$f=k_1(l_1-l_1),$$
$$dl_1/dt=K\sinh\alpha f,$$

and, for the condition of experiment,

$$pF+ql+rt=0.$$

This equation represents the most general restraint that can be integrated conveniently. It includes, as special cases, a constant rate of elongation, $\rho$, and a constant rate of loading, $P$. For these two cases the various variables are measured in the manner shown in Fig. 6. Also governed by this equation are the results of the pendulum-type tester, if the movement of the upper jaw is proportional to the load. Solving these equations for $f$ as a function of $t$ yields the equation

$$-\left(\frac{1}{k_1}+\frac{p}{pk_2+q}\right)\frac{df}{dt}-\frac{r}{pk_2+q}=K\sinh\alpha f. \quad (16)$$

This equation is of the form

$$\beta-d\phi/d\tau=\sinh\phi, \quad (17)$$

which is integrated to give

$$\frac{2}{(1+\beta^2)^{\frac{1}{2}}}\tanh^{-1}\left\{\frac{e^{+\phi}-\beta}{(1+\beta^2)^{\frac{1}{2}}}\right\}=\tau-c$$

Solving this equation for $\phi$ gives

$$\phi=\ln\left\{\beta+(1+\beta^2)^{\frac{1}{2}}\tanh\left[\frac{(1+\beta^2)^{\frac{1}{2}}}{2}(\tau-c)\right]\right\}. \quad (18)$$

When $\tau=0$, $\phi=0$, so

$$c=\frac{2}{(1+\beta^2)^{\frac{1}{2}}}\tanh^{-1}\left\{\frac{\beta}{(1+\beta^2)^{\frac{1}{2}}}\right\}. \quad (19)$$

Now, it is desired to obtain a reduced equation, so following a procedure like that employed in the linear case, the equation

$$af=\ln\left\{\beta+(1+\beta^2)^{\frac{1}{2}}\tanh\left[\frac{(1+\beta^2)^{\frac{1}{2}}}{2}(bt-c)\right]\right\} \quad (20)$$

is solved for $a$ and $b$, under the conditions that when $t=\infty$, $f=1$, and when $t=1$, $f=\frac{1}{2}$. After a series of algebraic manipulations the reduced equation

$$f=\frac{\ln\left\{\dfrac{1+\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}\tanh(At)}{1+\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}\tanh(At)}\right\}}{\ln\left\{\dfrac{1+\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}}{1+\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}}\right\}} \quad (21)$$

is obtained, where

$$A=\tanh^{-1}\left\{\frac{\left[\left(\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}+1\right)\left(\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}+1\right)\right]^{\frac{1}{2}}-1}{\left(\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}+1\right)\left(\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}+1\right)-1}\right\}. \quad (22)$$

With this function of $t$ and $\beta$ it is possible to calculate a whole family of working curves, depending on the shape factor, $\beta$. The larger $\beta$ is, the more non-Newtonian is the behavior of the working curve. To compute $\beta$ from the working curve, the behavior of the reduced force at some suitable value of $t_{\text{red}}$ can be investigated. It was shown above that for the Newtonian case for $t=2$, $f=0.75$. In the non-Newtonian case this force is always larger, approaching unity as $\beta$ increases indefinitely. The quantity $f_2$ *versus* $\beta$ is shown in Fig. 7.

The meaning of the increase of $f_2$ with $\beta$ is found in the fact that the more non-Newtonian a dashpot is, the more insensitive it is to forces below the yield force. In the limit, the com-

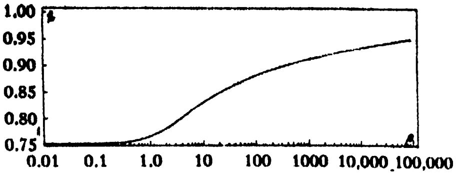

FIG. 7. Diagram for evaluating $\beta$ from the reduced force, $f_2$, acting on the dashpot at a time, $t_2$, which is twice the time elapsed from the application of the load until it reaches one-half its final value.

pletely non-Newtonian dashpot yields quite sharply at a given force, independent of the rate of elongation, and does not move below this force. For practical purposes of constant evaluation the shape factor is only of the roughest significance, but at this point it is appropriate to give the constants of the viscous law as a function of the observed quantities. For the case of a constant rate of elongation $K=\rho/\beta$ and $\alpha=1/f_\infty$ arc sinh$\beta$. The ultimate value of the force on the dashpot is written $f_\infty$. Similarly for the case of constant rate of loading, $P$, $K=P/\beta k^2$ and

$$\alpha=1/f_\infty \text{ arc sinh}\beta.$$

Various other ways of evaluating $\beta$ are given in the original references, along with a treatment of relaxation and creep and a more detailed discussion of the Eyring viscous element.

The practicable way of evaluating $\beta$ is found when the change of the ultimate force, $f_\infty$, with rate of elongation is considered. If $r_n$ is the ratio of $f_\infty$ at a speed $n$ times a basic speed $\beta$, to $f_\infty$ at the unit speed, then one has

$$r_n=f_\infty(n)/f_\infty(1)=\phi_n/\phi_1, \tag{23}$$

$$\phi_1=\text{arc sinh}\beta,$$
$$\phi_n=\text{arc sinh}n\beta,$$

and, therefore,

$$r_n=\text{arc sinh}n\beta/\text{arc sinh}\beta. \tag{24}$$

Therefore, $\beta$ can be determined as a function of $r_n$. If $\beta$ is large, the approximation arc sinh$\beta$ $\approx \ln 2\beta$ holds, and $\beta$ can be found explicitly:

$$\beta=\tfrac{1}{2}n^{(1/r_n-1)}. \tag{25}$$

This equation provides a way to determine $\beta$ as a function of scale factors alone, and independent of shape.

The three-element non-Newtonian model is quite successful in accounting, qualitatively at least, for many stress-strain curves. It should be emphasized that the non-Newtonian nature of the dashpot is responsible for its remarkable qualitative fidelity. In complicating the three elements, very little progress can be made merely by having many Newtonian elements hooked together. Most existing material concerning the visco-elastic behavior of materials, however general and formal, has in it somewhere the assumption that the governing equations are linear. This is particularly true of the so-called superposition principle. The utility of such schemes is thus strictly limited. In fact, linear systems are usually found only in highly plasticized systems where the stresses are in the region of $10^7$ dynes per square centimeter. In textiles, where stresses are of the order of $10^9$ dynes per square centimeter, no case has come to the author's attention. Further discussion of this topic is found in the original references. The most fruitful complications are found when the elements themselves are changed, retaining the three element model.

In deriving the Eyring viscous law, the assumption is made that flow is retarded by a symmetrical potential barrier. It was always realized that this simplification might be unjustified, and it has been observed that it is often not available. That is, the force, notably in the case of wool, is much more effective in producing flow in one direction than in the opposite one. Clearly, if the potential barrier is unsymmetrical, the rate of reaction up the steep side will be less affected by the force than the rate up a more gradual slope. This, then, is in harmony with the experimental observation. With an unsymmetrical barrier, the expression for the rate of shear is

$$dl_1/dt=(K/2)(e^{2\mu\alpha f}-e^{-2(1-\mu)\alpha f}), \tag{26}$$

where $\mu$ is the symmetry coefficient. The form

$$dl_1/dt=Ke^{+(2\mu-1)\alpha f}\sinh\alpha f \tag{27}$$

is equivalent to this expression, which shows the perturbing influence of the lack of symmetry on the original hyperbolic sine law. For convenience, $\sigma$ is written for $2\mu-1$.

Using this new viscous law, the equation governing the working curve becomes

$$\beta-(d\phi/d\tau)=e^{+\sigma\phi}\sinh\phi, \tag{28}$$

which gives

$$-\tau=\int\frac{d\phi}{\beta+e^{\sigma\phi}\sinh\phi}, \tag{29}$$

which is not integrated. The measurement of the ratio

$$(f_n/f_1)_\infty=(\phi_n/\phi_1)_\infty$$

still permits determination of the constants, even if the exact shape of the working curve is not calculated.

Using the notation $\phi_1{}^{\text{out}}$ for the ultimate value of $\phi$ with the dashpot going forward at speed 1, and similarly $\phi_n{}^{\text{out}}$, $\phi_1{}^{\text{in}}$, and $\phi_n{}^{\text{in}}$ for the other three ultimate values, the equations when $d\phi/d\tau$ becomes zero, are

$$\begin{aligned}\beta&=e^{+\sigma\phi_1{}^{\text{out}}}\sinh\phi_1{}^{\text{out}},\\ n\beta&=e^{+\sigma\phi_n{}^{\text{out}}}\sinh\phi_n{}^{\text{out}},\\ \beta&=e^{-\sigma\phi_1{}^{\text{in}}}\sinh\phi_1{}^{\text{in}},\\ n\beta&=e^{-\sigma\phi_n{}^{\text{in}}}\sinh\phi_n{}^{\text{in}}.\end{aligned} \tag{30}$$

Using the approximation $\sinh x\approx e^x/2$ for large $x$, these equations become

$$\begin{aligned}\ln 2\beta&=(1+\sigma)\phi_1{}^{\text{out}},\\ \ln n+\ln 2\beta&=(1+\sigma)\phi_n{}^{\text{out}},\\ \ln 2\beta&=(1-\sigma)\phi_1{}^{\text{in}},\\ \ln n+\ln 2\beta&=(1-\sigma)\phi_n{}^{\text{in}}.\end{aligned} \tag{31}$$

From this set of equations, a set of ratios may be derived as follows:

$$R^{\text{out}}=(\ln 2\beta+\ln n)/\ln 2\beta=R^{\text{in}}, \tag{32}$$

$$R_n=(1+\sigma)/(1-\sigma)=\phi_n{}^{\text{in}}/\phi_n{}^{\text{out}}; \tag{33}$$

where

$$\begin{aligned}R^{\text{out}}&=\phi_n{}^{\text{out}}/\phi_1{}^{\text{out}}=f_n{}^{\text{out}}/f_1{}^{\text{out}},\\ R^{\text{in}}&=\phi_n{}^{\text{in}}/\phi_1{}^{\text{in}}=f_n{}^{\text{in}}/f_1{}^{\text{in}},\\ R_n&=f_n{}^{\text{in}}/f_n{}^{\text{out}}.\end{aligned}$$

From these equations for large $\phi$ $\beta=\frac{1}{2}n^{1/R-1}$ (as is found for this approximation when $\sigma=0$), and

$$\sigma=\frac{R_1-1}{R_1+1}=\frac{R_n-1}{R_n+1}, \tag{34}$$

or

$$\mu=\frac{R_1}{R_1+1}=\frac{R_n}{R_n+1}, \tag{35}$$

where the formulas with $R_n$ are obviously better approximations.

In the other approximation, where $\phi$ is small, the four equations become so simple that $\sigma$ disappears completely, in harmony with the necessary equality at the rates of reaction at equilibrium, satisfying the principle of detailed balancing.

As a second degree of approximation, consider that $\beta=\beta_0+\beta_1$, $\sigma=\sigma_0+\sigma_1$, and $\phi_1{}^{\text{out}}=\phi_0+\phi_1$, where $\phi_0=(1+\sigma_0)^{-1}\ln 2\beta_0$. Upon expansion in the small correction factors, using the approximate equation for the zero-order values, closer values for the constants can be found.

Of some utility is the limiting concept of the completely unsymmetrical barrier, where $\mu=1$. Flow in one direction is not affected by force at all. The equation for shear becomes

$$dl_1/dt=(K/2)(e^{2\alpha f}-1). \tag{36}$$

If the slightly altered definitions $\phi=2\alpha f$, $\beta=(2\rho/K)+1$, and

$$\tau=k_1\alpha Kt$$

are made, the differential equation for the working curve becomes

$$\beta-(d\phi/d\tau)=e^{\phi}, \tag{37}$$

which yields

$$\tau+\text{const.}=(1/\beta)[\phi-\ln(\beta-e^{\phi})]. \tag{38}$$

A reduced equation will be obtained, subject to the conditions, that when

$$\begin{aligned}t&=0, & f&=0\\ t&=\infty, & f&=1\\ t&=1, & f&=\tfrac{1}{2}.\end{aligned}$$

The equation is

$$t=\frac{(f\ln\beta-\ln(\beta-e^{f\ln\beta})+\ln(\beta-1))}{(\ln\sqrt{\beta}-\ln(\beta-\sqrt{\beta})+\ln(\beta-1))}, \tag{39}$$

an equation which changes when $-f$ is substituted for $f$.

The only type of experiment considered above was one in which a linear relationship existed between force, elongation, and time:

$$pF+ql+rt=0,$$

because only this restraint makes the equations amenable to simple treatment. In practice, it is often desirable to calculate behavior that is characterized by its dependence on any restraint, assuming in this discussion that the constants of the model have been evaluated from simple experiments and hence are available for computation. However, in solving even the simplest cases analytical difficulties are met, and it is of interest to consider here simple point-by-point methods. The method of synthesizing the total force, $F$, from the partial forces, $f$, on the dashpot and spring in series, and $F-f$, on the single spring will be employed, as before. If the restraint is of the form $l=R(t, F)$, then $F-f=k_2l=k_2R(t, F)$. The value of $f$ must be considered with more care. First the case of constant rate is considered. The value of $\phi$ is

$$\phi=\ln\left\{\frac{1+\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}\tanh\dfrac{\tau}{2}(1+\beta^2)^{\frac{1}{2}}}{1+\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}\tanh\dfrac{\tau}{2}(1+\beta^2)^{\frac{1}{2}}}\right\} \tag{40}$$

with a new set of normalization conditions.

The time values were normalized previously to the half-value of the ultimate force (that is, when $t=1, f=\frac{1}{2}$), but now the ratios between the initial slopes must be preserved in their proper values. This is made necessary by the new variable that is now considered. Thus, the three conditions defining the old reduced variables variables were as follows: when

$$\begin{aligned} f&=0, & t&=0,\\ f&=\tfrac{1}{2}, & t&=1,\\ f&=1, & t&=\infty, \end{aligned}$$

and the definitions of the new reduced variables are as follows: when

$$\begin{gathered} f=0, \qquad t=0\\ Kak_1=1,\\ \alpha=1. \end{gathered}$$

This curve, or family of curves, depending on $\beta$, is adequate to predict the value of $f$ from its initial value, $f_0$, as long as $f_0$ is below $f_\infty$ in value. For values of $f_0$ greater than $f_\infty$ it is necessary to determine the family of curves where the extreme boundary value $f_0=\infty$ is employed. The general solution

$$f=1/\alpha\ \ln[\beta+(1+\beta^2)^{\frac{1}{2}}\tanh(bt+c)] \tag{41}$$

yields at $f=\infty$, $t=0$

$$\begin{aligned} \infty &=\ln[\beta+(1+\beta^2)^{\frac{1}{2}}\tanh c],\\ c&=\pi/2(-1)^{\frac{1}{2}}. \end{aligned}$$

This yields, as a special solution,

$$\phi'=\ln\left\{\beta+\frac{(1+\beta^2)^{\frac{1}{2}}}{\tanh bt}\right\}. \tag{42}$$

(The constant $b$ is then $(1+\beta^2)^{\frac{1}{2}}$ to agree in scale with $f$.) This equation represents a family of curves asymptotic to $t=0$ and $f'=f_\infty$, because when $t=\infty$

$$\phi_\infty'=\ln[\beta+(1+\beta^2)^{\frac{1}{2}}], \tag{43}$$

and for the other set of curves passing through $t=0, f=0$

$$\phi_\infty=\ln\left\{\frac{1+\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}}{1+\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}}\right\} \tag{44}$$

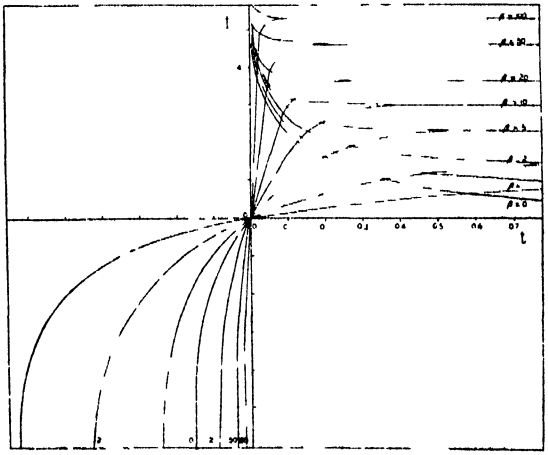

FIG. 8. The working curves for various values of $\beta$ from 1 to 100.

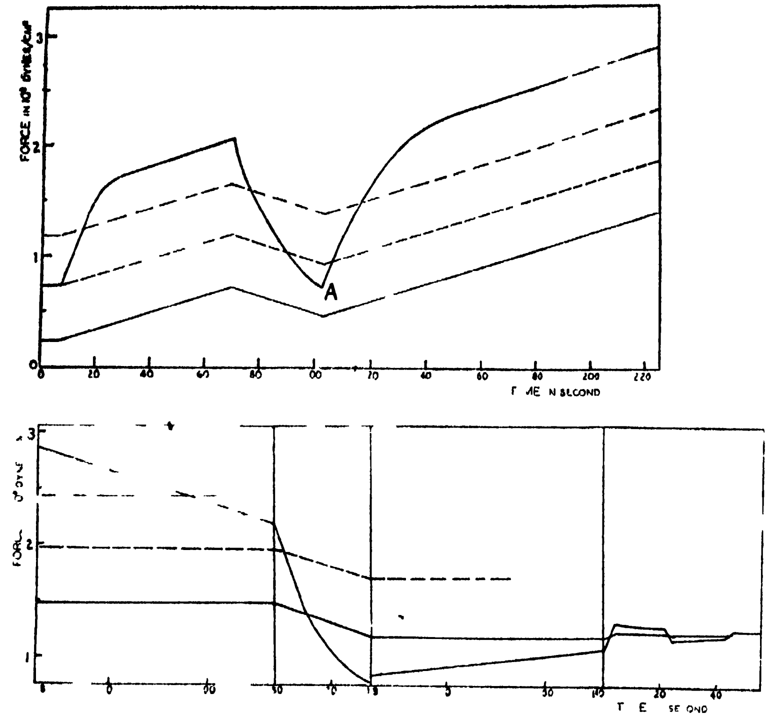

FIG. 9 A typical stress-strain curve showing the inadequacy of the three-element model It is 6-denier textile rayon, elongated at a rate $6\ 5\times 10^{-4}$ per second at 0 35 R H

and, since

$$\beta+(1+\beta^2)^{\frac{1}{2}}=\frac{1+\dfrac{1+\beta}{(1+\beta^2)^{\frac{1}{2}}}}{1+\dfrac{1-\beta}{(1+\beta^2)^{\frac{1}{2}}}}=e^{\text{arc sinh}\,\beta},$$

$$\phi_\infty{}'=\phi_\infty$$

These two families, which together cover the entire range of $f$ from $-\infty$ to $\infty$, are plotted in Fig. 8. Thus with a given velocity and initial conditions, subsequent conditions can be predicted at that velocity by following the proper curve But since

$$l=R(F,t),$$

or $$dl/dt=\rho=R'(F,t) \tag{45}$$

is no longer a constant, it is possible to predict the initial velocity if $f_0$, $F_0$ and the constants are known to be

$$\beta_0=\rho_0/K=R'(F_0,0)/K. \tag{46}$$

Proceeding along the proper curve $\beta_0$ an amount $\Delta t_1$, from $f_0$ gives

$$\Delta(F-f)_1=\rho_0 k_2\Delta t. \tag{47}$$

Here $k_2$ is the force constant of the parallel spring $\Delta F_1$ is obtained from Fig 8

$$\Delta l_1=\rho_0\Delta t_1$$

Then a new $\beta$ is determined

$$\beta_1=\rho_1/K=R'[(F_0+\rho_0 k_2\Delta t_1+\Delta f_1),\ \Delta t_1]/K \tag{48}$$

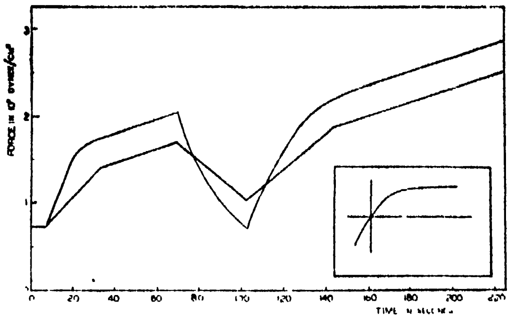
Then, from the point $f_0+\Delta f_1$, curve $\beta_1$ is followed for a time $\Delta t_2$, and another point is thus constructed. This process is repeated until the required curve is produced.

Now, in order to work a specific problem where the values of the constants are presented in centimeter-gram-second units, it is necessary to reduce the units. First, the value of the force unit is taken, so that $\alpha$ becomes unity in terms of the new force variable. Then, time is taken so that the product $K\alpha k_1$ equals unity, whereupon the variables are reduced. Then $\beta_{\text{initial}}$ is computed from $\rho_{\text{initial}}$ and $K$, and $k_2$ are expressed in terms of reduced force, and the computation begins. The only numbers that characterize a given computation, then, are the experimental restraints such as inertia (which must again be in reduced units), the value of $k_2$ in reduced units, and $\rho_{\text{initial}}$.

Although a large amount of material can be explained with the three-element model, almost any material can be made to show the presence of a distribution of relaxation times by a suitably prolonged experiment. Before going into the general theory of complex arrangements of non-linear elements, it will be helpful to consider a simple system that shows some of the qualitative features of the distribution.

The use of any sort of model containing more than one viscous element is a difficult undertaking. However, the most rudimentary considerations of the molecular structure of a fiber make it seem highly unlikely that the fiber can be described with a single viscous element, no matter how involved its law of operation. Nevertheless, a single element serves to a remarkable degree to reproduce the behavior of materials which do not exhibit plastic flow to an appreciable extent. The "distribution" used here contains only two elements; no particular significance, however, can be attached to this, except perhaps that the data do not warrant further extension. The actual fiber, no doubt, involves a continuous distribution. It is necessary to remark that this distribution has nothing in common with the Wiechert distribution of linear elements; this latter is totally inadequate to explain the experiment. It is much farther from the facts than the three-element, non-Newtonian model.

In the analysis of a large number of stress-strain curves, using the method of the three-element model of previous papers, certain persistent difficulties have been encountered. The curve of Fig. 9 shows an extreme case. The ultimate slope is well defined. Therefore, simple permanent set cannot be a factor over moderate time ranges. Repeated cycles could then be expected to yield a limiting curve. In order to place the line of ultimate relaxation, three procedures are resorted to, using the well-defined ultimate slope. First, the line is drawn from the origin. This is unsatisfactory for two reasons: the line does not cut the experimental curve with constant angle and it does not agree with the position of ultimate relaxation as determined at the end of the experiment. An attempt to draw a line through the points of constant slope meets with even less success. Using the established slope, it is impossible to go through all of the points. The line is too high for the relaxation curve, and, of course, it fails completely to agree with the determination of the point of ultimate relaxation. Projecting the line back from this point also fails completely. It leaves the point *A*, which is obviously a point below the spring line, hopelessly above it.



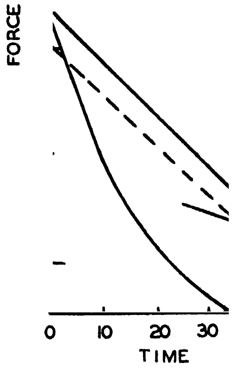


FIG. 11. The curve of Fig. 9 here is analyzed on the basis of the model of Fig. 10. Only a small excerpt from the second part of Fig. 9 is shown.

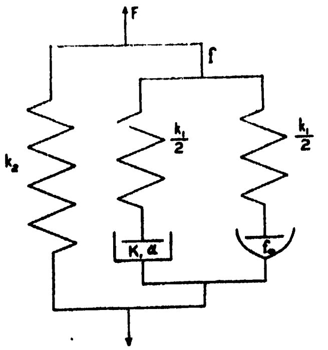

FIG. 10. The five-element model used in this paper to explain the curve of Fig. 9.

These considerations obviously lead to the conclusion that the model is not a correct picture of this fiber. However, the qualitative as-

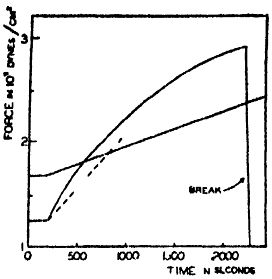

FIG. 12. The experiment of Fig. 9 carried out at one twenty-fifth the former rate. It shows the presence of a distribution but is interrupted by breakage of the fiber

pects of the diagram are the same as a curve produced by a perfect three-element model. No widely separated processes exist. The sharpness of the initial yield point completely disallows a wide distribution of yield forces of a simple non-thixotropic character. These yield forces must be within perhaps 10 percent of one another. Equally impossible is any type at all of three-element model. A single dashpot, even if unsymmetrical and thixotropic, cannot explain point *A*. That is, a true point of ultimate relaxation cannot always be achieved by finite process.

The model suggested by these considerations is one containing a number of elements of the same yield strength. A simple method of this type suffices to explain the curve in Fig. 9. This model (Fig. 10) contains two dashpots of equal yield value. One is quite non-Newtonian and the other is more nearly Newtonian. The effect of this arrangement is that the non-Newtonian dashpot reinforces the spring when it is not at the yield force. When the point of ultimate relaxation is found by hunting, it does not represent the place where the force on the compound element is zero, but the place where the force on the Newtonian dashpot is zero. Therefore, the slope to be used in leaving this point to connect with other similar points is not the well-defined slope but a steeper slope calculated by connecting several points of the proper slope. This slope must yield to the well-defined slope when the yield value is reached. That this model accounts for the curve is apparent (Fig. 11). During the relaxations, the model must be abandoned in favor of a smoother distribution of some unknown character. At a finite rate, however, this crude model is the most complicated that can be justified. Its importance is that it is the *simplest* model that possibly can give rise to the experimental facts.

When the force is divided among several viscous elements, there are at least two ways to express the constants. If the actual force on an element is used to compute the constant, then this represents the exact mechanical element that would reproduce the behavior when combined with its fellow springs and dashpots. However, if constants are based on the total viscous force along with a "concentration," then the situation is conceptually clearer. Thus, if one desires to make a three-element model with two identical dashpots instead of one, it seems desirable that the constants should be the same as if he had used only one because the behavior would be identical.

So far as a single rate of elongation is concerned, the model of Fig. 10 seems quite adequate. Figure 12 shows the effect of changing the rate of elongation to one twenty-fifth of its former value. Unfortunately, the viscose rayon fiber soon broke The shape of the curve, however, shows that the hypothesis of equal yield forces is no longer good The presence of a distribution of relaxation times is clearly indicated. This is as it should be, for if at one speed the yield force of the dashpots is equal, then at other speeds the yield forces must diverge from one another. Figure 12 shows that the dashpot of the more Newtonian character is almost completely yielded at all times, and that the yield force is approximately accounted for by the completely non-Newtonian dashpot if that yield force, by hypothesis, is considered constant. The gradual nature of the yielding process shows that this hypothesis is only qualitatively correct, and that the completely non-Newtonian dashpot is beginning to split into several more or less non-Newtonian dashpots.

Proceeding in a manner similar to that described above and observing the convention therein described, one obtains the following results:

Springs: $k_1 = 0.94 \times 10^{11}$ dyne/cm$^2$,
$k_2 = 1.19 \times 10^{10}$ dyne/cm$^2$;
First dashpot: 0.66 concentration
$f_\infty = 0.874 \times 10^9$ dyne/cm$^2$;

Second dashpot: 0.34 concentration

$\rho = 6.5 \times 10^{-4}$,

$\beta = 3$ (from shape),

$k = 2.2 \times 10^{-4}$,

$\alpha = 2.09 + 10^{-9}$,

$\Delta F\ddagger = 23{,}650$ calories,

$V_h = 5.5$ A cubed.

In Fig. 11, second part, the agreement with the established line of no relaxation is shown by the difference between the dashed line and the solid line. In Fig. 12, the dashed line gives the slope used before to represent the single dashpot. At this new speed, it no longer has meaning.

## SIX RULES FOR ANALYZING STRESS-STRAIN CURVES

In the analysis of the stress-strain properties of a material there is a certain advantage to the making of haphazard stress-strain curves, following no particular pattern and depending, almost, on the whim of the experimenter. Then these curves are subjected to an analysis that must meet many novel conditions of experiment. For path-finding purposes this procedure is very useful. Until the present writing, stress-strain work in the laboratory has followed such a pattern, or lack of pattern. However, as more painstaking analyses are attempted, and as the model is refined, this procedure becomes very wasteful and the results meager. An attempt has been made to improve the situation by setting up a series of six rules for the analysis of the stress-strain curves of a material.

In the present paper, the general distribution of non-Newtonian relaxation times is included in the scheme of analysis. The introduction of the distribution has been avoided in previous papers because its great complexity obscured the exposition of simpler ideas, such as non-Newtonian behavior and the unsymmetrical potential barrier. The importance of the distribution is realized when more complex experiments are performed. It is seldom if ever found absent when experiments are devised that accentuate it. Similarly, the existence of multiple equilibrium positions at the same value of the flow coordinate (thixotropy) is of very great importance. The protein fibers seem especially thixotropic. Because both of these complications are introduced here, the scheme is more general in application than the analysis given in previous papers.

Each of the proposed six rules contains a simplifying criterion. If the criterion in the first rule is satisfied, then the procedure of the second rule becomes usable, and so on through the rules. If all six criteria are obeyed, then the material under study is representable by a hyperbolic sine-law model. When a criterion is violated, the notes to the rules suggest the proper procedure. At times this procedure can only be sketched, because the mechanics of the complex analysis is still being worked out. However, the principles governing the calculation are usually clear. The six rules suggest an orderly mode of experiment which is outlined in a note. The language of the rules is that of experiments conducted at a constant rate of elongation, but obvious modifications will occur to those interested in the other types of experiments. It also seems pertinent to observe that whenever the general criterion for the existence of a simple system (the three-element model) has been established, the single dashpot has its kinetics, however peculiar, completely bared, and the necessity for employing the rules vanishes. The concept of compound models, because of its great difficulty from the experimental standpoint and its complicated and involved nature from the theoretical standpoint, is reserved for a final note.

The typical experimental material available is a complex stress-strain curve like Fig. 13, which consists of many cycles of elongation, relaxation, and contraction. In Fig. 13 the curve is plotted, for compactness, on a load-elongation plane, rather than the alternative plot on the load-time plane. The six rules are as follows.

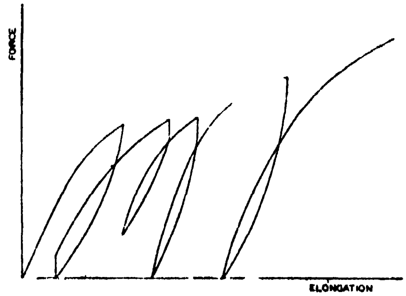

FIG. 13. A complex stress-strain curve. Relaxation is indicated by a straight vertical line.

### THE SIX RULES

I. The complex stress-strain curve is compared with simple experiments in which samples of the material under study are elongated to break at the rates of elongation under study (Fig. 14). The complex stress-strain curve at a given rate on the load-elongation plane must lie within the simple curve taken at the rate considered as an envelope (criterion I) (Fig. 15). Any portion of the complex curve lying outside of the envelope (Fig. 16) must be analyzed on the basis of a theory of thixotropy.

An obvious exception to this rule is encountered when the rate is changed rapidly enough to leave the stress-strain curve within the envelope at the old, faster rate, but outside of the envelope at the new, slower rate (Fig. 17).

II. A large number of points of no relaxation is determined. A point of no relaxation is determined by finding an elongation where the force decreases upon relaxation, then contracting the sample until a point is reached where the force increases with relaxation, eventually bracketing the force value when the initial rate of relaxation is zero (Fig. 18). Out of the totality of points so determined, a special group is defined as follows: a member is taken directly by one contraction starting from a point where the complex curve lies on its envelope. This definition will have to be approximated by doing as little searching as possible, and a certain amount of discretion must be used in placing a point in the special class.

Because there is only one defined way of achieving a member of this group from a definite elongation on the envelope, the totality of these points will form a line underneath the envelope that is a function of the elongation. Consider the difference in force between the envelope and these points. If this difference increases monotonically and becomes constant, then, in terms of spring-dashpot language, the elements that are determining the point of no relaxation are the same after this constancy has been achieved. When this condition of constancy is satisfied early in the experiment, criterion II is obeyed. The group of elements that determine the points of no relaxation can then be investigated as an entity. Before criterion II is satisfied the region, if it is satisfied ultimately, is to be treated under the rules given below concerning the return (contraction) curves. Data in this region, for most practical cases, are fragmentary and unimportant.

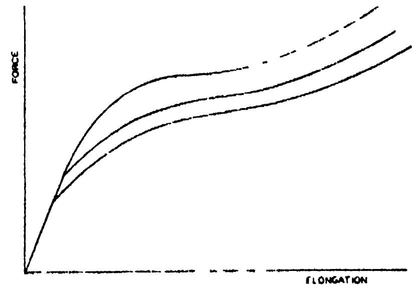

FIG. 14. Samples elongated to break at several rates.

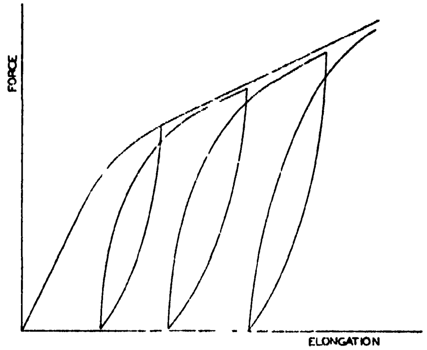

FIG. 15. A complex curve lying completely within the envelope (conforming to criterion I).

When this condition of monotonic increase and constancy is not satisfied, then some change in the determining flow process with elongation is implied.

III. *The residue of points* of no relaxation, after the special group is considered, is divided into sections totally separated from one another by any relaxation occupying a longer time than is the criterion of direction of movement, for determining the point of no relaxation. It is, of course, also separated by any determination of a point of the special class or any return to the envelope. The process described in this rule is repeated for each group of points isolated by these occurrences. Within such a section, a spring line is drawn from the terminal point of such a long relaxation or from the point of a determination of the special group, with a slope that makes it pass as closely through the points in the section (Fig. 19) as possible. If it is possible to pass this line through all the points in the section, and if it is possible to do this with the same slope in every section, then the concept of a single relaxing dashpot for determining the point of no relaxation is applicable. (Criterion III.) The example of a simple "distribution" given above is of this kind.

IV. If the previous criteria are observed, it remains to consider the shape of the return loops. A simplifying criterion is the existence of a well-defined slope in the region of no relaxation. If this constant elastic slope exists throughout the experiment, then it is established that the same totality of Hookean springs is operating throughout the experiment. (Criterion IV.) When this criterion is not observed, some condition of thixotropic flow or non-Hookean elasticity is implied.

V. When the elastic slope of rule IV is established, the working curves are transcribed, using the slope of rule III as spring line and the points of no relaxation as origin. If a well-defined working curve exists, the appropriate theory can be applied (Criterion V)

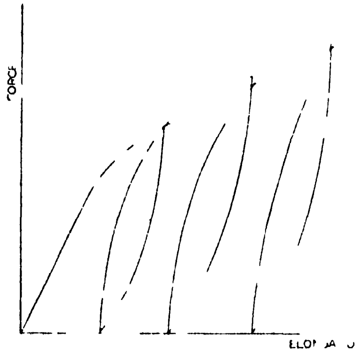

FIG. 16. A complex curve with a portion outside the envelope (violating criterion I).

VI. If the working curve is the same for elongation and contraction and the constants determined from relaxation agree with those from shape and rate change, then the simple hyperbolic-sine model can be employed. (Criterion VI.)

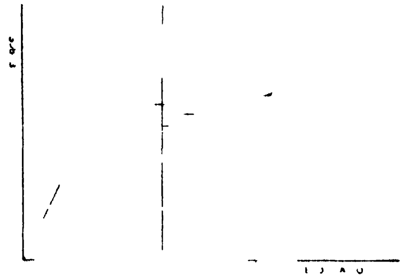

FIG. 17. The case of a change from a fast to a slow rate in which the curve can be said to obey criterion I because it approaches the envelope, although from the outside.

### NOTES AND EXCEPTIONS TO THE RULES

I. When only a certain small portion of the curve appears outside of the envelope, this part can often be neglected, and points of no relaxation taken from it excluded from the special class. Usually this "hump" is observed just as the curve reaches the envelope after a series of elongations and contractions confined to the interior of the permitted area. By a careful study of when the humps appear, a proper thixotropic scheme can be devised (see below). Although the special class of points of no relaxation is not affected, the behavior of the other points must be carefully studied in the light of the thixotropic scheme. When, however, the position of the curve is a complete departure from the envelope ("strain hardening"), an extremely thorough study of the effect of order of succession in the performing of experiments becomes necessary. This complication of experiment is required because the great simplification of the possibility of proceeding to a reproducible state (the envelope) at will, is no longer available. When the general thixotropic scheme has been devised for the envelope, it is still a much greater task to go to the return loops and points of no relaxation. There is no example where this has been done.

Certain deviations from the envelope in the sense that the complex curve lies below the envelope when it is obviously parallel to it and therefore unable to reach it, can be ascribed to true permanent set, or quasi-permanent set from a later relaxation process. Because of the usual highly non-Newtonian nature of the yielding process, it is not an important occurrence. Even when the first criterion is not satisfied, as long as the curve over a given range conforms within appropriate limits, the procedures of the following rules can be applied with caution. When the general thixotropic scheme has been elucidated,

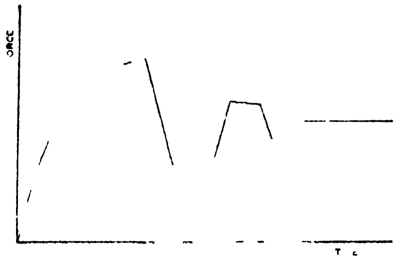

FIG. 18 The determination of a point of no relaxation.

then more general modifications of subsequent rules can be applied.

When thixotropy is established, it is quite apparent that for the envelope curves themselves whenever a dashpot is changing its rate of flow, thixotropy is likely to enter. Therefore, there might be some advantage in constructing a hypothetical, experimentally unrealizable envelope curve calculated on the basis of all of the dashpots continuously having their ultimate viscosity. The obvious reason for rejecting this procedure is the uncertainty of any theory that might be used to calculate such a curve.

The essential nature of the envelope criterion is that all curves should approach a common curve when the sample is pulled for a length of time with no reversals or halts. It is conceivable that the nature of the multiple state flow might be rheopectic, and at first the viscosity be lower than its ultimate value. No striking test for this situation is apparent, and a careful study of the consequent varying rate of approach to the envelope is required. A curve that almost parallels the envelope at a distance for a time and then ultimately approaches, indicates rheopexy, but this criterion is necessarily more vague than the corresponding one for thixotropy. When a large number of points of no relaxation are not experimentally available, then a study of the envelope curves themselves is of some use. At first, the curves at the varying rates are coincident, corresponding to the action of spring forces alone, and then they diverge as the rate-dependent dashpots come into action. The lines will then roughly parallel one another, until further yielding processes are discovered, when they will separate farther or perhaps, because of a non-Hookean parallel spring, come closer together.

II. It is to be observed that the selection of slope in rule III has no effect on the special group of points of no relaxation. The adherence to the criterion merely implies that whatever the elements that are important in the inside area, they remain the same. No assumptions of independent action of relaxation or simplicity of moving dashpot enter. When the criterion holds, it is possible to treat the single contraction curve starting at the envelope as an individual. If it, transcribed as a working curve, does not maintain constant shape while the criterion continues to hold, then a change in symmetry of potential barrier with elongation is implied.

When the compression force on the other side of the line of points in the special class is considered, it becomes quite conceivable that, while the contraction curve from the envelope to the line of the special class may be of unchanging shape and length, the prolongation of the curve may deviate from this constancy on the compressive side of this line. When this situation is encountered, it is proper to define some minor special classes, supplementing what can be called the major special class, of rule II. A suitable member would be defined as the points determined directly after going to a given line parallel to the envelope, and below the major class line. This new line would be parallel to the major line, because, by hypothesis, criterion II is already satisfied. Then if the new line of points of no relaxation is also parallel, the determining elements are identical with those determining the major line. It is apparent that very peculiar elements indeed would be implied if these lines were not parallel.

Other improper special classes can be designated by using the line of no forces as a reference. These special classes are improper because they involve both the envelope and the line of no force as references. These lines diverge as elongation increases, and so the points determined are not comparable at differing elongations. The significance of any special class is that the points it comprises are obtained from a fixed reference (the envelope) by a defined procedure. Then elongation becomes the only variable. For example, the improper class of points taken directly after a contraction from the envelope to zero force will ultimately parallel, not the envelope, but the line of zero force when the determining dashpot system is flowing at a constant rate. It is apparent that for most purposes, the major special group is sufficient and that for any situation this group is of paramount importance.

The point of no relaxation with the greatest value of force at a given elongation is attained by going into relaxation at the envelope for as short a time as is found to be necessary, contracting a very little, and looking for reversed relaxation. A similar process at zero forces finds the point with the lowest value of force.

When the second criterion fails to hold, and the envelope is a straight line when it is failing to hold, it is reasonable to assume that the cause of the failure is not the discovery of any new dashpots, but a change in the dashpots already concerned. The dashpot is of the quasi-viscous type, and the proportion of the energy dissipated to the energy stored is changing as a function of elongation, or perhaps even of history (thixotropy). Dashpot systems of this type are of fundamental importance when recycling experiments reveal dissipation with perfect elasticity (Nylon rubber).

III. While it would appear on first glance that the slope determined in III enters into the position of the points in the special group, it is nevertheless true that one of the residual points is necessary to fix this slope. The special class depends only on the envelope slope. The slope of III can often be guessed by passing the spring line through the points where the elongation and contraction curves have equal slopes (the "well-defined" slope of IV). This process depends, of course, on the adherence to criterion IV.

IV. In the case of wool, a lowering of slope because of continued working in the region of no relaxation shows that the molecular chains are resting in temporary positions of high energy when it becomes easy to coil and uncoil them. A relaxation of sufficient time restores the original slope. The initial slope is often steeper than subsequent ones. This can be ascribed to a deep-seated thixotropy, or to a non-Hookean behavior.

V. If there is definite evidence for the presence of a distribution, the transcription of a working curve will probably fail, unless the singleness of the determining dashpot is established. Then, over moderate ranges, a working curve for this single element can be established. In a recycling within a short time after being on the envelope, the yield to the envelope will be very sharp, no matter how broad the distribution, because all of the elements are in phase. Under these conditions the securing of a working curve for the determining element is facilitated. However, after a long relaxation, the yield is very gradual because the more non-Newtonian dashpots have held the compression of the associated springs. Here the hypothesis of singleness of determining dashpot is most likely to break down.

To treat the relaxation curve quantitatively, the first portion of it is ascribed to the determining element. From this portion, the constants of the determining element are estimated, and the result compared with those from shape. Then the change in envelope with rate is investigated, and the amount ascribable to the finding element subtracted. The remainder of the relaxation curve is split into enough parts to absorb the residue. This process can be made to yield a number which characterizes the distribution. The number of independently acting dashpots to which the relaxation curve must be attributed to make the non-Newtonian flow ratio, determined from speed change, come out right, is a measure of the extent of the distribution. Then, this distribution must be harmonized with the shape factor by postulating a distribution in activation energy instead of yield value. Because the determining dashpot changes with rate, this briefly indicated process must be a matter of cut and try, with a gradual assimilation of all of the data.

## NOTE CONCERNING THE TYPE OF EXPERIMENT TO BE PERFORMED

Except for certain path-finding experiments, the effort should be made to test the criteria in

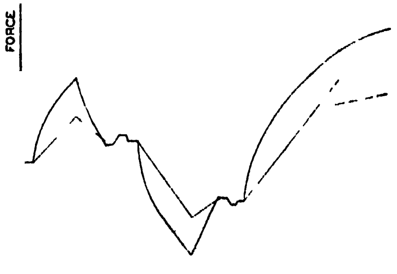

FIG. 19. The determination of the spring line.

the order given. First, a number of elongations to break, at differing rates, should be performed. These serve as general guides to the shape of the curves, and indicate the presence of the various yielding mechanisms. To find the difference in yield force because of rate, the effect of sample variation must be obviated. This is done by changing the rate, while at a point of no relaxation, on a single sample. Then the complete elongations at one rate are used to extrapolate to various elongations not covered by the complex rate experiment. The order in which the rates are applied must be permuted to determine if any strain hardening exists. (See the note to I.) If it does, then this portion of the experimental investigation must be prolonged until the rules governing the hardening can be ascertained and incorporated on a thixotropic scheme.

Then, experiments must be performed to get representative members of the special group at no relaxation points. These can be performed at one rate for each experiment, and keyed to one another by the earlier experiments at differing rates. In these experiments, the first proofs of thixotropy may be discovered, if thixotropy does not depend on backward relaxation, and manifests itself by a passing outside of the envelope. Thixotropy can be neglected until criterion II can be proved or disproved. If this criterion is obeyed, then the treatment is simplified.

Next, the experiments consisting of return cycles and the determination of the residue of relaxation points must be performed. If thixotropy is indicated, these experiments must contain many attempted returns to the envelope to elucidate the thixotropic scheme. In the presence of thixotropy, little more can be accomplished because the thixotropic working curves remain to be calculated although the principles governing the calculation are clear. However, even in the presence of thixotropy, the finding dashpot may not be thixotropic, and thus can be studied more easily if return loops starting at a thixotropic peak are not present. Last, a study of relatively long time relaxation should be undertaken.

## NOTE CONCERNING THE REPRODUCIBILITY OF THE EXPERIMENTS

Extremely poor reproducibility enormously complicates single fiber work. A trivial type is lack of scale reproducibility. If two constant-rate-of-elongation experiments differ only by the scale of the force, then a suitable area correction can be applied.

The most significant type of deviation is encountered in the early part of most curves. The first yield value may be abnormally low. This can be ascribed to greater than usual initial tension or lack of over tension ever occurring in the preparation. On the other hand, much more commonly the initial yield force may be very high, showing that at some time in the preparation the sample received an over tension that more or less permanently moved some highly non-Newtonian elements, leaving them in compression in the unstressed state. Because of the long-term relaxation, or probably more precisely creep recovery, the yield in this case is high but gradual. Because of the almost endless possibility of the concealment of progressively less Newtonian elements, it is wise to neglect and adjust for the first cycle in the early experiments. Thus, after the first good approach to the envelope, the curves will reproduce. Later on, long-time creep and relaxation studies will be required to elucidate the first part of the curve.

For this reason in analyzing stress-strain curves the position of the curve as a function of rate is known very accurately, while the position of the true spring line must be estimated by an unsure speculation. The formula for calculating $\beta$ from two rates and the position of the spring line is thereby limited in accuracy to the precision with which the spring line can be placed. It seems a logical step to replace this formula involving two rates and the spring line by the formula based on three rates alone. If $\beta$ is the value of this constant referred to the lowest rate, then for rates $m$ and $n$ times as fast, the corresponding values are $m\beta$ and $n\beta$. Thus $f_1=(1/\alpha)\,\text{arc sinh}\beta$, $f_m=(1/\alpha)\,\text{arc sinh}m\beta$, $f_n=(1/\alpha)\,\text{arc sinh}n\beta$.

The measured ratio $R_{mn}$ is defined

$$R_{mn}=\frac{f_n-f_1}{f_m-f_1}$$

$$=\frac{[\text{arc sinh}n\beta-\text{arc sinh}\beta]}{[\text{arc sinh}m\beta-\text{arc sinh}\beta]}.$$

To the approximation that

$$\text{arc sinh}\beta = \ln[\beta + (1+\beta^2)^{\frac{1}{2}}] \approx \ln 2\beta,$$

this equation becomes, for large $\beta$

$$R_{mn} = \ln n / \ln m.$$

That is, to a good approximation, this measured ratio remains independent of $\beta$ and thus this method of calculating $\beta$ fails. Hence, it is apparent that if only the experimental values of the curve envelopes are being considered, the carrying of the constant $\beta$ is redundant. The one-constant non-Newtonian element is immediately suggested. Taking the dimensional datum $f_n - f_1$ as the measured quantity, a dimensioned $\alpha$ can be directly computed from:

$$f_n - f_1 = (1/\alpha)(\text{arc sinh} n\beta - \text{arc sinh}\beta).$$

If the spring line is sufficiently far away to make $\beta$ large, then the approximation for arc sinh can be employed, and

$$f_n - f_1 = 1/\alpha_\infty \ln n$$

or

$$\alpha_\infty = (\ln n)/(f_n - f_1).$$

The symbol $\alpha_\infty$ then denotes a limiting value of dimensional $\alpha$ as $\beta$ becomes very large. It should not be confusing that $\alpha$ in reduced units reaches no limiting value but goes on increasing. The new $\alpha_\infty$ has been computed directly in the units of force used for $f_n - f_1$. The utility of this reduction in the number of constants is increased when it is applied to the more complex models for viscous elements described under the heading "The Thixotropic Viscous Element."

Any other lack of reproducibility at present is ascribed to essential differences in the samples.

Having eliminated the spring line, it is now possible to apply the formula for $\alpha$ to cases where it is known that the three-element model is inapplicable. Whenever the envelope curves taken at the varying rates are parallel, the quantity $f_n - f_1$ in the equation for $\alpha_\infty$ can be measured. The constant so obtained applies to whatever dashpots are affected by rate. Now if criterion III is obeyed, so that a single dashpot determines the major special group, then it follows that this dashpot is markedly more affected by rate than the others, and therefore the constant $\alpha_\infty$ applies almost exclusively to it. Even when the criterion has not been established, this method of dealing with a group of envelope curves is satisfying and a good approximation.

It is in reality a first viscous datum for any material, because, while the value of the yield force is a function of history and generally increases after a few cycles to meet any stress situation, the constant $\alpha_\infty$ is always applicable to define the effect of changing rate, and therefore impact, on the material.

## NOTE ON COMPOUND MODELS

### Higher Order Experiments

If in a stress-strain experiment a point of no relaxation is found and then a relaxation curve is taken starting at this point, a definite relaxation, although at a very low rate, is encountered. At a given elongation this second-order relaxation can be either upwards or downwards depending on the force on the fiber. By a judicious interpolation of relaxations the median force where this relaxation is neither up nor down, and constants for this second-order dashpot can be found. The position of the median can be followed as a function of elongation and the second order version of rule II can be used, if some definite mode of finding the median be adopted. If the position of the median is independent of the mode of finding it, at a given elongation, then the second-order analog of the three-lement model has been established. As the rudiments of a third-order investigation, the very slow relaxation of the median itself can be investigated as a function of a second-order length parameter.

### Lower Order Experiments

Although certain of the criteria may fail for the stress-strain curve as a whole, in the region of the plane bounded by the envelope a small stress-strain curve that contains no part on the envelope can be investigated. It may be found that among the easily moved elements that come into play in this region, definite yield envelopes can be identified.

The curves inside these sub-envelopes can then be investigated exactly like the gross stress-strain curve, except that experiments must be refined. The same rules have a greater chance of success in this region of less drastic forces. If various sub-sections, separated by stretches of curve on the gross envelope, yield to the same analysis, up to and including rule V, then with *these constants of a simple hunting element* sub-curve, a gross curve with a doubly compound hunting element can be defined. In fact, a gross curve that did not yield to rule II could be satisfactorily analyzed if its sub-curves yielded to the rules. The constants so obtained for the sub-curves would show how the make-up of the determining or hunting element of the gross curve varied with elongation.

## THE THIXOTROPIC VISCOUS ELEMENT

It is possible to construct a viscous element with a dependence on history of treatment, and with a state that changes in time by postulating a double (or multiple) series of potential energy curves, one of which represents the molecules in a rest state when flow is difficult, and the others repeated promoted states revealed by flow and by thermal agitation. In this development of the simple thixotropic element, the volume of flow displacement, $\alpha$, will be considered constant.

The equations developed will be for true viscous elements, that is, the external force will be the sole agent causing flow, and when it is removed flow will stop. Several forbidden systems will be discussed to show that this is not always the case. The second condition for a true viscous element, namely, the identity of behavior at any value of the flow measuring coordinate, will be observed in all cases. When several intercommunicating positions of rest (potential wells) at one value of the flow coordinate are available, then the rate of flow of the system is not a simple function of the force on the system alone. The population of the wells becomes a factor.

To take a specific example, if two positions of rest are available, transformations can conceivably be of importance along all of the paths indicated in Fig. 20 where the circles designate positions of rest and the lines, transformations. Transformations along these lines are governed by laws of the type

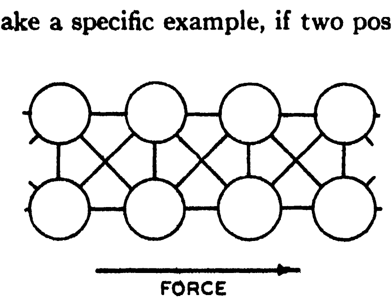

FIG. 20. A schematic representation of a complex flow system. The circles denote positions of rest while the lines represent flow processes.

$$K=(kT/h)(F^{\ddagger}/F_1)e^{-\epsilon/kT},$$

where $K$ is a "rate constant." There will be two of these equations for each connecting path. The total rate of shear is the sum of the rates of reaction in the forward direction minus the sum of the rates in the backward direction. If $n$ is the population of the top state, and $1-n$ the population of the bottom state, then similarly $dn/dt$ equals the sum of the $k$'s going upward minus the sum of the $k$'s going down.

The equations for the complex two-position model could be written out, but they quite obviously contain too many parameters to be readily used. Two principles hold: First, the assignment of constants must be symmetrical with respect to plus and minus force, or otherwise, when the force is removed from the element and the populations are in any state but the equilibrium one, there will be residual motion associated with the assumption of the equilibrium state. Second, if this symmetrical assignment is made, the force will exert no influence on the populations (the populations will remain at rest equilibrium) unless the potential barriers of the diagonal transformations are unsymmetrical.

In order to simplify the treatment, certain transformations are given sufficiently high activation energies to make them unimportant. This is symbolized in the diagram by the absence of the line representing this transformation. This transformation then is "forbidden" in both directions.

It is contrary to the principle of detailed balancing to forbid a transformation in one direction alone. A satisfactory substitute is found in the completely unsymmetrical barrier. In the normal symmetric barrier if the forward rate is increased by a multiplicative factor $\Phi\equiv e^{\phi}\equiv e^{\alpha f}$, then the backward reaction is retarded by the same factor. In the case of the completely unsymmetrical barrier, the reaction in one direction is affected by $\Phi^2$, while the reaction in the other direction is unaffected. This is diagrammatically expressed by a line with an arrow head on the end toward which reaction is affected by the force.

The simplest true viscous element will now be formulated (Fig. 21). The undisturbed rate along the horizontal arrow will be denoted by $K$. Then

$$\begin{aligned} k_{\longrightarrow} &= (1-n)K\Phi, \\ k_{\longleftarrow} &= (1-n)K\Phi^{-1}, \\ k\nearrow &= (1-n)KD, \\ k\nwarrow &= (1-n)KD, \\ k\searrow &= nKD\Phi^2, \\ k\swarrow &= nKD\Phi^{-2}, \end{aligned} \tag{49}$$

when $D$ is a factor for the difference between the diagonal passage rate and the horizontal rate. Then the rate of elongation is

$$dl/dt = K[(1-n)(\Phi-\Phi^{-1})+nD(\Phi^2-\Phi^{-2})], \tag{50}$$

and

$$dn/dt = KD[2(1-n)-n(\Phi^2+\Phi^{-2})]. \tag{51}$$

In these equations it has been assumed that the two available positions are at equal energies, and thus at equilibrium with no force applied, $n=0.5$.

To calculate working curves, the condition of experiment must be specified. At a constant rate of elongation from (2)

$$\begin{aligned} dl/dt &= \rho-(1/k_1)(df/dt) \\ &= K[(1-n)\sinh\alpha f+nD\sinh 2\alpha f)], \end{aligned} \tag{52}$$

where the factor $\frac{1}{2}$ in the definition of sinh has been adsorbed in $K$, and

$$dn/dt = KD[(1-n)-n\cosh 2\alpha f]. \tag{53}$$

In reduced units

$$\beta - d\phi/d\tau = (1-n)\sinh\phi + nD\sinh 2\phi. \tag{54}$$

Now, if the constants are known, a point-by-point calculation will give the working curve. To calculate the constants from the experimental working curve is more difficult.

If experiments are available at high rates of shear, when the ultimate population of the upper state $n_\infty \approx 0$, then it is simple to calculate all of the constants but $D$ from the law governing the change of yield force with rate of experiment, utilizing the ultimate force values at two or more rates of experiment. At high rates it can be assumed that when the maximum in force occurs, sufficient reaction has not taken place to alter $n$ appreciably from its initial value if $D$ is small. If this value is the equilibrium value, then at the point of maximum force $n=\frac{1}{2}$. If $D$ is very small, then

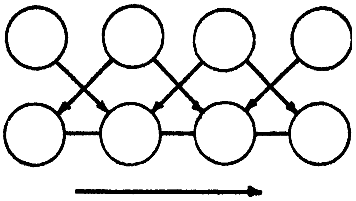

FIG. 21. The simplest true viscous element with two positions of rest.

$$\beta = \tfrac{1}{2}\sinh\phi_{\max}. \tag{55}$$

Now, by hypothesis

$$\beta = \sinh\phi_\infty. \tag{56}$$

Because $\beta$ is large, by hypothesis

$$\begin{aligned} \phi_{\max} &= \ln 4\beta, \\ \phi_\infty &= \ln 2\beta, \end{aligned}$$

and if

$$r = \phi_{\max}/\phi_\infty$$

then

$$r = \ln 4\beta/\ln 2\beta = 1+(\ln 2/\ln 2\beta). \tag{57}$$

If the contribution of $D$ is of importance

$$\beta = \tfrac{1}{2}\sinh\phi_{\max} + 2D\sinh 2\phi_{\max}, \tag{58}$$

and replacing hyperbolic sines with exponentials and using

$$\begin{aligned} \phi_{\max} = r\phi_\infty &= \ln(2\beta)^r, \\ 4\beta &= (2\beta)^r + D(2\beta)^{2r}, \end{aligned}$$

or

$$D = 4\beta - (2\beta)^r/(2\beta)^{2r}. \tag{59}$$

It is quite apparent that a model wherein the lowest state $n=0.5$ is not adequate except when thixotropy is slight. The largest permissible value of $r$ is 2, and practical values will be much lower because $\beta$ is usually high.

If it is desired to express the results solely in terms of force difference, analagous to the one constant treatment of non-Newtonian viscosity above, the argument is as follows:

$$\begin{aligned} \beta &= \sinh\phi_\infty, \\ \beta &= \tfrac{1}{2}\sinh\phi_{\max} + \tfrac{1}{2}D\sinh 2\phi_{\max}. \end{aligned} \tag{60}$$

Replacing the hyperbolic sine with the exponential form

$$\begin{aligned} 2\beta &= e^{\phi_\infty}, \\ 4\beta &= e^{\phi_{\max}} + De^{2\phi_{\max}}. \end{aligned} \tag{61}$$

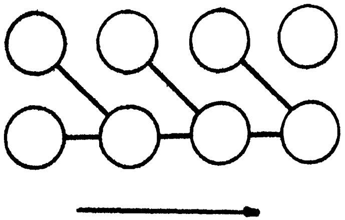

FIG. 22. A viscous system of the forbidden type

Then

$$\phi_\infty = \ln 2\beta,$$

$$\phi_{\max} = \ln\left[\frac{(1+16D\beta)^{\frac{1}{2}}-1}{2D}\right],\tag{62}$$

$$\Delta f = \frac{1}{\alpha}(\phi_{\max}-\phi_\infty) = \frac{1}{\alpha}\ln\left[\frac{(1+16D\beta)^{\frac{1}{2}}-1}{4D\beta}\right];$$

whence

$$D\beta = [2-e^{\alpha\Delta f}]/[e^{2\alpha\Delta f}].\tag{63}$$

This depends on rate, and the final expression of the answer takes the form

$$D/K = \rho[2-e^{\alpha\Delta f}]/[e^{2\alpha\Delta f}]\tag{64}$$

when $\alpha$ comes from the change in $f_\infty$ with rate, and $\rho$ is the rate of elongation. This formula applies only when $e^{\alpha\Delta f}<2$ as otherwise the model is invalidated.

This limitation could be removed by placing the upper state at an advantage thermodynamically, but this modification would introduce another constant. A permissible system, having no more constants, which does not have $n_0=0.5$ can be designed by modifying the previous system by making $D$ a difference in well energy rather than an activation energy factor. The activation energy for the diagonal process, from the bottom state, will be the same as that for horizontal flow along the bottom states. The equations expressing this are

$$\begin{aligned}
k_{\longrightarrow} &= (1-n)K\Phi,\\
k_{\longleftarrow} &= (1-n)K\Phi^{-1},\\
k\nearrow &= (1-n)K,\\
k\nwarrow &= (1-n)K,\\
k\searrow &= nKD\Phi^2,\\
k\swarrow &= nKD\Phi^{-2},\\
1-n_0/n_0 &= D,\\
n_0 &= 1/D+1.
\end{aligned}\tag{65}$$

The equation for $dl/dt$ remains the same. But repeating the approximation for

$$\begin{aligned}\beta &= (1-n_0)\sinh\phi_{\max}+n_0D\sinh 2\phi_{\max}\\ &= (D/D+1)(\sinh\phi_{\max}+\sinh 2\phi_{\max}).\end{aligned}\tag{66}$$

Then

$$D = [(2\beta)^{2r-1}+(2\beta)^{r-1}-1]^{-1}.$$

In terms of force differences

$$2\beta = e^{\phi_\infty},$$

$$2\beta = (D/D+1)(e^{2\phi_{\max}}+e^{\phi_{\max}}),\tag{67}$$

whence

$$\phi_\infty = \ln 2\beta,$$

$$\phi_{\max} = \ln\frac{[1+8(D+1/D)]^{\frac{1}{2}}-1}{2},\tag{68}$$

$$\alpha\Delta f = \tfrac{1}{2}\ln 2/\beta D,\quad (\beta \text{ is very large}),$$

$$D/K = 2\rho e^{2\alpha\Delta f}.\tag{69}$$

A system which is of interest is shown in Fig. 22. It is of the forbidden unsymmetrical type and, for this reason, can function without unsymmetrical potential barriers. The equations governing its motion are

$$\begin{aligned}
k_{\longrightarrow} &= (1-n)K\Phi,\\
k_{\longleftarrow} &= (1-n)K\Phi^{-1},\\
k\searrow &= nKD\Phi,\\
k\nwarrow &= (1-n)KD\Phi^{-1},\\
dl/dt &= K[(1-n)(\Phi-\Phi^{-1})\\
&\qquad +nD\Phi-(1-n)D\Phi^{-1}],\\
dn/dt &= KD[(1-n)\Phi^{-1}-n\Phi]
\end{aligned}\tag{70}$$

At a constant rate of elongation, when $d\phi/dt=0$,

$$\begin{aligned}\beta &= (1-n)\sinh\phi_{\max}+nD(e^{\phi_{\max}}/2)\\ &\qquad -(1-n)D(e^{-\phi_{\max}}/2).\end{aligned}\tag{71}$$

If $n$ has its equilibrium value $\frac{1}{2}$, following a similar procedure gives

$$\beta = \tfrac{1}{2}\sinh\phi_{\max}+\tfrac{1}{2}D\sinh\phi_{\max},$$

or

$$\begin{aligned}2\beta &= (1+D)\sinh\phi_{\max} = (1+D)\beta^r,\\ D &= (2\beta/\beta^r)-1.\end{aligned}\tag{72}$$

If $n$ has the extreme value, unity,

$$\beta = \frac{De^{\phi_{\max}}}{2} = \frac{D(2\beta)^{r_{\max}}}{2},$$

$$D = (2\beta)^{1-r_{\max}}.\tag{73}$$

For this third "forbidden" case the argument based on force differences is as follows:

$$\begin{aligned} 2\beta &= e^{\phi_\infty}, \\ 2\beta &= \tfrac{1}{2}e^{\phi_{\max}} + \tfrac{1}{2}De^{\phi_{\max}}, \qquad \text{if } n=\tfrac{1}{2}, \\ \phi_\infty &= \ln 2\beta, \\ \phi_{\max} &= \ln(4\beta/1+D), \\ -\alpha\Delta f &= \ln(1+D/2), \\ D &= 2e^{-\alpha\Delta f}-1. \end{aligned}$$

If $n=1$,

$$\begin{aligned} 2\beta &= De^{\phi_{\max}}, \\ \phi_{\max} &= \ln 2\beta/D, \\ -\alpha\Delta f &= \ln D, \\ D &= e^{-\alpha\Delta f}. \end{aligned} \tag{74}$$

The simplest of all models is an improper one, containing an unsymmetrical barrier (Fig. 23) The equations governing this model are, assuming all activation energies and energy levels equal,

$$\begin{aligned} k_{\rightarrow} &= (1-n)K\Phi, \\ k_{\leftarrow} &= (1-n)K\Phi^{-1}, \\ k_{\searrow} &= nK, \\ k_{\nwarrow} &= (1-n)K\Phi^{-2}, \\ dl/dt &= K[(1-n)(\Phi-\Phi^{-1})+n-(1-n)\Phi^{-2}]. \end{aligned} \tag{75}$$

At a constant rate of elongation, when $\phi$ is maximized

$$\beta = (1-n)\sinh\phi_{\max} + n - (1-n)e^{-2\phi_{\max}}. \tag{76}$$

Because there is no extra constant, $n$ can be fixed as a function of $r$

$$n = 1 - 1/(2\beta)^{r-1}. \tag{77}$$

For the last and simplest case, the following argument holds in terms of force differences:

$$\begin{aligned} 2\beta &= (1-n)e^{\phi_{\max}}+n, \\ \phi_{\max} &= \ln 2\beta/1-n, \\ -\alpha\Delta f &= \ln(1-n), \\ n &= 1-e^{-\alpha\Delta f}. \end{aligned} \tag{78}$$

These equations will be employed in the analysis of some typical thixotropic curves.

## Rules for Analyzing the Working Curves

The examples of special two-position working curves given above make clear the principles governing the calculation of curves of this type, and indicate methods of calculating the constants when the curve is found experimentally.

The complexity introduced with only one new constant, and in one case with no new constants, is apparent. Realizing that these cases were selected for their simplicity rather than for their reality, it becomes apparent that the selection of the particular multiple-position model is a difficult task.

A series of rules is set up for analysis, assuming that the over-all analysis has been carried to such a point that the working curve of the element in question is known at least to an extent of uncertainty no greater than the presence of an unknown additive factor.

I. The working curve must have a constant slope at and near the origin (criterion I).

II. The working curve is investigated at several velocities and the behavior of the ultimate value of the force investigated. If this force is a function of the velocity alone, strain-hardening is absent (criterion II).

Using these ultimate forces, a value of $\beta$ is computed for the bottom process of flow. Similarly, the behavior of the hump itself is investigated as a function of the treatment after leaving a steady value of ultimate force. The shape should depend only on this recent history (criterion IIA).

III. The difference between the maximum force (at the hump) and the ultimate force is investigated after cycles of elongation and contraction followed by periods of no force. If the largest maximum force always follows the longest period of no force, other conditions being equal, then a symmetrical model is indicated (criterion III).

IV. The maximum value of $r$ is compared with the value $r=\ln 4\beta/\ln 2\beta$. If $r$ is ever greater than this value, it is necessary to employ a model with the difficult-to-flow state thermodynamically favored.

V. If $r$ is not greater than $\ln 4\beta/\ln 2\beta$, the

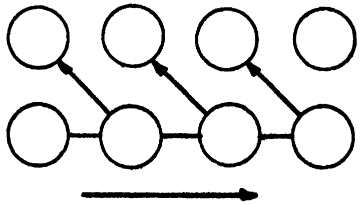

FIG. 23. The simplest (improper) model.

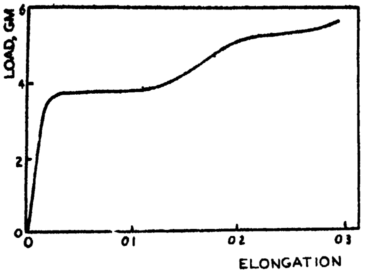

FIG. 24. Elongation *vs.* load to break for the chicken keratin fiber, diameter of 90$\mu$, $\rho=0.402\times10^{-3}$

single constant can go into an activation energy factor to hinder the diagonal reaction.

These rules have been carried only far enough to provide for a single new constant. They could be expanded to include tests of a quantitative nature to employ more constants. No radically different behavior would be encountered within the framework of two equilibrium positions.

If the first criterion is disobeyed; it becomes necessary to employ a "thixotropic spring" model; if the second criterion is disobeyed, strain hardening is involved. If the third criterion is disobeyed, an unsymmetrical model is implied, and, in any one of the three cases, the simple definition of a viscous element fails.

## Experiments with Chicken Keratin

When Dr. Harold P. Lundgren of the Department of Agriculture's Western Regional Research Laboratory visited the Textile Research Institute Laboratories, he left a sample of the fiber prepared from chicken feather keratin in his laboratory. This material shows many interesting properties, including flow thixotropy, constant force springs, and the presence of a complex distribution of relaxation times. The fiber is very sensitive to humidity. When it is wet, it is very soft. At 40 percent relative humidity, it has a stress-strain curve that does not have any thixotropic hump but which shows very clearly the constant force spring. Figure 24 shows an elongation to break. At 50 percent humidity the thixotropic hump appears, and all of the curves of this section except Fig. 24 were made at this humidity. The region of flatness is moved up and is correspondingly longer than the flat region of Fig. 24. At 60 percent relative humidity, the fiber becomes so stiff that it often breaks before the yield point; therefore, long-range experiments become impossible except in the region below the yield point.

Because the fiber was prepared in a small-

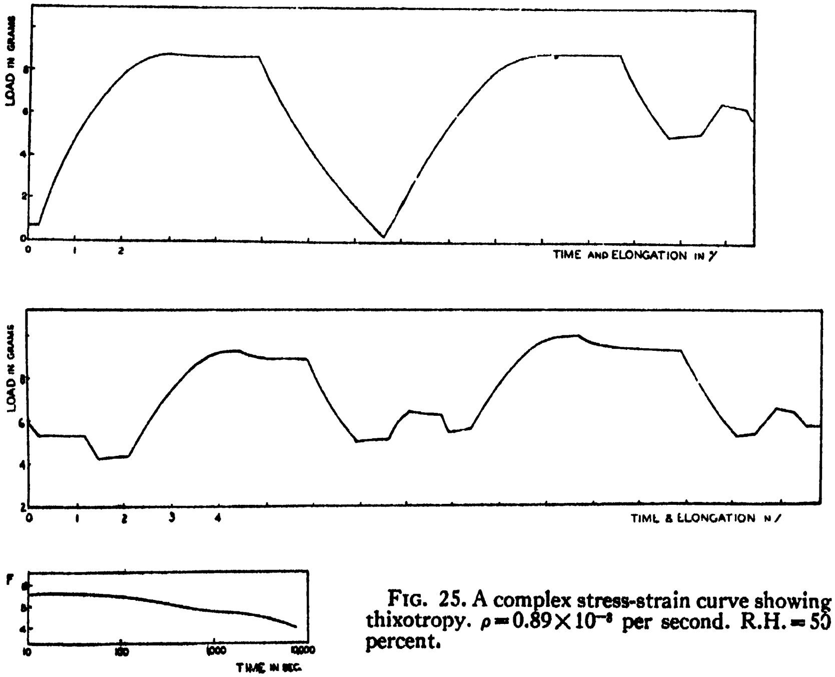

FIG. 25. A complex stress-strain curve showing thixotropy. $\rho=0.89\times10^{-3}$ per second. R.H.=50 percent.

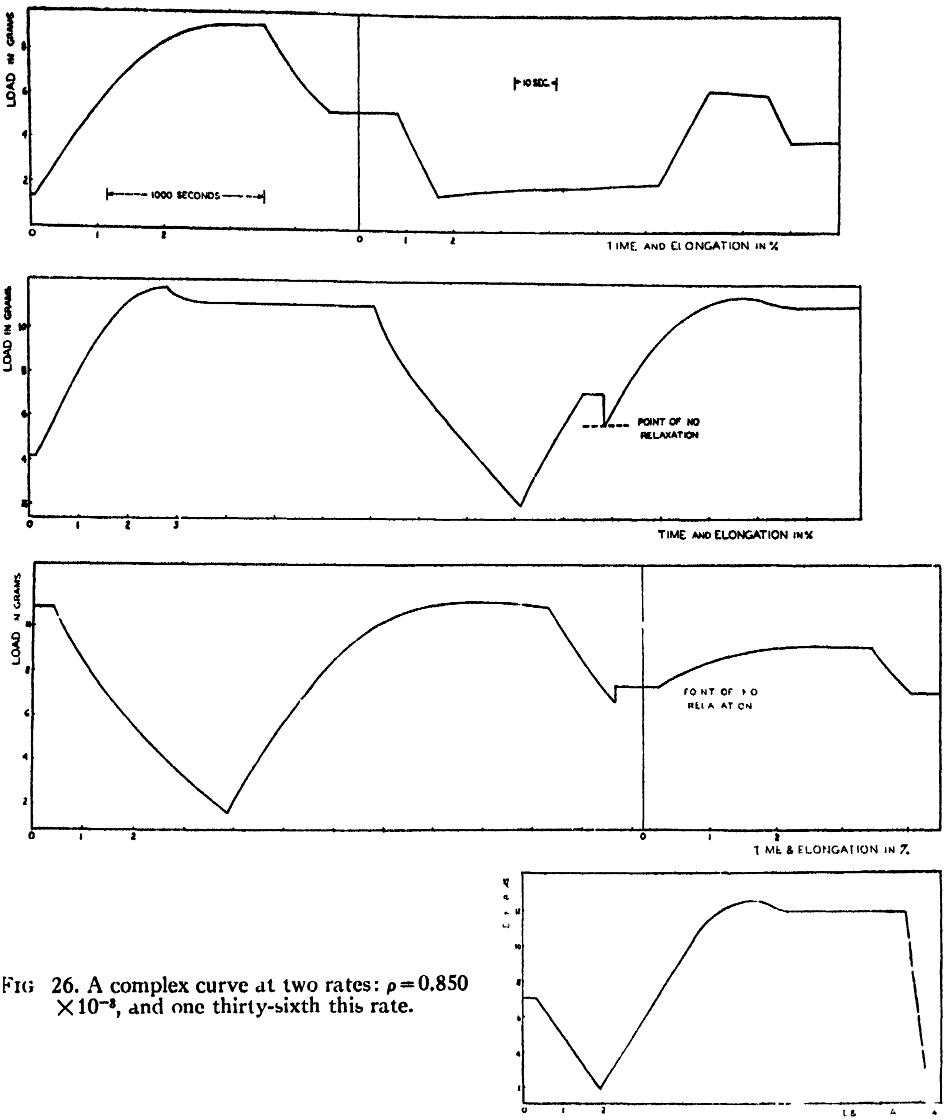

FIG. 26. A complex curve at two rates: $\rho=0.850 \times 10^{-3}$, and one thirty-sixth this rate.

scale experimental fashion, it was quite irregular in behavior. Therefore an investigation to determine the exact components of its visco-elastic system would have been very trying. For that reason, the method of expressing constants that depends only on differences in force and not on the position of the ultimate spring line will be employed.

Figure 25 shows results of an experiment. The first panel shows that in the beginning of the experiment there was very little hump in the curves. After working some time to determine a point of no relaxation, a pronounced hump of about one gram has developed. A situation of this nature shows that the unsymmetrical "forbidden" type of element must be employed. As will be shown later, the meaning of the unsymmetrical element can be expressed in configura-

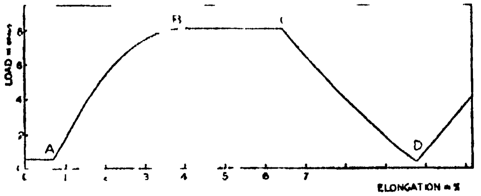

FIG. 27. A portion of the stress-strain curve for chicken feather keratin. The diameter of the fiber is approximately $90\mu$, and $\rho=0.835\times 10^{-3}$ per second, R.H. = 50 percent.

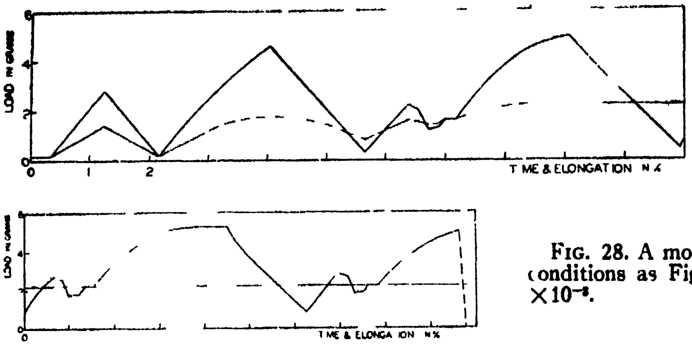

FIG. 28. A more complex curve prepared under similar conditions as Fig 27 except R.H.=60 percent, $\rho = 0.40 \times 10^{-6}$.

tion space. Hence, there is no uncertainty about the use of such an element.

Now a very long experiment with many differing treatments would be necessary to justify a very complex picture of the flow system in configuration space. Because of the fragility of the fiber, this is very difficult to realize. The two-constant improper thixotropy theory is adequate to explain the curves here which are of a fair degree of complexity. The last panel of Fig. 25, in which the relaxation over a long period of time, starting with a point of no (instantaneous rate of) relaxation, shows clearly that a complex distribution of relaxation times enters into a complete description of the fiber. By using the one-constant method, the analysis of this feature of the curves can be avoided and attention focused on the problem of thixotropy

The stress-strain curve of Fig. 26 is complex enough to allow a computation of some constants. The change in ultimate force caused by a rate change of a factor of 36 was 2 0 grams. Thus $\alpha_\infty = \ln 36/2.0 = 1.8$ per gram. $\Delta F$ is very close to 1.0 gram when carefully taken from a point of no relaxation. Therefore, $\alpha\Delta F = 1.8$, $e^{-\alpha\Delta F} = 0.17$. Because this is a rather small quantity, denoting a large thixotropy, the over-simplification of the simplest forbidden case is not appropriate. The other forbidden case discussed in the text had an equilibrium value of $n_0$ of one-half and is similarly only slightly thixotropic.

A slight modification of this treatment can be made in which, instead of the rate of flow between states differing by a factor $D$ from the forward and backward rates, the inaccessible state is made a factor $D$ lower than the state when forward flow is direct. That is the two states differ by $\Delta F'$, and $D = e^{-\Delta F'}/RT$. Then the equilibrium value

$$n_0 = 1/D+1,$$

and in terms of the infinite force expressions one finds by arguments similar to those given in the section above

$$D/D+1 = 2e^{-\alpha\Delta F}. \qquad (79)$$

From this experiment, at 300°K, the difference in energy is found to be 1410 calories.

## CONSTANT FORCE SPRINGS

The only requirement that a true spring must satisfy is that it should store energy completely reversibly. This in turn means that the energy of a spring must be a monotonic function of the elongation. The force on the spring is the slope of the energy function, and it is expected that the force can rise, go through a maximum, and descend to zero, but never become negative. Although it is easy to construct springs of this sort artificially, there are few illustrations of them in nature.

In the analysis of the stress-strain curves of protein fibers it has been found necessary to employ non-Hookean springs in which, if it does not descend, it reaches a constant value. In Fig. 27 a portion of a stress-strain curve for the chicken feather keratin fiber is shown. At point $B$ the fiber is completely yielded to zero slope. If at point $B$ the direction of elongation had been reversed, then the contraction would have taken place quite reversibly but not to such an extent that the elongation was any less than that at point $A$. Indeed, as the strain at the reversal was decreased, recovery would asymptotically approach $A$ from the $B$ side. In the actual experiment, the reversal of direction was not made at point $B$, but the fiber was elongated at constant force, for several percent of elongation, to point *C*. Because there was no increase in force, one would expect that the entire portion of the curve from *B* to *C* would be completely dissipative and, therefore, all reversal curves from this point onward would be superposable. That this is not the case is manifest in that the elongation *CD* is greater than *BA*. That is, between *B* and *C* energy was being stored at a constant rate of elongation. This shows that a spring system was present that was operative at constant force. In Fig. 28 a more complex curve of the same type is analyzed on the basis of the three-element model incorporating for the spring in parallel a non-Hookean element of the type described. It is quite apparent that the spring cannot operate at constant force throughout its entire range, but that it must start at some Hookean slope. That slope is determined here by connecting the first point of no relaxation with the origin using a line of the proper constant slope. It is to be noted that even if at times the resulting line passes above the ultimate force of the spring, as long as the first point of no relaxation is sensibly below this ultimate, then the determined slope is valid below the ultimate, and must be rounded off when it approaches the ultimate. This is shown in Fig. 28 by the dashed lines. The working curve, which is well defined for the whole experiment, is shown in Fig. 29. However, it is known that this fiber cannot be successfully represented under every condition by the three-element model and obviously all of the points of no relaxation determined belong to the special class.[3] The three-element model is quite satisfactory over this particular range and any constants determined would be average values of some unspecified nature.

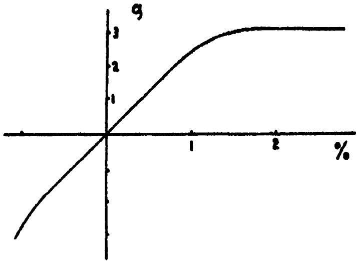

FIG. 29. The working curve for Fig. 28.

The important point, however, is that no combination of non-Newtonian, unsymmetrical and/or thixotropic elements coupled with Hookean springs could reproduce this behavior. A spring operating at *constant force* is definitely demonstrated. These springs obviously could not exist uncoupled in the free state because the elongation at the ultimate force would be undefined. But when they are coupled with viscous elements this difficulty is removed.

### ACKNOWLEDGMENTS

I wish to thank Mr. Charles H. Reichardt for valuable suggestions, and Dr. J. H. Dillon for reading the manuscript and clarifying the presentation.

# A Magnetron-Resonator System

E. C. Okress
*Westinghouse Electric Corporation, Lamp Division, Bloomfield, New Jersey*

(Received May 26, 1947)

The present exposition deals with the fundamental multiplet spectrum of a multi-sectorial cavity or vane-type magnetron and specific applications involving the evaluation of the $\pi$-mode wave-length thereof. The consequence of mutual coupling between the sectorial cavities through the interaction space of an infinitely long anode is evaluated for the linear case and subsequently applied to the cylindrical case. Although both the qualitative and quantitative results are reasonable in the limit for relatively very long anodes, in practice the latter are relatively short and since the mode separation, order thereof, and hence the component wave-lengths are more or less influenced by the actual relative anode and end cavity lengths at each end of the anode, the results naturally differ from "cold" test data. Predictions of $\pi$-mode wave-length have been obtained to about 10 percent, depending upon the degree to which the parameters of the actual vane magnetron approximate the assumptions on which the present treatment is based. With the aid of "cold" test data the preliminary theoretically derived resonator geometry may be appropriately "trimmed" to produce the exact $\pi$-mode wave-length desired.

Included in this article is a discussion of the need and function of straps of the resonator system and dimensional scaling, which preserve certain desirable properties of the prototype at the new wave-length, or operating point, in terms of magnetron performance-chart parameters. Finally, in Part III, a brief consideration is allotted to the derivation of the rectangular cavity or slot-type resonator system from the more general relation for the sectorial cavity in this article.

## I. INTRODUCTION

THE subject of this paper is based on a Westinghouse radar report[1] concerning an investigation of the symmetrical multi-sectorial-type cavity, commonly referred to as the vane magnetron illustrated essentially by Fig. 3 and practically by Fig. 9.

The analytical evaluation of the wave-length spectrum of the fundamental multiplet for the resonator system of the vane magnetron was initiated some time prior to its invention,[2] with the original object of developing a cheaper, lighter, more readily manufacturable product possessing excellent electrical properties, in contrast to the parallel slot or hole- and slot-type of resonator systems. Eventually these objectives were realized during the war, aided by the cooperative efforts of other laboratories; the vane magnetron was and is being continually introduced to many important uses to which it is especially suited.

Prior to August 1942 no results on the evaluation of the principal wave-length of the vane magnetron were known or available, so that in order to establish some basis for a preliminary design of a 10-centimeter, 8-vane magnetron the aforementioned work[1] was initiated and reported upon.

M.K.S. units are used throughout this paper unless otherwise noted.

It is appropriate to point out that only the travelling-wave magnetron oscillator is considered in this article. These oscillations are also referred to in the pre-war literature, as the transit time oscillation of higher order and type $B$. The characterization of this oscillator lies in the fact that the electronic interaction and phase relations are incorporated with the tangential and radial components of the rotating electromagnetic field in the interaction space, between the cathode and anode, respectively, in accordance with the Slater, Hartree, and Block theories of oscillation.

## II. THE RELATION FOR THE NORMAL MODES OF OSCILLATION

Consider an isolated, infinitely long sectorial cavity, with metallic confining walls, with a longitudinal slot adjoining the cylindrical hole shown in Fig. 1. Note that this cavity represents the generalization of the rectangular case to be commented on later. A mode of oscillation of future utility is chosen such that the associated components of the electromagnetic field in the sectorial cavity satisfy the conditions:

$$E_r = E_z = 0,$$

$$H_r = H_\phi = 0,$$

$$E_\phi = E_\phi(r),$$

$$H_z = H_z(r).$$

---

[1] C. C. Wang and E. C. Okress, "The vane type magnetron," Radar Report B-1, Bloomfield-29, August 1942.

[2] Patent applied for.

Since Maxwell's equations in cylindrical coordinates may be expressed as:

$$\frac{\partial E_z}{r\partial\phi}-\frac{\partial E_\phi}{\partial z}=-i\omega\mu H_r,\quad \frac{\partial H_z}{r\partial\phi}-\frac{\partial H_\phi}{\partial z}=(\rho+i\omega\epsilon)E_r,$$

$$\frac{\partial E_r}{\partial z}-\frac{\partial E_z}{\partial r}=-i\omega\mu H_\phi,\quad \frac{\partial H_r}{\partial z}-\frac{\partial H_z}{\partial r}=(\rho+i\omega\epsilon)E_\phi,$$

$$\frac{\partial}{r\partial r}(rE_\phi)-\frac{\partial E_r}{r\partial\phi}=-i\omega\mu H_z,$$

$$\frac{\partial}{r\partial r}(rH_\phi)-\frac{\partial H_r}{r\partial\phi}=(\rho+i\omega\epsilon)E_z,$$

which, for the conditions enumerated, become

$$\frac{\partial}{\partial r}(rE_\phi)=-i\omega\mu rH_z, \tag{1a}$$

$$-\frac{\partial}{\partial r}H_z=i\omega\epsilon E_\phi, \tag{1b}$$

for a perfect dielectric medium in the cavity of Fig. 1. The angular frequency, velocity of light, permeability, and dielectric constant are denoted by $\omega$, $c$, $\mu$, and $\epsilon$, respectively. By eliminating $E_\phi$ in Eqs. (1a) and (1b), Bessel's equation is obtained in the form

$$\frac{\partial^2}{\partial r^2}H_z+\frac{1}{r}\frac{\partial H_z}{\partial r}+k^2H_z=0, \tag{2a}$$

where the wave number $k=\omega(\epsilon\mu)^{\frac{1}{2}}=\omega/c$.

By a similar process, eliminating $H_z$ from Eqs. (1a) and (1b), is obtained Bessel's equation in another form

$$\frac{\partial^2 E_\phi}{\partial r^2}+\frac{1}{r}\frac{\partial E_\phi}{\partial r}+\left(k^2-\frac{1}{r^2}\right)E_\phi=0. \tag{2b}$$

In compact form the complete solution of (2a) may be written as:

$$H_z=aJ_0(kr)+bN_0(kr), \tag{3a}$$

wherein $J_0(kr)$ and $N_0(kr)$ denote the usual Bessel functions of zero order, first and second kinds, respectively.

Similarly in compact form the complete solution of (2b) or the result of the substitution of (3a) in (1b) may be written as:

$$\frac{i}{z_0}E_\phi=aJ_1(kr)+bN_1(kr), \tag{3b}$$

wherein $J_1(kr)$ and $N_1(kr)$ denote the usual Bessel functions of the first order, first and second kinds, respectively. $z_0$ denotes the intrinsic impedance of the confined space, $(\mu/\epsilon)^{\frac{1}{2}}$.

Relations (2a) and (2b) constitute all possible solutions of (1a) and (1b).

Now, applying the boundary conditions at

$$r=r_b,\quad E_\phi=0,$$
$$r=r_a',\quad H_z=0,$$

wherein $r_a'$ denotes the uncoupled sectorial cavity radius, to (3a) gives

$$H_z=aJ_0(kr_a')+bN_0(kr_a')=0, \tag{4a}$$

and to (3b) gives

$$\frac{i}{z_0}E_\phi=aJ_1(kr_b)+bN_1(kr_b)=0. \tag{4b}$$

So that from (4a) and (4b) $T_0(kr_a)$ and $T_1(kr_b)$ are defined and related at $r=r_a'$ by:

$$-\frac{J_0(kr_a')}{N_0(kr_a')}=T_0(kr_a')=\frac{b}{a}=-\frac{J_1(kr_b)}{N_1(kr_b)}=T_1(kr_b),$$

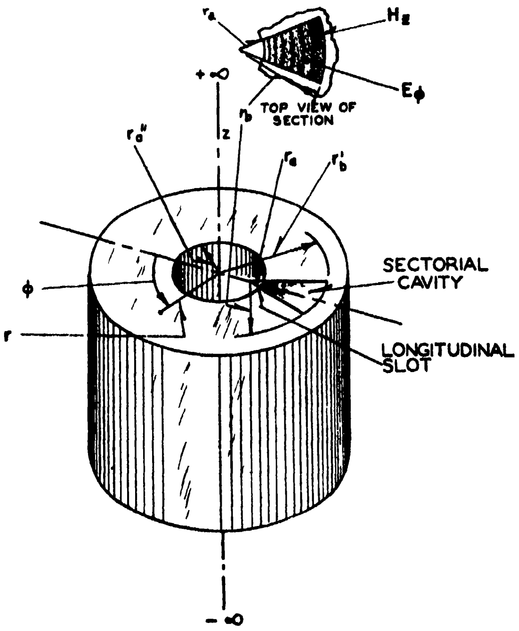

FIG. 1. A section of an infinite length sectorial cavity and adjoining chamber.

or

$$T_1(kr_b)=T_0(kr_a'). \tag{4c}$$

Equations (3a) and (3b) may be rewritten, with $E_\phi=E_{r_a}$ (and $H_z\neq 0$) at $r=r_a$, as

$$z_0H_z=E_{r_a}\cdot i\cdot\frac{J_0(kr)+T_1(kr_b)N_0(kr)}{J_1(kr_a)+T_1(kr_b)N_1(kr_a)}, \tag{5a}$$

$$E_\phi=E_{r_a}\cdot\frac{J_1(kr)+T_1(kr_b)N_1(kr)}{J_1(kr_a)+T_1(kr_b)N_1(kr_a)}, \tag{5b}$$

where $r_a$ represents the radius of the sectorial cavity coupled to the interaction space such that $(r_a-r_a')=\Delta/k$, where $\Delta$ is a small quantity.

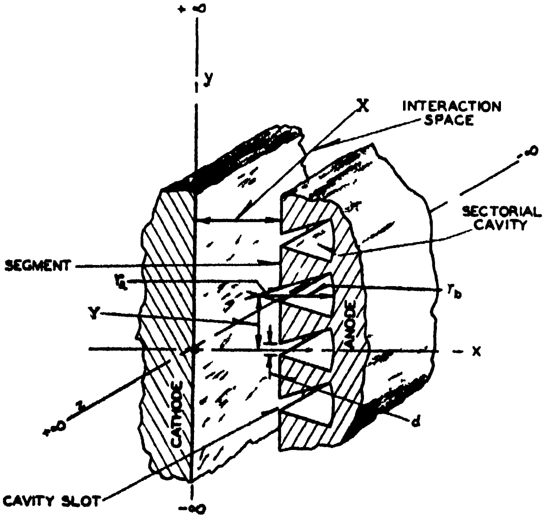

FIG. 2. A section of infinite linear multi-sectorial cavity magnetron.

Now consider the linear magnetron with an array of sectorial resonators as shown in Fig. 2. The electromagnetic fields in the interaction space (between the cathode and anode along the $y$ axis) must be constructed, and then $E_y$ and $H_z$ matched at the slots. The match or continuity of $E_y$ at the slot is exact, whereas for $H_z$ only an approximate continuity condition will be resorted to, although this is quite satisfactory for narrow slots ($d\ll Y$). In the interaction space a solution of Maxwell's equations,[3] for the electromagnetic field, of the type

$$E_y=\sum_{m=0,\pm1\cdots}-ik_{xm}\times\frac{c^2}{\omega}B_m\sinh k_{xm}Xe^{i(k_{ym}y-\omega t)}, \tag{6a}$$

$$B_z=\sum_{m=0,\pm1}B_m\cosh k_{xm}Xe^{i(k_{ym}y-\omega t)} \tag{6b}$$

is used. $k_x$ and $k_y$ denote the magnitudes of the imaginary and real components of the complex propagation vectors, $k_i$ and $k_r$, along the abscissa and ordinate in Fig. 2, respectively. The coefficient $B(=\mu H$ in rationalized M.K.S. units) denotes the magnitude of the real component of the flux density normal to both components of the complex propagation vectors. The relation between $k_{ym}$ and $k_{xm}$ may be expressed as

$$k_{xm}^2=k_{ym}^2-k^2.$$

Observe that the electromagnetic wave in the interaction space is damped along $k_i$ and propagated along $k_r$. The electromagnetic field in the $j$th slot of the sectorial resonator by (5a) and (5b), in corresponding notation, becomes

$$E_{yj}=-i\frac{kc^2}{\omega}B\{J_1(kr_a)+T_1(kr_b)N_1(kr_a)\}e^{i(k_{y0}jY-\omega t)}, \tag{7a}$$

$$B_{zj}=B\{J_0(kr_a)+T_1(kr_b)N_0(kr_a)\}e^{i(k_{y0}jY-\omega t)}, \tag{7b}$$

wherein the propagation vector $k_{y0}$ is related to $k_{ym}$ by the relation $k_{ym}=k_{y0}+2\pi m/Y$, in which $m$ is a positive or negative integer.

The boundary conditions imposed are

$$E_y=E_{yj}\left(jY-\frac{d}{2}\right)\leq y\leq\left(jY+\frac{d}{2}\right), \tag{8a}$$

$$E_y=0,\quad\text{for}\quad(jY-Y/2)\leq y\leq(jY-d/2), \tag{8b}$$

$$\text{for}\quad(jY+Y/2)\geq y\geq(jY+d/2),$$

$$B_z=B_{zj}\quad\text{at}\quad y=jY. \tag{8c}$$

The equality in (8c) is not strictly valid within

$$(jY-d/2)\leq y\leq(jY+d/2).$$

Although the field varies sinusoidally with $y$, it is small provided $d\ll Y$.

Hence, equating the electric and magnetic components of the electromagnetic fields, (6a, 6b,

---

[3] J. C. Slater, "The theory of the magnetron oscillator," M.I.T. Radiation Laboratory Report D-1-9, Office of Publications Board, Report PB-3777, p. 23, 1941. It may be procurable from the Department of Commerce, Washington 25, D. C. Slater's method, for the multi-rectangular cavity case described in his report, serves as a guide in our subsequent analysis.

7a, 7b) in the interaction space and sectorial cavities at the slots, and applying the associated boundary conditions (8a, 8b, 8c), the solution of (6a, 6b) and (7a, 7b) assumes the form

$$\sum_{m=0,\,\pm1\cdots}\frac{d}{Y}\frac{k}{k_{xm}}\left[\frac{J_1(kr_a)+T_1(kr_b)N_1(kr_a)}{J_0(kr_a)+T_1(kr_b)N_0(kr_a)}\right]\times\frac{1}{\tanh k_{xm}X}\frac{\sin\left(k_{y0}+\dfrac{2\pi m}{Y}\right)\dfrac{d}{2}}{\left(k_{y0}+\dfrac{2\pi m}{Y}\right)\dfrac{d}{2}}=1. \quad (9)$$

Recalling that

$$\Delta=kr_a-kr_a', \quad (10)$$

and introducing the contraction $Z_0(kr_a')$ in (4a),

$$J_0(kr_a')+T_1(kr_b)N_0(kr_a')=Z_0(kr_a')=0. \quad (11)$$

Observing that

$$Z_0'(kr_a)=-[J_1(kr_a)+T_1(kr_b)N_1(kr_a)].$$

Now, applying Taylor's expansion to (11), since $\Delta/k$ is sufficiently small, gives

$$Z_0(kr_a')=Z_0(kr_a-\Delta)$$
$$=Z_0(kr_a)-Z_0'(kr_a)\cdot\Delta+\cdots=0,$$

so that

$$\frac{J_1(kr_a)+T_1(kr_b)N_1(kr_a)}{J_0(kr_a)+T_1(kr_b)N_0(kr_a)}\simeq\frac{1}{\Delta}.$$

In addition it will be assumed that

$$k_{x0}\simeq k_{y0}=\frac{\pi}{Y}-\delta;\quad k_{x,-1}=\frac{\pi}{Y}+\delta$$

where $\delta$ is a small quantity,

$$\frac{\sin\left(k_{y0}+\dfrac{2\pi m}{Y}\right)\dfrac{d}{2}}{\left(k_{y0}+\dfrac{2\pi m}{Y}\right)\dfrac{d}{2}}\simeq1,$$

and

$$\tanh k_{xm}X\simeq1,$$

which implies in sequence that $k^2\ll(\pi/Y)^2$; $(Y/2(r_b-r_a))^2\ll1$, and $d$ and $X$ are sufficiently small and large, respectively, to justify these assumptions. With these assumptions, using but two terms of (9) in the region of large $k_{y0}$, Eq. (9) reduces to

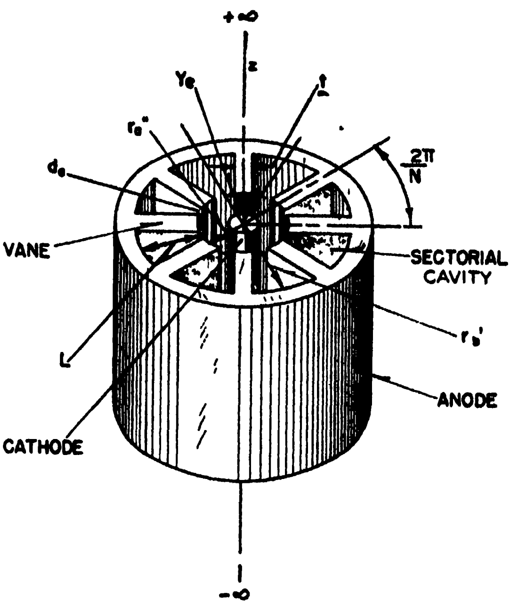

FIG. 3. A section of infinite length multi-sectorial cavity or vane magnetron.

$$\frac{d}{\pi}\frac{k}{\Delta}[(1-Y\delta/\pi)^{-1}+(1+Y\delta/\pi)^{-1}]=1, \quad (12)$$

which on applying the Binomial theorem, introducing $kL=kr_b-kr_a$, with the definition $(\pi/2)\Lambda(kL')=(kr_b-kr_a')$ where $L'=(r_b-r_a')$ and by virtue of (10), (12) reduces to the closed form for the wave-length

$$\lambda=\frac{1}{\Lambda(kL')}\left[4L+\frac{8d}{\pi}\{1+(\delta Y/\pi)^2\cdots\}\right], \quad (13)$$

which is valid for $k_{y0}(=\pi/Y-\delta)$ between $\pi/2Y$ to $\pi/Y$ for the linear case.

Now on the premise that only the region near the anode is of material consequence and that the velocity of propagation in the interaction space is unaltered, these results may be applied to the cylindrical magnetron, illustrated by Fig. 3. Incidentally, only discrete modes of oscillation are permitted in contrast to the linear case. Now, note that

$$\delta=\frac{\pi}{Y_e}-k_{y0},\quad Y_e=\frac{2\pi r_e}{N},$$

where $Y_e$ denotes the arc length between centers of adjacent cavities at $r_e''$.

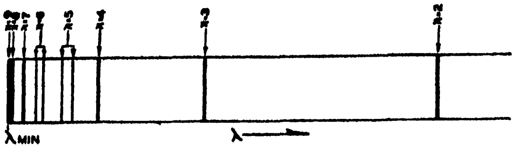

FIG. 4. An example of the fundamental multiplet band structure of modes measured on a Westinghouse 18-vane magnetron ($n_{\max}=N/2=9$; $n_{\min}=1$).

$k_{y0}r_a=n$
$=1, 2, \cdots N/2$ modes of oscillation for even $N$
$=1, 2, \cdots (N-1)/2$ modes of oscillation for odd $N$

and

$$\delta=\frac{\pi}{Y_e}\left(1-\frac{2n}{N}\right)$$

(12) for the cylindrical case, becomes

$$\lambda=\frac{1}{\Lambda(kL')}\left\{4L+\frac{8d_e}{\pi}\left[1+\left(1-\frac{2n}{N}\right)^2+\cdots\right]\right\}. \quad (14)$$

Since the $n=N/2$ or $\pi$ mode of oscillation is invariably sought, for reasons to be revealed presently, and the remaining modes of the fundamental multiplet receive consideration only from a competitive aspect, (14) may be simplified to read

$$\lambda=\frac{1}{\Lambda(kL')}\left(4L+\frac{8d_e}{\pi}\right), \quad (15)$$

which for the sake of brevity suffices in the subsequent discussions, although one can readily derive the complete spectrum of the fundamental multiplet from (14).

It is now appropriate to comment on the characteristics of the mode spectrum of a multicavity cylindrical magnetron in order to present a pictorial interpretation of the analytical results culminating in (14) for the vane magnetron.

The allowed modes of oscillation of the symmetrical cylindrical multicavity magnetron are grouped on a wave-length scale similar to band spectra. The longest wave-length band is referred to as the fundamental multiplet, its band structure or mode components are defined by Eq. (14) for the vane magnetron. It may be characterized by variations in $\phi$ of the electromagnetic field in the plane normal to the axis of the magnetron, for which edge effects are neglected. The modes of the band are characterized by phase differences between alternating potentials on the successive segments in the interaction space. Other bands of the spectrum have shorter wave-lengths, and their electromagnetic fields vary longitudinally as well. Each component of the fundamental multiplet has a different wave-length, although the differences are relatively small and depend upon the effective circuit constants of the cavity and the number of them. Figure 4 presents a pictorial

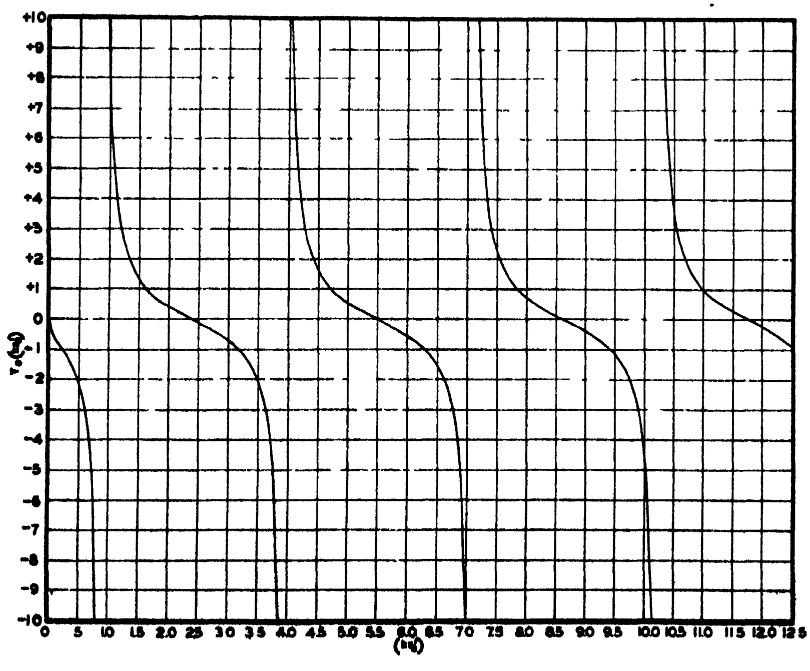

FIG. 5. Graph of the Bessel function, $T_0(kr_a')$, *versus* its argument $(kr_a')$. Values of $T_0(kr_a')$ for arguments less than 0.20 were evaluated from

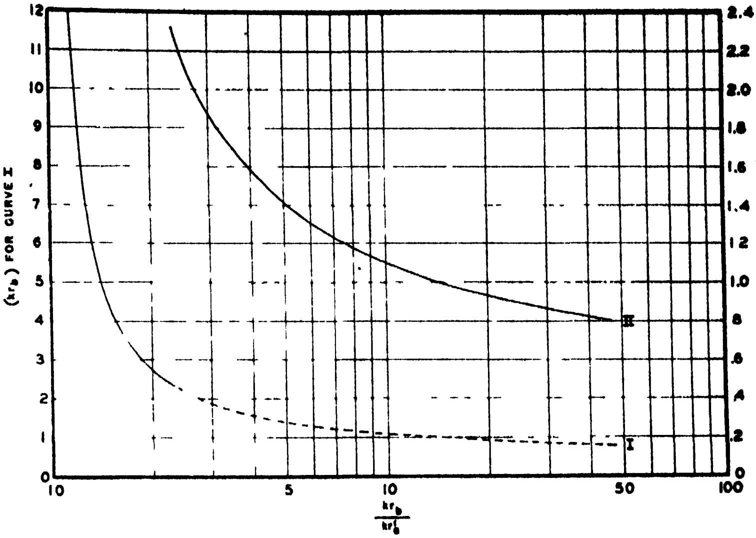
$$T_0(kr_a')=-\frac{1}{\frac{2}{\pi}\ln\left[\frac{2}{\delta(kr_a')}\right]},$$

where $\delta=e^{\gamma}=1.781$, and $\gamma$ is Euler's constant.

FIG. 6. Solution of Eq. (4c), $T_0(kr_a')=T_1(kr_b)$. Curve II is a single dimensional magnification of the dashed portion of Curve I.



representation of the band structure or mode components of the fundamental multiplet from "cold" measurements for an unstrapped Westinghouse 18-vane magnetron. Modes 5 and 6 have been split into doublets by inherent unsymmetries. The relative intensities of the components in the fundamental multiplet are governed by the respective coupling between the resonators and the electronic system *via* the interaction space.

All except one of the modes in the fundamental multiplet for which the number of component resonators, $N$, of the magnetron is even, are doubly degenerate when the resonant system is completely symmetrical, whereas all the modes in the fundamental band, for which $N$ is odd, are doubly degenerate under the same conditions. The term doubly degenerate refers to the number of linearly independent modes, with the degenerate frequency, which in turn is defined as having more than one mode of oscillation though only one frequency. [It may be recalled however, that there are at least two exceptions for which certain unsymmetries do not result in removal of the degeneracy]. Such a split mode is known as a doublet and is characterized by two identical opposite traveling waves around the anode in the interaction space. For a symmetric magnetron with an even number of resonators there are, in the fundamental multiplet, $N-1$ modes with $n=1, 2, \cdots N/2$ separate wave-lengths, whereas for an odd $N$ there are $N-1$ modes though only $n=1, 2\cdots(N-1)/2$ separate wave-lengths. The non-degenerate mode is referred to as the $n=N/2$ or $\pi$ mode. Besides this non-degenerate mode there is an abnormal one, which is associated with the interaction space exclusively and is negligibly influenced by the multi-cavity geometry in a symmetrical multi-cavity system. This abnormal mode is referred to as the $n=0$ or zero mode and is usually well separated on a wave-length scale from the normal components of the fundamental multiplet. For these and other reasons its influence is negligible for symmetrical multi-cavity magnetrons. The electromagnetic field in the interaction space associated with these two modes is of the stationary type, though the zero-mode field is independent of the angular coordinate, whereas the $\pi$ mode field is periodic in this respect. The lower order modes of the fundamental multiplet of the infinite length symmetrical multi-cavity magnetron are ideally found at longer wave-lengths. The $\pi$ mode of the fundamental multiplet is characterized by non-degenerate property and highest conversion efficiency and for these reasons is invariably sought in practice.

In deriving Eq. (14) approximations which are explicitly or implicitly referred to were used. Hence, the present results must not be accepted unconditionally, though quantitatively they are not seriously in error.

Sometime after the completion of this work further efforts by others (in their unpublished

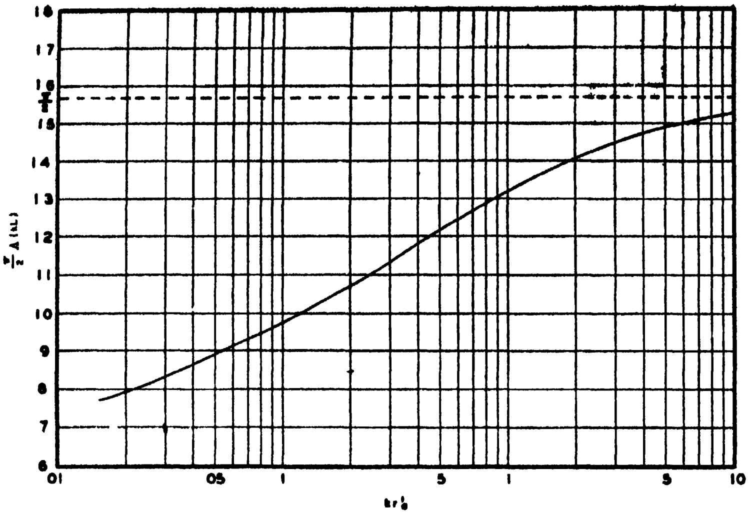


FIG. 7. A graph for the evaluation of the geometry of the sectorial cavity in terms of a given wave-length. It is derived from Fig. 5.

works),[4] concerning the infinite cylindrical case of the vane magnetron were able to be directed by the utilization of a method developed and applied by Clogston to the slot, and hole- and slot-type magnetrons in his unpublished thesis.[5] However, the influence of actual lengths of the end cavities and anode, which influence the order of the modes, their mutual separation, and consequently the wave-length of the $\pi$ mode are not explicitly included. Hence, predictions made in accordance with them, though more accurate in the ideal case than the results of the present method, are also inaccurate when applied to actual magnetrons by about the same percentage in some cases. Generally, however, they[4] are more accurate.

## III. APPLICATIONS

In order to utilize (13) it is necessary to first evaluate (4c). Figures 5 and 6 portray the results of this evaluation. Figure 7 is derivable from the results of Fig. 6. Incidentally, examination of Fig. 7 in conjunction with trigonometric expansions[6] for the components of Bessel functions (4) reveals that the transformation from the sectorial to the rectangular cavity, as $r_a$ and $r_b$ approach infinity together, provides that

$$kr_b - kr_a \to \pi/2$$

as the limit. So that

$$r_b - r_a \to \lambda/4,$$

which is the condition for the rectangular cavity.

Note that the solution of $kr_a'$ nearest to $kr_b$ is chosen by virtue of the mode considered in the sectorial cavity $\delta = 0$ in (13) for $n = N/2 = \pi$ mode.

In order to evaluate the radial vane length, $L$, or major cavity radius, $r_b'$, when the anode radius, $r_a''$, free space wave-length of a desired mode of oscillation, $\lambda_\pi$, vane thickness, $t$, and number of resonators, $N$, are known, the following procedure is convenient. Refer to Fig. 3 for identification of symbols.

Given data:

wave-length, $\lambda_\pi = 9.46$ cm

$$\left(k = 0.664 \frac{1}{\text{cm}},\right)$$

number of sectorial cavities, $N = 18$,
vane thickness, $t = 0.263$ cm,
anode diameter, $2r_a'' = 3.46$ cm,
effective anode length $= 3.36$ cm,
cathode diameter, $2r_c = 1.100$ cm,
cathode to anode ratio, $r_c/r_a'' = 0.318$.

Determine $L$ or $r_b'$ by the following procedure:

the coupled cavity radius,

$$r_a = r_a'' - \frac{t}{2 \sin \pi/N} = 0.972 \text{ cm},$$

---

equivalent slot width,

$$d_e=\frac{\pi 2r_a''}{N}-t=0.441\text{ cm},$$

from relation (12), for the $\pi$ mode $\delta=0$, so

$$\Delta=\frac{2d_e k}{\pi}=0.1867,$$

from Fig. 7, for $kr_a'=kr_a-\Delta=0.459$; $(\pi/2)\Delta(kL')=(kr_b-kr_a')=1.20$,
hence $kL=(kr_b-kr_a')-\Delta\simeq 1.013$ cm,
so that $L=1.525$ cm
and $2r_b'=6.51$ cm,
which differs by about 6 percent from its experimental value on a magnetron (Westinghouse VA-1) possessing these dimensions.

In order to evaluate the wave-length for the $\pi$ mode of oscillation when the anode radius, major cavity radius, vane thickness, and number of resonators are known, it is merely necessary to evaluate the ratio $(kr_b/kr_a')$ and $kr_b$ with the aid of Fig. 6, as illustrated by the following results for the previous Westinghouse magnetron. Refer to Fig. 3 for identification of symbols.

Given data:

number of sectorial cavities, $N=18$,
vane thickness, $t=0.263$ cm,
anode diameter, $2r_a''=3.46$ cm,
effective shell diameter, $2r_b'=6.90$ cm,
effective anode length $=3.36$ cm,
cathode diameter, $2r_c=1.100$ cm,
cathode to anode ratio, $r_c/r_a''=0.318$.

Determine $\pi$ mode wave-length, $\lambda_\pi$, by the following procedure:

$$d_e\simeq\frac{\pi 2r_a''}{N}-t=0.341\text{ cm}$$

$$r_b=r_b'-\frac{t}{2\sin\pi/N}=2.693\text{ cm}$$

$$r_a=r_a''-t/2\sin\pi/N=0.973\text{ cm}$$

$$r_a'=r_a-2d_e/\pi,\ \{\text{from (10) and (12) }\delta=0\text{ for }n=\pi\text{ mode}\},\ =0.756\text{ cm}$$

$$r_b/r_a'=3.54$$

$$(kr_b)\text{ from Fig. 6}=1.70$$

$$\lambda_\pi=2\pi r_b/(kr_b)=9.95\text{ cm}$$

percent difference $\simeq$5 percent from operating wave-length of 9.46 cm for $n=9$ or $\pi$ mode. (Westinghouse VA-1.)

Because of assumptions, such as infinite anode length, linear approximation, etc., inherent in the present method it is not surprising to be confronted with differences of the order of 10 percent more or less between the experimental and theoretical values of $\pi$ mode wave-length. For instance, the length of the anode and end cavity

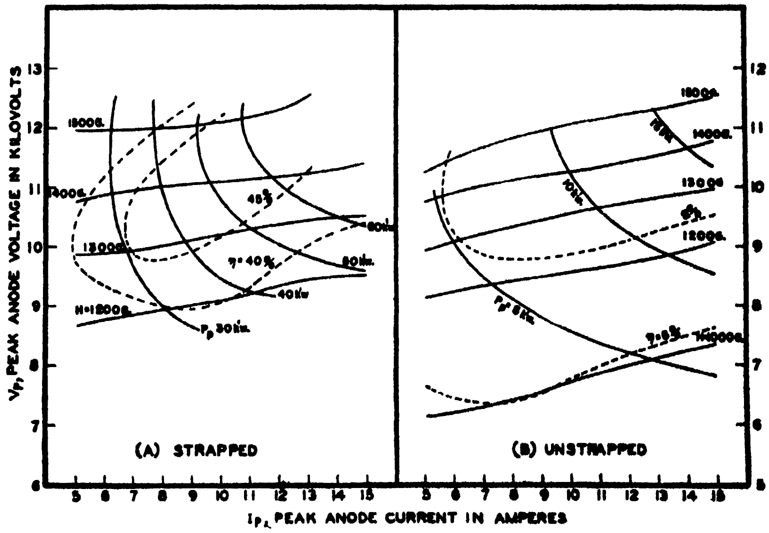

FIG. 8. Performance charts of Westinghouse 8-vane magnetrons, WX-3256, illustrated in Fig. 9. The magnetrons are terminated by a 50-ohm matched coaxial line. The operating unstrapped and strapped wave-lengths are 8.0 and 9.6 cm, respectively.

in terms of free space wave-length will have more or less of an influence on the order and separation of the modes in the multiplet and obviously on the wave-length of the $\pi$ mode.[7] The method, nevertheless, provides reasonable approximate data for a preliminary design, which can then be corrected accordingly by "cold" test.

After examining "cold" test data of a number of similar 8-vane unstrapped 10-centimeter magnetrons constructed with the aid of the preceeding theory, it was discovered that for end cavity and effective anode lengths of the order of $\lambda/10$ and $\lambda/4$ of free space wave-length, respectively, that the perimeter of the sectorial cavity normal to the axis of the magnetron, was nearly equal to half the free space $\pi$-mode wave-length. Since the end cavity and anode lengths have a more or less influence on the order, mode separation, and wave-lengths of the modes of the fundamental multiplet in a practical magnetron, this perimeter index is useful only as a guide in deriving the magnitude of the $\pi$-mode wave-length for a vane magnetron

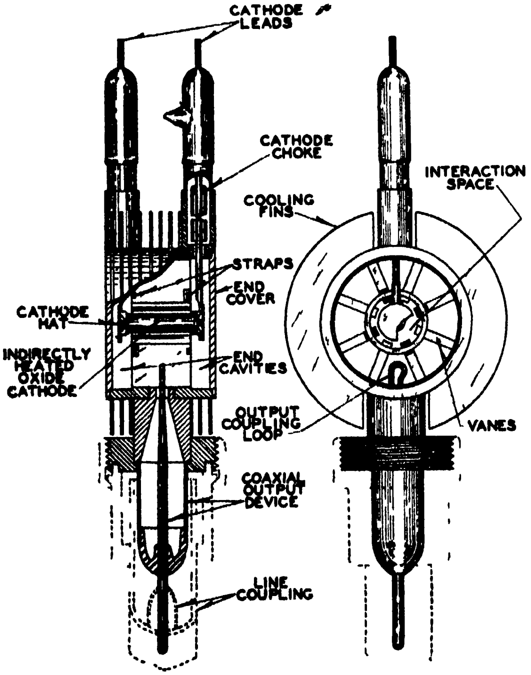

FIG. 9. Westinghouse vane magnetron, WX-3256.

## IV. APPLICATION OF STRAPPING TO THE RESONATOR SYSTEM

Because of the inherent assumptions in the theoretical methods for the determination of mode-frequency spectrum of a multi-cavity magnetron, varying degrees of error result in application so that one often uses the theoretically derived values only as a guide in obtaining a magnetron-resonator system possessing mode-frequency spectrum in the desired wave-length range, for subsequent "cold" tests. From such tests are derived the actual mode spectrum; and if undesirable for one reason or other the resonator system is modified in order to achieve the desired mode separation (about 5 percent or more) and distortion of competing modes, for efficient operation. When the modes are too close together, ($\ll$5 percent say) as is the case with symmetrical multi-cavity magnetrons (for $N \gg 2$) without straps, the competing modes cause the efficiency of the desired mode to be low, as illustrated by Fig. 8. In order to achieve the requisite mode separation between the desired mode (usually the $\pi$ mode since it is non-degenerate and associated with the highest theoretical conversion efficiency) and competing ones in the fundamental spectrum of a symmetrical magnetron, in contrast to the "rising sun" type, strapping is resorted to. Strapping is a mechanical means of joining segments of like phase, usually at one or both ends of an anode, adjacent to the interaction space, in such manner as to increase the normal coupling between resonators and hence the effective capacity of the resonator system. Strapping usually distorts the competing mode patterns so that their interaction with the space-charge field at the slot is poor. The $\pi$ mode is not significantly distorted by proper strapping, so that efficient electronic interaction ensues for this mode. The coupling between cavities for a particular mode may be selective with straps and thereby further increase mode separation.

Essentially two types of strapping are utilized. The symmetrical type of strapping, such as the "echelon,"[7] separates the components of the fundamental multiplet but actually does not split the degenerate modes, whereas the unsymmetrical type of strapping, such as the "Y–B,"[7] which adequately distorts the competing modes, only slightly influences the $\pi$-mode pattern. The type

of assymmetry and degree of coupling or "tightness" of strapping will govern the mode separation and number of degenerate modes which are split by unsymmetrical strapping.

The use of unsymmetrical straps provides one of several necessary conditions for efficient operation in the $\pi$ mode. Figure 8(a) illustrates a typical improvement in performance over that of Fig. 8(b) for the same 10-centimeter, 8-vane magnetron after straps and strap-breaks are incorporated, as illustrated by Fig. 9. "Single recess ring" straps at both ends of the anode are illustrated. The cathode "hat" illustrated, serves to establish an axial component of electric field in order to reduce the number of electrons which would otherwise leave the interaction space and bombard the end covers.

The ratio between the unstrapped, $\lambda_{\pi U}$, and strapped, $\lambda_{\pi S}$, wave-lengths may be expressed

$$\left(\frac{\lambda_{\pi U}}{\lambda_{\pi S}}\right)^2=\frac{1}{1+\dfrac{C_S}{C_T}},$$

in terms of $C_S$ and $C_T$, which denote the total lumped effective values of strap to vane- and resonator-system capacities, including mutuals. The resonator-system capacity is a product of the number of resonators and the effective lumped capacity of each cavity, less straps. The strap capacity will obviously vary with the number and type of straps used and the geometry at the strap-vane intersection. Both $C_T$ and $C_S$ may be derived either by simple electrostatic approximations, by means of models in the electrolytic tank, or by the more elaborate conformal transformations. Practical results are available.[8]

To increase further effectiveness of straps, strap-breaks over the segments are incorporated at judicious places with respect to the load coupling in order to distort the unwanted mode by proper phasing and reduce the tendencies to mode shifts during load variations. With proper type of strapping and number and orientation of strap-breaks, relatively stable competing-mode free operation may be realized.

Since the ratio of equivalent effective capacity to inductance of the cavity (which is a product of the reciprocal of the number of cavities and the effective inductance of one of them) of a magnetron-resonator system is altered by strapping, the frequency pulling characteristics are also

---

altered. Of course, altering the anode length and end cavity length of a symmetrical magnetron with or without straps will influence the mode separation, mode wave-length, and order or distribution between components of the fundamental multiplet. For instance, by altering the anode length of an unstrapped anode, of given end cavity geometry, the order between the components may be completely reversed and consequently wave-lengths changed.

## V. APPLICATION OF DIMENSIONAL SCALING[9]

After incorporation into the magnetron of all the necessary features known to be desirable and after obtaining performance characteristics, a suitable prototype may be obtained which may be dimensionally scaled to other wave-lengths, voltages, powers, etc., while the original efficiency is retained during the transformation. Scaling of vane magnetrons requires that the geometry of the straps, its vane recess, and position on the vane be scaled so as to maintain the strap in the original relative position on the vane. Scaling of a prototype is a very profitable design procedure since it avoids the expensive and time consuming development which would otherwise be required. Since these scaling relations are very useful and appropriate to the present subject, they will be briefly considered herein, though without derivation. Approximate scaling relations have been derived,[10] on the basis of Newton's and Maxwell's differential equations applied to the electrons in the interaction space of the magnetron, and provide conditions for which two magnetrons, differing by some scaling factor, possesses the same efficiency or equivalent operation. These conditions of anode voltage, $V$, and magnetic field, $H$, for constant ratio of anode to cathode radii, $\sigma$, mode of oscillation, $n$, or number of cavities, $N$, and loaded, $Q$, $Q_L$, may be expressed as the invariant magnetron scaling relations,

$$H\lambda,\ V\cdot\left(\frac{\lambda}{r_a}\right)^2;\ \frac{I\lambda^3}{r_a{}^2L},$$

in which $V$ and $H$ are frequently expressed in kilovolts and Gauss, respectively; anode current, $I$, is expressed in amperes, anode length, $L$, anode radius, $r_a$, and wave-length, $\lambda$, in centimeters. This restricted type of scaling is illustrated in terms of the performance chart parameters, for constant $\sigma$, $n$, $N$, and $Q_L$, in Table I. Note that the scaling is valid for either input or output values of anode voltage, $V$, and power, $P$. The current density, $J$, is applicable at either the cathode or anode.

Table I also illustrates the general scaling relations, in which the restraints on the restricted type of scaling have been removed. Note that for the general scaling the current density is applicable only at the cathode. Another relation can be derived for the anode. Very often it is desirable to wave-length, voltage, or power scale a desired operating point of a magnetron under the conditions of the restricted case. For this purpose, the corresponding restraints on the shape and wave-length of the magnetron are inserted into the expressions for the restricted ($N$ fixed) case. The result of which is illustrated by Table II. For both the restricted and general types of scaling, end effects are neglected such that the anode current, $I$, per unit length is independent of length.

With the aid of the scaling relations illustrated by Tables I and II it is possible to scale a selected operating point on the performance chart of a magnetron, as the prototype, to another point in terms of the operational parameters. This process may or may not involve a change of the number of cavities,[11] depending upon whether the general or restricted forms of scaling are applied. Though very often it is only necessary to apply the

[10] A. M. Clogston, M.I.T. Radiation Laboratory Report 52. This was later extended by H. C. Hu in Radiation Laboratory Report 1043-3. These reports may be procurable from the Office of Publications Board, previously referred to.

[11] When a large change in the number of cavities, $N$, is contemplated, in general scaling, the error may be significant, so that one ought to consult reference 10 by H. C. Hu for details.

restricted type of scaling in the forms illustrated by Table II.

The application of the scaling processes illustrated by Table I is readily acquired. For example, consider the often used restricted scaling process in the form illustrated by Table II, which is to be applied to a prototype in order to permit operation at another wave-length and power output. The first step is to make a wave-length scale by altering the effective magnetron's dimensions linearly, in proportion to the new to the old wave-length, in accordance with column two of Table II Then voltage scale by evaluating the anode radius of the interaction space from a knowledge of the desired power by the appropriate relations given under the restricted voltage scaling column. Obviously, one must use the physical and operational parameters derived from wave-length scaling for voltage scaling. This two-step scaling process is convenient, since it affords an inspection of the change in parameters from the prototype to the fully scaled magnetron. Sometimes both power and wave-length must be increased so much above that of the prototype that the consequence of increased physical size may be undesirable; then the prototype may be only wave-length scaled to the desired region according to Table II. After this the desired power may or may not be achieved with undesirable characteristics by mere extrapolation of the applied fields above the chosen operating point of the prototype. In scaling or extrapolation involving a change of the cathode-current density one should, for economic and stability considerations, maintain this as near its stable value as possible. The extent to which simple extrapolation of this sort is practical is usually unknown in advance of tests, because of various implicit properties of the magnetron. Obviously, the performance characteristics of such a "new" magnetron, if operable, are no longer those of the prototype since the above invariance conditions are not satisfied by such an extrapolation.

## VI. RELATED TOPICS AND PRACTICAL CONSIDERATIONS

The distribution of the electric component of the electromagnetic field in the sectorial cavity may be plotted from (5b) as a function of $(r-r_a)/(r-r_b)$, with $r_b/r_a$ as a parameter.

Using (5a) and 5(b), together with the boundary conditions (4a) and (4b), enables the evaluation of the total stored energy per unit length and hence the $Q$.

Practically, for symmetrical magnetrons having $N=6$ to 16 inclusive, the reduced cathode radius, $1/\sigma$, varies from 0 to 17 percent greater than Slater's[3] theoretical optimum value, $(=(1-4/N)/(1+4/N))$, and for $N=18$ this reduced cathode radius amounts to about 5 percent less than this theoretical optimum value. However, the reduced cathode radius may radically deviate from its theoretical optimum value when considerations related to oscillation build-up time and maximum $\pi$-mode (applied) voltage or current in pulsed and C.W. magnetrons are of paramount importance. For example, the 5J26 magnetron possesses a reduced cathode radius amounting to 64 percent greater than the theoretical optimum value, and this at 48 percent over-all efficiency, which incidentally is a product of 58 percent electronic and 82 percent circuit efficiencies.

In voltage scaling symmetrical, strapped magnetrons one must consider the alteration in mode separation, $(\lambda_{n_\pi}-\lambda_{n_\pi\pm1})$, by virtue of the alteration in strap lengths. Since there exists an optimum mode separation (except possibly for rising sun structures with large $N$) for the attainment of the maximum $\pi$-mode input voltage (or current), aside from any further curtailment under pulsed conditions by virtue of inadequate oscillation build-up time, one should determine whether or not the resultant mode separation will seriously curtail the desired $\pi$-mode input voltage or current, under either C.W. or pulsed conditions, after voltage scaling.

# Gyroscopic Effects in a Vibratory System*

G. S. Bennett**
*Naval Research Laboratory, Washington, D. C.*

(Received June 18, 1947)

An analytical investigation is made to determine the influence on a vibrating elastic system of a high speed rotating element. A fundamental condition for the presence of any gyroscopic effect is that the vibration be such as to produce a tilt of the spin vector of the rotor. Equations are derived showing (a) that if precession be prevented, no gyroscopic effects are present, and (b), that if precession be permitted, the gyroscopic action contributes a force opposed to the tilt, and proportional to the angle of tilt, in effect increasing the stiffness of the elastic system. Calculations based on an arbitrarily chosen rotor intended to approximate a typical small motor armature indicate that this additive spring force is small, and that the increase in natural frequency caused by the added stiffness is exceedingly small—on the order of 0.1 percent—in the case where the precessional motion is not restrained

IN many cases, especially aboard aircraft, equipments subjected to vibration have as component parts dynamotors or other rotating elements. It is the purpose of this investigation to determine whether gyroscopic effects caused by rotating elements exert any marked influence on the vibration characteristics of the equipment.

The fundamental condition necessary for gyroscopic action to appear is that a torque be applied tending to change the direction of the axis of rotation of a spinning body. A pure translation will produce no such effects. Assuming such a torque, and using Euler's angles (see Fig. 1) as coordinates for a rigid body in space, we can write Euler's equations for the applied torques about the three principal axes as[1]

$$M_1=A\omega_1-(B-C)\omega_2\omega_3, \quad (1a)$$

$$M_2=B\omega_2-(C-A)\omega_3\omega_1, \quad (1b)$$

$$M_3=C\omega_3-(A-B)\omega_1\omega_2, \quad (1c)$$

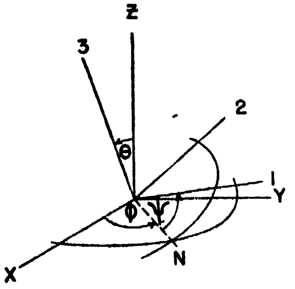

FIG. 1. Euler's angles as coordinates of a rigid body in space.

where $A$, $B$, and $C$ are the moments of inertia about the principal axes 1, 2, and 3, respectively.

Consider the case of a rigid object symmetrical about one axis, and identical with respect to the other two, such as a cylinder rotating about its axis of figure, or a motor armature. Specifying the principal axes and moments of inertia as in Fig. 2, it is apparent that $A=B$. Writing $(B-C)=-(C-A)=H$, and stipulating that $M_3=0$, by use of the equations

$$\omega_1=\dot{\theta}\cos\psi+\phi\sin\theta\sin\psi, \quad (2a)$$

$$\omega_2=\dot{\theta}\sin\psi+\phi\sin\theta\cos\psi, \quad (2b)$$

$$\omega_3=\psi+\phi\cos\theta \quad (2c)$$

substituted in Eqs. (1), we easily find

$$M_1=\cos\psi[A\theta+\phi\psi C\sin\theta-H\phi^2\sin\theta\cos\theta] +\sin\psi[A(\partial^2\phi/\partial t^2)\sin\theta-C\theta\psi +(A+H)\phi\theta\cos\theta] \quad (3a)$$

$$M_2=\cos\psi[B(\partial^2\phi/\partial t^2)\sin\theta-C\theta\psi +(B+H)\phi\theta\cos\theta]-\sin\psi[B\ddot{\theta}+\phi\psi C\sin\theta -H\phi^2\sin\theta\cos\theta] \quad (3b)$$

$$0=C\psi+C(\partial^2\phi/\partial t^2)\cos\theta-C\phi\theta\sin\theta]. \quad (3c)$$

From Eqs. (1c) and (2c), in place of Eq. (3c), we may write

$$\omega_3=K=\psi+\phi\cos\theta. \quad (4)$$

Examination of Eqs. (3a) and (3b) shows immediately that the torques about the moving principal axes 1 and 2 may be considered as the projections of two torques not rotating with the principal axes; one lying along the nodal line $N$ and designated as $P$, the other perpendicular to this line but in the 1, 2 plane and designated as

---

* Paper presented at the 277th meeting of the American Physical Society.

$Q$. Thus,

$$P=A\ddot{\theta}+\dot{\phi}\sin\theta(CK-A\dot{\phi}\cos\theta), \tag{5a}$$

$$Q=B(\partial^2\phi/\partial t^2)\sin\theta-\dot{\theta}(CK-2B\dot{\phi}\cos\theta). \tag{5b}$$

The first term of Eq. (5a) is recognized as the usual Newtonian torque, while the second term is gyroscopic in nature. The first term of Eq. (5b) is, similarly, the Newtonian torque about the precession axis making an angle $(\pi/2-\theta)$ with the 1, 2 plane caused by a torque lying in that plane. Again, the second term of Eq. (5b) is gyroscopic in nature.

There are two cases to be considered; (I) precession is prevented by suitable restraints, and (II) the torque $Q$ is zero (precession not restrained).

For case I, Eqs. (5) reduce to

$$P=A\ddot{\theta}, \tag{6a}$$

$$Q=-CK\dot{\theta}, \tag{6b}$$

where $Q$ is then the torque exerted by the restraint in order to prevent precession, and $P$ the torque which produces tilting—the Newtonian torque.

For case II, rewriting Eqs. (5) with the aid of Eq. (4), and setting $Q=0$,

$$P=A\ddot{\theta}+(K-\dot{\psi})\tan\theta[CK-A(K-\dot{\psi})], \tag{7a}$$

$$0=B(\partial^2\phi/\partial t^2)\sin\theta-C\dot{\theta}(2K-\dot{\psi})+2B\dot{\theta}(\dot{\psi}-K). \tag{7b}$$

Substituting $\theta$ for $\tan\theta$ (for small $\theta$) and letting $\dot{\psi}$ be constant, we can write

$$P=A\ddot{\theta}+R\theta, \tag{8a}$$

$$0=B(\partial^2\phi/\partial t^2)\sin\theta-S\dot{\theta}. \tag{8b}$$

Equation (8a) shows that the gyroscopic effect is that of adding a spring stiffness to the inertia torque. If the system be mounted on springs in the $\theta$ direction, the effect is that of raising the natural frequency. Equation (8b) shows that the torque producing precession is proportional to the velocity of tilt.

Let us now examine the relative importance of the constants $R$ and $S$. Equations (7) and (8) give

$$R=CK(K-\dot{\psi})-A(K-\dot{\psi})^2, \tag{9a}$$

$$S=C(2K-\dot{\psi})-2A(K-\dot{\psi}). \tag{9b}$$

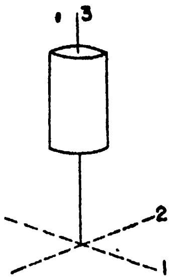

FIG. 2. Arbitrarily chosen rotor. 1, 2, and 3 are principal axes about which the moments of inertia $A$, $B$, and $C$ are taken, respectively. Rotor is taken to be 5 inches long, 2 inches in diameter, and with the lower end 5 inches from the 1, 2, plane. The weight of the rotor is 5 lbs. and the spin velocity chosen as 6000 r.p.m.

Now in general, for systems of the sort here considered, the resultant angular velocity $K$ will be only slightly greater than the spin velocity $\dot{\psi}$, so that $(K-\dot{\psi})$ is small.

From Eq. (9a), $R$ is a quadratic function of $(K-\dot{\psi})$, and is zero when $(K-\dot{\psi})=0$, and when $(K-\dot{\psi})=CK/A$, or $(K-\dot{\psi})/K=C/A$. Between these limits, $R$ reaches a maximum at $(K-\dot{\psi})/K=C/2A$, and for values outside these limits $R$ is negative. Now a negative value of $R$ is physically absurd, as this would indicate a gyroscopically produced torque tending to aid the external torque, which is contrary to all experience. Thus $(K-\dot{\psi})/K$ must lie between $0$ and $C/A$.

For a rough estimate as to the magnitude of $R$, let us assume the rigid body as is shown in Fig. 2 with the axes of rotation as shown. This is thought to be a fair representation of a typical motor armature. Assuming the dimensions and weight shown, and a motor speed of 6000 r.p.m., the maximum value of $(K-\dot{\psi})/K=C/A=0.019$ and the value of $(K-\dot{\psi})/K$ for maximum $R$ is $C/2A=0.0095$. Putting these values in Eq. (9a), the maximum value $R$ can assume is found to be 10,500 lb. in./sec., which gives for a natural frequency about the fixed point (in the $\theta$ plane) approximately 0.95 c.p.s. This is much lower than the usual run of vibration frequencies, implying that the added apparent spring stiffness is small compared to the actual springs present.

$S$ can be rewritten as

$$S=CK-(K-\dot{\psi})(2A-C), \tag{10}$$

which is a linear function of $(K-\dot{\psi})$. Again, $S$

must be always positive, or the limiting value of $(K-\psi)/K=C/(2A-C)$, which is somewhat larger than the value found above giving the maximum value of $R$. As $C$ becomes small compared to $A$, the value of $(K-\psi)/K$ approaches the value for maximum $R$, and as $C$ approaches $A$, the value of $(K-\psi)/K$ approaches the value found above as an upper limit. It is to be noted that $S$ is a direct function of $K$, the resultant angular velocity—as the spin velocity increases, the torque-producing precession increases. For the particular values here chosen, (for maximum $R$) $S$ is 35.5 in lb $^2$/sec.$^2$.

The rotor might well be mounted on springs such that the stiffness would be four-hundred times the apparent stiffness calculated here. For the rotor alone this would mean a natural frequency of 19 c.p.s., which is not uncommon. The effect of added inertia would be to reduce both natural frequencies (real and gyroscopic) without affecting the spring stiffness. In this case then, the gyroscopic effect will be to raise the natural frequency in the ratio

$$\frac{f_{g+s}}{f_s}=\left(\frac{401}{400}\right)^{\frac{1}{2}}=1.0012,$$

and the change is on the order of 0.1 percent.

# Frequency Stabilization of Microwave Oscillators by Spectrum Lines*

William V. Smith, José L García de Quevedo, R L Carter, and W S Bennett
*Department of Physics, Duke University, Durham, North Carolina*

(Received June 25, 1947)

A 2K50 microwave oscillator has been electronically coupled to the $NH_3$ 3,3 rotational spectrum line at 23,870 megacycles in such a manner as to maintain the frequency of the oscillator at the spectrum-line frequency The theory of the "spectrum-line discriminator" designed to produce this frequency stabilization is developed.

## INTRODUCTION

THE possibility of stabilizing the frequency of a microwave oscillator by means of a spectrum line has already been mentioned in the literature.[1] The present article deals with one form of "spectrum-line stabilizer" which has been used to tie the frequency of a 2K50 klystron to the $NH_3$ 3,3 spectrum line at 23,870 megacycles. It is believed that this is the first time any oscillator has been thus "tied to a spectrum line" although variations in the absorption properties of gases have been previously used to modify the properties of cavity stabilizers.[2] Since the first laboratory model of the stabilizer is relatively simple and reliable, it is to be anticipated that engineered versions of the stabilizer will be of considerable importance not only as frequency standards substantially independent of temperature, but also as frequency controlling elements of communications devices, since transmitter and receiver can be set unerringly on the same frequency merely by tying each to the same spectrum line

## THEORY

In developing the theory of this spectrum-line stabilizer, frequent reference will be made to Pound's article on the stabilization of microwave oscillators,[1] as the present stabilizer design is in some features similar to his direct-current cavity stabilizer circuit. The comparable elements of the two stabilizers, i.e., the discriminators, are shown in Figs. 1a and 1b. The operation of both circuits is, essentially, that an input signal of variable frequency is reflected from the terminations of the two tee sections, finally being rectified by crystals $A$ and $B$. The reflections are frequency sensitive, particularly the reflection from arm 2 of tee $A$, which can be so designed that the rectified output of crystals $A$ and $B$, suitably added, is a linear function of frequency near the resonant frequency $\nu_0$ of the element terminating arm 2. In general, the output is adjusted to be zero at $\nu_0$, and is amplified and applied to the re-

---

[2] A. Roberts, Y. Beers, and A. G. Hill, Phys. Rev. 70, 112 (1946).

flector electrode of a microwave oscillator. Since the frequency of oscillation of the oscillator is a linear function of the voltage applied to the reflector electrode, it is possible to feed back the output of the discriminator circuit in such a phase as to correct for any tendency of the oscillator to drift away from the resonant frequency $\nu_0$ of the discriminator.

The only apparent difference between the two discriminators consists in replacing Pound's cavity at $x-\lambda_g/8$ by a short circuit and inserting symmetrical windows $C$ and $D$ in the tee near its junctions, so that one or both of the lengths of guide can be evacuated and filled with gas at a low pressure. (These windows may conveniently be made of mica, and if window $D$ is reflectionless and arm 1 is filled with air, window $C$ can be omitted.) If, then, the gas in arm 2 is resonant at a frequency $\nu_0$, it can be shown that the combined reflections from arms 1 and 2 are the same as for a cavity of frequency $\nu_0$ terminating arm 2, when no gas is present in the arm. Physically, the phenomena occurring in the case of the spectrum-line discriminator are different from those in the cavity discriminator. Energy is absorbed all along arm 2 in the first case, and only in the terminating cavity in the second case. Also, for the spectrum-line case arms 1 and 2 must be long enough so that appreciable absorption takes place at $\nu_0$, but not so long that the incident wave is completely absorbed at $\nu_0$, as then complete absorption may also take place at frequencies in the immediate vicinity of $\nu_0$. For the cavity discriminator, on the other hand, the optimum condition is a match at $\nu_0$, i.e., complete absorption of incident energy. Finally, it should be noted that in the spectrum-line case the two arms differ by $\lambda_g/8$ in electrical length, which is not necessarily the same as the physical length as the dielectric constant (at a frequency well removed from $\nu_0$) may differ in the two arms.

The mathematical analysis will be undertaken for arms 1 and 2 of equal electrical lengths $l$, and the reciprocal of the difference in input impedances to the two arms will be shown to be the same as the input admittance of a cavity. It then follows that if the lengths differ by $\lambda_g/8$, the electrical properties of Fig. 1b will be those of the cavity discriminator of Fig. 1a. Expressing the input impedances $Z_1$ and $Z_2$ to arms 1 and 2 in terms of the characteristic impedance $Z_0$ of the guide, and ignoring the small change in $Z_0$ caused by the gas in comparison with the change in propagation constant, then

$$\begin{aligned} Z_1 &= Z_0 \tanh \gamma_0 l, \\ Z_2 &= Z_0 \tanh \gamma l, \end{aligned} \tag{1}$$

where $\gamma_0$ and $\gamma$ are the propagation constants in vacuum and in gas.

If $\alpha_0$ is the attenuation of the guide walls in nepers per cm, and $\epsilon_1$ and $\epsilon_2$ are the real and imaginary parts of the dielectric constant of the gas,

$$\begin{aligned} \gamma_0 &= \alpha_0 + \frac{2\pi}{\lambda_g} j, \\ \gamma &= \gamma_0 + \frac{\pi}{\lambda_g}[j(\epsilon_1 - 1) + \epsilon_2]. \end{aligned} \tag{2}$$

Also, according to Van Vleck,[3] if the line breadth $\Delta\nu$ is caused solely by collision broadening

$$\begin{aligned} \epsilon_1 - 1 &= \frac{A\nu_0}{2} \frac{\nu_0 - \nu}{\Delta\nu^2 + (\nu - \nu_0)^2}, \\ \epsilon_2 &= \frac{A\nu_0}{2} \frac{\Delta\nu}{\Delta\nu^2 + (\nu - \nu_0)^2}, \end{aligned} \tag{3}$$

where $A$ is a constant.

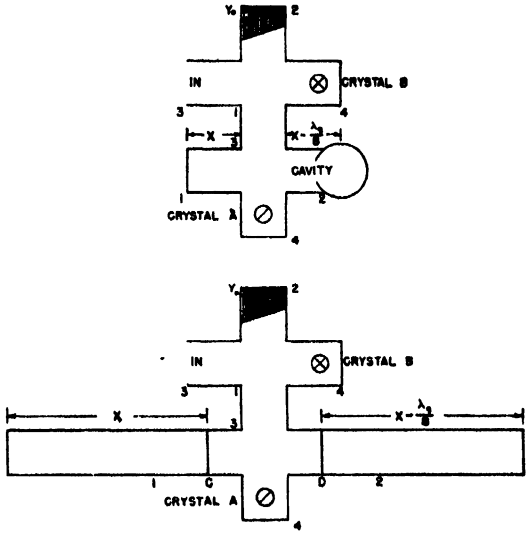

FIG. 1. Spectrum-line discriminator and frequency stabilizer.

---

[3] J. H. Van Vleck, "The relation between absorption and the frequency dependence of refraction," Report 735, M.I.T. Radiation Laboratory.

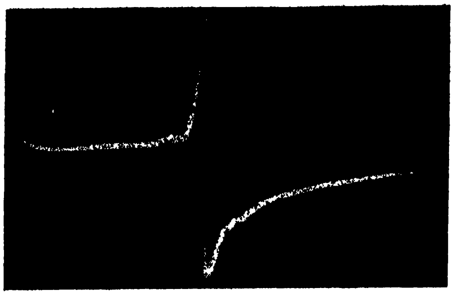

FIG. 2. $NH_3$ 3,3 discriminator characteristic, showing fine structure. The spacing between the center of the linear portion of the discriminator curve and the first satellite is 1.72 megacycles, establishing the frequency scale.

Expanding Eqs. (1), (2), and (3) for $\epsilon_1-1$, $\epsilon_2$, $\Delta\nu/\nu_0$ and $\tanh\gamma l$ all very small compared to 1

$$Y=\frac{1}{Z_2-Z_1}=\frac{2\lambda_g\Delta\nu}{\pi lA\nu_0}\left[\frac{2jQ_0(\nu-\nu_0)}{\nu_0}+1\right]Y_0, \quad (4)$$

where

$$Q_0=\frac{\nu_0}{2\Delta\nu}. \quad \text{If} \quad \alpha=\frac{\pi lA\nu_0}{2\lambda_g\Delta\nu} \quad \text{and} \quad a=\frac{2Q_0(\nu-\nu_0)}{\nu_0},$$

Eq. (4) may be rewritten as

$$Y=\left(\frac{1}{\alpha}+j\frac{a}{\alpha}\right)Y_0, \quad (5)$$

which is Eq. (1) of reference 1 describing the admittance properties of a resonant cavity.

For collision broadening, $A/\Delta\nu$ is independent of pressure.[3] Thus, for a cell of fixed length, as the pressure is lowered the parameter $\alpha$ remains constant while $Q_0$ increases until at sufficiently low pressures effects other than collision broadening begin to influence the line breadth. A discussion of these effects is given by Townes.[4] He states that Doppler effect and collisions with the wave guide walls should begin to affect the line width at $2\Delta\nu=150$ kilocycles, while saturation effects causing an increase in line breadth with input power may limit the line breadth to over one megacycle for high input power.

Townes' data indicate that these saturation effects are just noticeable for an input power of 1.8 milliwatts into an absorption tube of 10.7-mm by 4.3-mm cross section for a pressure of $4\times10^{-2}$ mm of mercury. At this pressure he gets for the ammonia 3,3 line a peak absorption of $5\times10^{-4}$ neper per cm in wave guide and a line width of $2\Delta\nu=1.9$ megacycles. Since the attenuation in nepers/cm $=(2\pi/\lambda_g)\epsilon_2$, the parameters of Eq. (4) are found to be

$$\begin{aligned} Q_0&=\frac{23{,}879}{1.9}=12{,}500, \\ \alpha&=\left(\frac{\pi l\epsilon_2}{\lambda_g}\right)_{\nu=\nu_0}=\frac{l}{3200}. \end{aligned} \quad (6)$$

The slope $dv/d\nu)_{\nu_0}$ of the discriminator curve as derived by Pound is

$$\left.\frac{dv}{d\nu}\right)_{\nu_0}=DP_0\frac{Q_0}{\nu_0}\frac{2\alpha}{(1+\alpha)^2} \quad (7)$$

volts per megacycle, where $P_0$ is the input power to the discriminator and $D$ is a constant. Typical cavity constants are $Q_0=12{,}500$, $\alpha=1$, and $P_0\approx1$ milliwatt, where the upper limit to $P_0$ is set by the amount of decoupling necessary to prevent frequency discontinuities in tying the discriminator to the oscillator. For the spectrum-line discriminator with a 2-meter cell, the constants are $Q_0=12{,}500$, $\alpha=\frac{1}{16}$, and again $P_0=1$ milliwatt, the limit on $P_0$ this time being set by saturation effects. The ratio $dv/d\nu_{\text{spectrum line}}$ to $dv/d\nu_{\text{cavity}}$ can therefore be made at least 1 to 4.5. If Pound's value of $DP=1$ volt is applicable to 1-cm oscillators and crystals as well as to the 3-cm ones to which he applied it, this gives $dv/d\nu=250$ millivolts per megacycle for a cavity and 55 millivolts per megacycle for a spectrum line.

## OBSERVATIONS

Figure 2 is a photograph of the $NH_3$ 3,3 discriminator characteristic at a pressure of about one one-hundredth of a millimeter of mercury. The fine-structure satellites of the line are clearly visible, two on each side of the discriminator. The spacing between the center of the linear portion of the discriminator curve and the first satellite is 1.72 megacycles,[5] establishing the frequency scale. The slope of a similar characteristic measured at a somewhat higher pressure was 70

---

[4] C. H. Townes, Phys. Rev. 70, 665 (1946).

[5] B. P. Dailey, R. L. Kyhl, M. W. P. Strandberg, J. H. Van Vleck, and E. B. Wilson, Jr., Phys. Rev. 70, 984 (1946).

millivolts per megacycle, comparing favorably with the rough theoretical estimate of 55 millivolts per megacycle.

For purposes of comparison of spectrum-line discriminators and cavity discriminators, the above measured slope *dv/dν* is all the data needed. The ultimate purpose of such a discriminator, however, is to actually stabilize an oscillator. To this end, the microwave oscillator which had been frequency swept to obtain the discriminator characteristic was operated *CW*, and the discriminator output fed into a d.c. amplifier similar to that described by Pound. The amplifier output was fed to the reflector electrode only, and the oscillator frequency was observed as a function of the setting of a potentiometer controlling the reflector voltage. Thus the actual voltage on the reflector was the sum of the potentiometer control and the error signal from the amplifier. It was observed that if the pressure of ammonia in arm 2 was a centimeter or more, or if the ammonia were frozen out at liquid air temperatures, the oscillator frequency was a continuous function of the potentiometer control. If, however, the pressure was in the range corresponding to a line width of one-half to two megacycles, approximately, the frequency would "lock in" to the line frequency of 23,870 megacycles over a range of potentiometer settings, jumping discontinuously to a different frequency when the limit of control of the discriminator was exceeded. At approximately optimum conditions as the potentiometer was continuously varied in such a direction as to tend to increase the oscillator frequency, the oscillator tuned continuously up to 23,841 megacycles, jumped to the line frequency of 23,870 megacycles, remaining constant within one megacycle until it again jumped to 23,892 megacycles. Control was thus maintained for variations in reflector voltage equivalent to a frequency spread of just under 51 megacycles. The measured variation of potentiometer voltage over which the frequency remained constant was 14 volts (of a total reflector-cathode voltage of 75 volts).

# The Efficiency of Thermoelectric Generators. I.*

MARIA TELKES
*Department of Metallurgy, Massachusetts Institute of Technology, Cambridge, Massachusetts*

(Received July 28, 1947)

The generation of electrical energy from thermal energy by thermoelectric means cannot be accomplished with thermocouples made of the available alloys generally used for temperature measurements, their efficiency being less than one percent.

A review of the theoretical efficiency calculations shows that higher efficiencies can be attained with thermocouple materials to which the Wiedemann-Franz-Lorenz relation is applicable, when their thermoelectric power is greater than 200 microvolts/°C. Some zinc-antimony alloys with added metals approach the above conditions and have produced an experimental efficiency in excess of five percent, in accordance with the theoretical calculations.

The criteria of higher efficiency are applied to semiconductors, deriving the optimum conditions. Lead sulfide with excess lead was found to be the only suitable material at present, which in combination with the zinc-antimony alloy produces an efficiency of seven percent.

Higher thermoelectric efficiencies can be produced only by developing new materials which can attain the theoretically required high values of thermoelectric power, low heat conductivity, and low specific resistance.

## SYMBOLS

| | |
|---|---|
| $T$ | temperature (°abs.) |
| $T_h$ | hot junction temperature (°abs.) |
| $T_c$ | cold junction temperature (°abs.) |
| $\Delta t = T_h - T_c$ | temperature difference (°C) |
| $E$ | open circuit e.m.f. of thermocouple, Seebeck e.m.f. (volt) |
| $e = \dfrac{E}{T_H - T_C}$ | the average thermoelectric power in the temperature range of $\Delta t = T_h - T_c$ (volt/°C) |
| $\theta = dE/dT$ | the instantaneous thermoelectric power at $T$ temperature (volt/°C) |
| $I$ | current flowing in thermocouple and external load circuit (amp) |
| $R$ | resistance of thermocouple (ohm) |
| $R_e$ | external load resistance, $R_e = R$ (ohm) |
| $W_0$ | output in external circuit (watt) |
| $W_i$ | thermal energy absorbed at the hot junction (watt) |
| $Q_c$ | heat conductance of thermocouple (watt) |
| $\rho'\rho''$ | specific electric resistance of thermocouple materials average between $T_h$ and $T_c$ (ohm cm) |
| $\sigma$ | specific electric conductivity at $T$ temperature (ohm$^{-1}$ cm$^{-1}$) |
| $k'k''$ | specific heat conductivity of thermocouple materials averaged between $T_h$ and $T_c$ (watt cm$^{-1}$ deg.$^{-1}$) |
| $s's''$ | cross-sectional area of thermocouple materials (cm$^2$) |
| $L$ | length of thermocouple materials, both of same length, (cm) |
| $d'd''$ | form factors of thermocouple materials denoting $s'/L$ and $s''/L$ (cm) |
| $\Delta\epsilon$ | energy level difference (electron volt) |
| $k_0$ | Boltzman's constant ($0.8617 \times 10^{-4}$ electron volt/°C) |
| $l_0$ | mean free path (cm) |
| $n_b$ | the number of bound impurity electrons/cm$^3$ |
| $e_0$ | electronic charge |

## HISTORICAL REVIEW

VARIOUS types of thermoelectric generators have been constructed in the past with the aim of producing a gas-heated low voltage direct-current source of relatively small but constant power output. The early efforts have been summarized in book form by F. Peters in 1908.[1] This summary shows that most of the thermoelectric materials then known have been used experimentally in a large variety of empirical designs. Only very few types of thermoelectric generators have reached the production stage. The best-known commercially produced apparatus was Gülcher's gas-heated thermoelectric generator with an over-all efficiency of one-half of one percent.

In more recent times the construction of thermoelectric generators was revived with the aim of producing a gas-heated power supply for radio receivers and for charging storage batteries. Koch's[2] antimony and German silver thermoelectric generator attained an efficiency of 0.5 percent. Wall[3] used iron-constantan thermoelements, attaining an efficiency of less than 0.05 percent. Milne[4] used thermocouples made of nickel and an alloy of copper-silver-selenium in a gas-heated battery charger for radio re-

ceivers, producing an efficiency less than one percent.

## THE EFFICIENCY PROBLEM

For the purpose of electrical power production an efficiency of one percent is definitely unsatisfactory. It is true that relatively small electrical power generators used at present are comparatively inefficient. Small steam-electric power generators operate with an efficiency of five percent or less. Power plants used on farms for the generation of electricity for household purposes operate with an efficiency of less than ten percent, which compares with the twenty-five percent efficiency rating of large modern electric power generating stations.

What is the cause of the low efficiency of thermoelectric generators? This question has been analyzed repeatedly in the literature. One of the suggested causes was the relatively imperfect heat transfer from the fuel burner to the hot junctions of the thermoelements. It is obvious that only that part of the heat of combustion is effective which is actually transferred to the hot junctions. Considerable heat may be lost in the flue gases and through the structural elements which are necessary to hold the thermoelements.

Peters[1] described numerous empirical designs which attempted to improve the heat transfer conditions, but there are relatively few measurements available concerning this phase of the problem. The over-all efficiency of the thermoelectric generator is best analyzed as the efficiency of the thermoelectric process itself as distinct from the efficiency of the heat transfer to the hot junctions.

The purely thermodynamic treatment of the thermocouple considers the thermocouple as a reversible heat engine (recent summary by W. F. Roeser[5]). The thermodynamic consideration establishes correlations between the Seebeck, the Peltier, and the Thomson effects disregarding the irreversible processes caused by heat conduction, lateral heat losses, and the Joule heat generated in the operating thermoelements. The thermodynamic treatment alone is insufficient to account for the performance of the thermoelectric generator, because the irreversible effects are unavoidable and predominant in the calculation of the efficiency.

The efficiency of the thermoelectric process (eff.) is defined as the ratio of useful electrical power output ($W_0$) delivered to an external load, to the electrical equivalent of the thermal energy absorbed at the hot junctions of the thermoelements ($W_i$)

$$\text{eff.} = W_0/W_i.$$

This definition has been used in previous calculations by Lord Rayleigh,[6] Kollert,[7] and Altenkirch.[8] The knowledge of the following physical properties of the thermoelectric materials is required: the thermoelectric power ($e$), the specific electrical resistance ($\rho$), and the specific heat conductivity ($k$) which are functions of the temperature. The above factors are the material constants of the thermoelements. The form factors (cross section, length, shape factors) may be selected according to certain conditions of best design. The previous calculations failed to produce any correlation between the calculated and the observed efficiency, which was primarily due to the inadequate data concerning the material constants.

In recent years the construction of radiation-measuring thermopiles has been improved considerably. Radiation-measuring thermocouples or thermopiles may be regarded as miniature thermoelectric generators, operating at a relatively small temperature difference. In most cases a high voltage output is desired at the expense of the efficiency. The efficiency calculations for thermoelectric generators and radiation-measuring thermopiles are otherwise identical. Such calculations have been published by Johansen,[9] Firestone,[10] Harris,[11] Cartwright,[12] Jones,[13] Kovalenko,[14] Emmons,[15] and others.

The theoretical calculations mentioned above are revised on the following pages, with the aim of deriving equations and conclusions concerning

the theoretical efficiency and the best design criteria of thermoelectric generators. During these calculations several assumptions are made which are now considered in detail.

### 1. Thermocouple Materials

The thermoelectric generator consists of a number of thermocouples, which are identical. The theoretical efficiency is not influenced by the number of the thermocouples and therefore in the following calculations only one thermocouple is considered. The couple is formed of two thermoelectric materials, with hot and cold junctions maintained at definite temperatures. The materials are assumed to be in the polycrystalline state. Their specific electric resistance ($\rho'\rho''$), specific heat conductivity ($k', k''$), and thermoelectric power ($e$) are known functions of the temperature ($T$). The materials should be suitably annealed and their physical properties should not change during the operation of the thermocouple

### 2. Junctions

A selection of solders, fluxes, or welding techniques is available for the preparation of satisfactory junctions It is important that the junction should be free of any additional electric resistance, caused by imperfect soldering or welding, due to the presence of oxide layers or other causes. It is assumed that the "junction resistance" is negligible compared to the total resistance of the thermocouple. This condition is relatively easily attained at the cold junction, but difficulties may arise at the hot junctions. During prolonged operation at relatively higher temperatures, thermal corrosion and deterioration may occur at the hot junction, increasing the electrical resistance and thereby decreasing the efficiency.

It is obvious that the hot junction cannot be operated above a certain temperature, limited by the melting points of the thermoelements. Actually the operating temperature of the hot junction is further limited by the nature of the thermoelectric materials and the contact at the hot junction. Even if oxidation is avoided by limiting the hot junction temperature, changes may occur during prolonged operation because of the diffusion of the two thermoelectric materials and the connecting layer. If the hot junctions are formed with the help of a solder, the components of the solder may diffuse into the thermoelectric materials, with the possibility of changing their composition and properties. Such changes may not be noticed except during prolonged life tests The effect of thermal diffusion may be minimized by using welding techniques or by limiting the amount of solder to a minimum, using a soldering material which does not interfere with the physical characteristics of the thermoelectric materials.

### 3. Heating the Hot Junctions

The experimental determination of the efficiency of thermocouples requires a controlled heating arrangement delivering measured amounts of thermal energy to the hot junctions. For experimental purposes electrical heating of the hot junctions is preferable

### 4. Cooling the Cold Junctions

Because of the irreversible heat conduction occurring in the thermoelectric materials a considerable amount of heat is conducted from the hot junction to the cold junction If this energy is not removed by suitable cooling, the temperature of the cold junction will increase The temperature of the cold junctions can be maintained at or near room temperature by using suitable water or air cooling. The use of higher cold junction temperatures is not desirable in thermocouples made of metallic conductors, because their electrical resistance increases with increased temperature, decreasing their efficiency

### 5. Lateral Heat Losses

It is obvious that the lateral or radial heat losses from the surface of the thermoelements should be as small as possible. In a thermoelectric generator, consisting of a large number of thermoelements, these losses may be minimized by arranging the thermocouples in a closely packed assembly, with the unavoidable minimum of insulating material between the couples. Experimental tests made with relatively few or with individual couples may minimize the lateral heat losses, by surrounding the thermocouples with adequate thermal insulation, or the lateral heat losses may be determined experimentally and corrections applied. During the efficiency calculations it is assumed that the lateral heat losses are negligible.

### 6. Form Factors

The thermoelectric materials are generally in the form of cylindrical or rectangular bars, wires, or sheets. Some constructors used wedge-shaped or tubular thermoelements with the aim of improving the performance. Actually, however, such forms failed to increase the efficiency. The construction is simplified if the lengths of the thermoelectric materials are equal, as in this case the distance between the hot and cold junction zones is fixed, facilitating the structural arrangement. Complex shape or form factors alone cannot improve the efficiency.

It can be shown by calculation that optimum conditions will prevail if the shape factor of the thermoelements is selected in such a way that equal amounts of heat are conducted away by the two thermoelectric materials, while at the same time the electric resistance of the two elements is also equal.

### 7. Internal and External Resistance

The maximum power output of a thermoelectric generator is obtained when its internal resistance is nearly equal to the external load resistance This criterion can be derived by calculation and has been proven by experiments.[3]

### 8. Joule Heat

During the operation of a thermoelectric generator with current flowing through the thermoelements, an internal Joule heat will be generated. Part of this heat will be removed at the cold junctions. This effect may be disregarded as long as the efficiency of the thermocouple is rather low.

### 9. Thomson Effect

During the operation of a thermoelectric generator on closed circuit the Thomson effect should influence the thermal distribution conditions. The effect is of relatively slight importance in most cases and therefore it is not considered in the following calculations.

### EFFICIENCY CALCULATIONS

The calculations apply to a definite operating temperature interval $\Delta t = T_h - T_c$.

The open circuit e.m.f. is $E = e\Delta t$. When the circuit is closed through an external resistance ($R_e$) which is equal to the internal resistance ($R$) of the thermocouple a current ($I$) will flow in the circuit: $I = E/2R$. The load e.m.f. will drop to $\frac{1}{2}E$. The Watt output in the external circuit will be:

$$W_0 = \tfrac{1}{2}EI = E^2/4R. \tag{1}$$

The total electrical energy produced in the thermocouple and the external load circuit is $2W_0$. A part of the thermal energy ($W_t$) absorbed at the hot junction will be used for the production of $2W_0$ electrical energy, while the larger part of $W_t$ will be conducted away by the thermocouple elements in accordance with their heat conductivity ($Q_c$) (irreversible loss). Applying the second law of thermodynamics, the amount of thermal energy required for the production of $2W_0$ electrical energy is:

$$\frac{2W_0T_h}{T_h - T_c} = \frac{2W_0T_h}{\Delta t}. \tag{2}$$

The efficiency is obtained by combining Eqs. (1) and (2):

$$\text{eff} = \frac{W_0}{W_t} = \frac{W_0}{\dfrac{T_h 2W_0}{\Delta t} + Q_c} = \frac{1}{\dfrac{2T_h}{\Delta t} + \dfrac{Q_c}{W_0}}$$

$$= \frac{1}{\dfrac{2T_h}{\Delta t} + \dfrac{Q_c 4R}{E^2}}. \tag{3}$$

We proceed substituting the values of the specific resistance, the specific heat conductivity $k'k''$, and the form factors $d'd''$ into the above equation:

The electric resistance

$$R = \rho'/d' + \rho''/d''. \tag{4}$$

The heat conductance

$$Q_c = \Delta t(k'd' + k''d''). \tag{5}$$

TABLE I. Calculated efficiency of thermocouples (percent); cold junction temperature 27°C; Wiedemann-Franz-Lorenz relation applicable.

| Temp. diff. $t$°C | Thermoelectric power in microvolts/°C 100 | 150 | 200 | 250 | 300 | 400 | 500 | 600 | 800 | 1000 |
|---|---|---|---|---|---|---|---|---|---|---|
| 100 | 0.75 | 1.56 | 2.53 | 3.54 | 4.55 | 6.3 | 7.7 | 8.7 | 10.1 | 10.8 |
| 200 | 1.30 | 2.70 | 4.35 | 6.04 | 7.69 | 10.5 | 12.7 | 14.3 | 16.0 | 17.4 |
| 300 | 1.72 | 3.57 | 5.71 | 7.92 | 10.0 | 13.6 | 16 2 | 18.2 | 20.6 | 22.0 |
| 400 | 2.06 | 4.25 | 6.78 | 9.35 | 11 8 | 15.8 | 18.8 | 21.0 | 23 8 | 25 3 |
| 500 | 2.34 | 4.80 | 7.63 | 10.5 | 13.2 | 17.6 | 20.9 | 23.2 | 26.2 | 27.8 |

From Eqs. (4) and (5) it follows that:

$$\frac{4RQ_c}{E^2}=\frac{4\Delta t(k'd'+k''d'')\left(\frac{\rho'}{d'}+\frac{\rho''}{d''}\right)}{e^2\Delta t^2}$$

$$=\frac{4\left(k'\rho'+k''\rho''+\frac{k'\rho''d'}{d''}+\frac{\rho'k''d''}{d'}\right)}{e^2\Delta t}. \qquad (6)$$

Before proceeding further we examine the optimum conditions for the selection of the form factors. It was stated above that the form factors should be selected in such a way that equal amounts of heat should flow through the two elements and that their electrical resistance should be the same. This condition will prevail if:

$k'd'=k''d''$ or $d''/d'=k'/k''$ (from Eq. 5),

$\rho'/d'=\rho''/d''$ or $d''/d'=\rho''/\rho'$ (from Eq. 4),

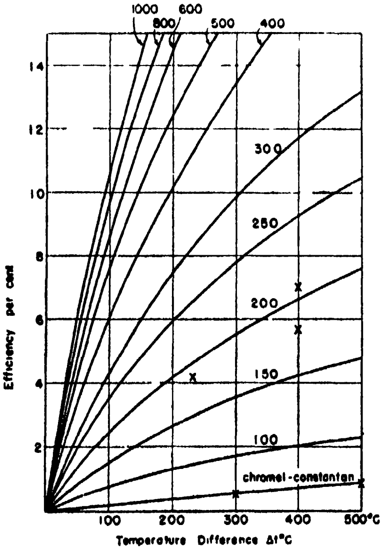

FIG. 1. Calculated efficiency of thermocouples as a function of the temperature difference; x-experimental results. The figures indicate the thermoelectric power in microvolts/°C.

combining the above

$$\frac{d''}{d'}=\left(\frac{k'\rho''}{k''\rho'}\right)^{\frac{1}{2}} \qquad (7)$$

substituting Eq. (7) into (6) we obtain:

$$\frac{4RQ_c}{E^2}=\frac{4\{k''\rho''+k'\rho'+2(k''\rho''k'\rho')^{\frac{1}{2}}\}}{e^2\Delta t}$$

$$=\frac{4\{(k''\rho'')^{\frac{1}{2}}+(k'\rho')^{\frac{1}{2}}\}^2}{e^2\Delta t}. \qquad (8)$$

Combining Eq. (3) and (8) the efficiency is:

$$\text{eff.}=\frac{1}{\frac{2T_h}{\Delta t}+\frac{4\{(k'\rho')^{\frac{1}{2}}+(k''\rho'')^{\frac{1}{2}}\}^2}{e^2\Delta t}}. \qquad (9)$$

Examining the efficiency equation (9) we find the expressions $k'\rho'$ and $k''\rho''$. On the basis of experimental observations, Wiedemann-Franz found (in 1853) that for many metals and alloys the ratio of the heat conductivity ($k$) and the electric conductivity ($\sigma$) is constant at room temperature, $k/\sigma=7.3\times10^{-6}$. As the specific resistance $\rho=1/\sigma$ it equally follows that $k/\sigma=k\rho=7.3\times10^{-6}$.

The specific resistance of many metals and alloys was found to increase with temperature. On the basis of further experimental evidence Lorenz (in 1877) found the general relation (Wiedemann-Franz-Lorenz-constant):

$$k/6=k\rho=2.45\times10^{-8}T. \qquad (10)$$

The theoretical explanation for the value of this constant has been given by Sommerfeld (in 1927).

The experimental evidence shows that the Wiedemann-Franz-Lorenz relation is applicable to most metals and many alloys (within the temperature range of thermocouple use). No metal or alloys have been found to show a lower value. Some alloys show a higher value, a deviation ($D$) from the normal Wiedemann-Franz-Lorenz constant. The deviation ($D$) may be explained by a consideration of the heat conductivity ($k$). The heat conductivity is due to two factors: the atomic part, which is of the same order of magnitude as that of insulators, and the electronic part, which in good heat conductors is preponderant. Metals (Bi, Sb) or alloys of low heat conductivity generally show a deviation ($D$) from the normal Wiedemann-Franz-Lorenz constant.

According to Eq. (9) the efficiency will be high if $k'\rho'$ and $k''\rho''$ are small, that is, if the Wiedemann-Franz-Lorenz constant is applicable to the thermocouple.

Optimum condition: *Wiedemann-Franz-Lorenz relation* applicable. Assuming that Eq. (10) is applicable to a thermocouple operating at an average temperature of $1/2(T_h+T_c)$ it follows that $\rho'k'=\rho''k''=2.45\times10^{-8}1/2(T_h+T_c)$.

In this case Eq. (9) is changed to:

$$\text{eff.}=\frac{1}{\dfrac{2T_h}{\Delta t}+\dfrac{16\rho k}{e^2\Delta t}}=\frac{1}{\dfrac{2T_h}{\Delta t}+\dfrac{19.7\times10^{-8}(T_h+T_c)}{e^2\Delta t}}. \quad (11)$$

This equation contains only the junction temperatures and the thermoelectric power. The cold junction temperature, $T_c$, may be regarded as fixed near the ambient or room temperature, which is about 300°abs. (27°C). Equation (11) permits the calculation of the efficiency for definite temperature differences and thermoelectric powers. The results of this calculation are summarized in Table I and Fig. 1.

It should be emphasized that the above efficiencies represented in Table I and Fig. 1, are based upon the assumption that thermoelectric materials can be produced to which the Wiedemann-Franz-Lorenz relation is applicable. At higher efficiencies (> 10 percent) the Joule heat cannot be neglected and therefore these values should be regarded as tenative indications.

The applicability of the Wiedemann-Franz-Lorenz relation for most metallic materials and alloys can be determined if the specific resistance and specific heat conductivity are known. For a temperature of 27°C (300°abs.) the Wiedemann-Franz ratio $\rho k=7.35\times10^{-6}$. For most materials the specific resistance is known, but the heat conductiyity may not be available. In such cases the following rule may be applied to determine whether a large deviation from the Wiedemann-Franz-Lorenz relation can be expected. The specific heat conductivity may be assumed to be as low as that of certain insulators, which average $k=0.01$. With this assumed value the corresponding $\rho$ value will be $7.35\times10^{-4}$. ***Any material which shows a specific resistance larger than 0.001 ohm-cm at room temperature probably cannot be expected to follow the Wiedemann-Franz relation.***

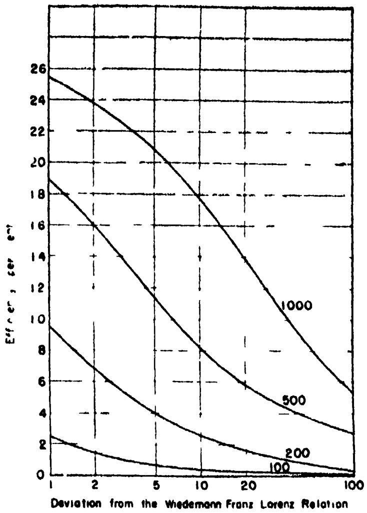

FIG. 2. Calculated efficiency of thermocouples in relation to their deviation from the Wiedemann-Franz-Lorenz relation; temperature difference 400°C; the figures indicate the thermoelectric power in microvolts/°C.

General condition: *Wiedemann-Franz-Lorenz relation not applicable.* Many thermoelectric materials of high thermoelectric power show a considerable deviation ($D$) from the Wiedemann-Franz-Lorenz relation. If the specific resistance, $\rho'$, and the specific heat conductivity, $k'$, of such materials is known, the deviation ($D$) at an average temperature ($T$) will be:

$$D=\frac{\rho'k'}{2.45\times10^{-8}T}.$$

A thermocouple formed of a thermoelectric material showing a deviation ($D$) in combination

with another material showing no deviation will show a diminished efficiency, as computed in Table II and shown in Fig. 2. The calculations were made for a cold junction temperature at 27°C, using a temperature difference of 400°C.

Table II indicates the importance of the deviation from the Wiedemann-Franz-Lorenz relation, which is very pronounced for the 100- to 250-microvolt/°C thermoelectric power values; the efficiency of such couples diminishes to half of the theoretical maximum with a deviation of two to five. For the 500- to 1000-microvolt/°C range the efficiency decreases to half of the theoretical value with a 10- to 20-fold deviation. Assuming that such materials would have a low specific heat conductivity of $k=0.01$, the corresponding $\rho$ value will be about 0.03 ohm-cm. *It is probable that in the above indicated temperature range thermoelectric materials with a specific resistance greater than 0.03 ohm-cm could not attain an efficiency in excess of 10 percent, even if their thermoelectric power were as high as 1000-microvolt/°C.*

## THERMOCOUPLE MATERIALS

Recent reviews[6,16,17] tabulate the properties of thermoelectric materials used for temperature measurements. Some of the best materials of this type are summarized in Table III.

As shown in Table III, the thermoelectric power of the commercially available thermocouples is considerably below 100-microvolt/°C. Even if the Wiedemann-Franz-Lorentz relation of these materials would not deviate from its normal value, the expected efficiency could not be greater than 2 percent, operating them at relatively high temperatures.

### The Chromel P–Constantan Thermocouple

This couple produces the highest thermoelectric power and may be regarded as the best commercially available couple. It was used, therefore, to verify the efficiency calculations, comparing them with the experimentally attainable efficiency. Chromel P (approximately 90 nickel–10 chromium) and constantan (55 copper–45 nickel) were used in the form of flat bars with welded hot and cold junctions. The hot junctions were electrically heated, the cold junctions water-cooled. The specific resistance, heat conductivity, and thermoelectric power of these alloys are shown in Table IV together with their calculated and experimentally observed efficiencies.

The calculated and observed efficiencies are in good agreement and show that the efficiency is less than one percent with the hot junctions operating at 520°C. This is approximately the highest temperature at which constantan can be used continuously without undue thermal corrosion. Assuming that constantan could be protected against oxidation at higher temperatures, the calculations show that an efficiency of two percent could be attained with a temperature difference of about 1000°C.

### The Bismuth-Antimony Couple

The use of this couple is limited by the melting point of bismuth (271°C). Instead of bismuth, an

alloy of 91 Bi–9 Sb can be used which shows a slightly better performance. The electrical properties of these materials have been determined by Gehlhoff and Neumeier[19,20] and are summarized in Table V, giving the calculated efficiency.

## THERMOELECTRIC PROPERTIES OF ELEMENTS AND ALLOYS

The thermoelectric power and the specific resistance of various alloys have been summarized.[5,16,17,19–23]

According to the literature the thermoelectric power of most elements is considerably less than 100-microvolt/°C, with the exception of Te, Se, Si, and Ge.

The thermoelectric power of most alloys was found to be considerably less than 100-microvolt/°C, therefore these alloys could not be expected to produce efficiencies higher than two to three percent, even when operated at relatively high temperature differences.

Thermoelectric power values in excess of 100-microvolt/°C apparatently are found only in alloys containing Sb, Bi, Se, Te, Si (group IVB, VB, VIB of the periodic table), in combination with other metals.

A thermocouple formed of 1Bi–99Te and 42Bi–58Te shows a thermoelectric power of 380 microvolt/°C. Efficiency experiments are in progress.

The following general rules have been derived from the study of binary alloy systems:

In a binary alloy series a high value of the thermoelectric power and a high value of the specific electric resistance generally occurs at or near an intermetallic compound.

A relatively small amount of added metal ("impurity") may diminish the specific resistance of an element or an intermetallic compound to a considerable extent, while the thermoelectric power is changed relatively slightly, the heat conductivity remaining practically unchanged.

### Tellurium and Tellurium Alloys

The general rules indicated above can be illustrated by tellurium and its alloys. The thermoelectric power of pure tellurium is rather low, while its specific resistance is high. Impure tellurium generally shows a high thermoelectric power, with variable specific resistance. Certain small additions (Bi, Sb) diminish the specific resistance about 100-fold, increasing the thermoelectric power of pure tellurium. The intermetallic compound $Bi_2Te_3$(52 Bi–48 Te) when

pure has a negative thermoelectric power, which changes sign when impurities are present. Another alloy 42 Bi–58 Te shows the highest negative thermoelectric power of this series. The properties of some Te alloys are shown in Table VI.

### Zinc-Antimony Alloys

It has been known[1] that an alloy of Zn and Sb forming the intermetallic compound ZnSb (35 Zn–65 Sb) is a suitable material for thermoelements. The specific resistance, specific heat conductivity, and thermoelectric power as a function of the temperature has been measured.[28, 29] Relatively small amounts of metals added to the ZnSb compound diminish its specific resistance considerably, while the thermoelectric power and the specific heat conductivity are altered only slightly. Efficiency measurements have been made with thermocouples of ZnSb with constantan, at a temperature difference of 400°C, the maximum allowable operating range. The observed efficiency values agree with the calculated values (Table VII).

A thermocouple formed of the above alloys in combination with an alloy of 91 Bi+9 Sb, Table V, attained an efficiency of 4.2 percent operating at a temperature difference of 230°C (hot junction at 250°C) which is the highest allowable temperature due to the low melting point of the bismuth alloy (near 270°C). At this relatively low temperature thermal corrosion is entirely absent. The Zn–Sb alloy thermocouples in combination with constantan or with the Bi–Sb alloy show a considerable improvement in efficiency (4.2 to 5.6 percent) compared with Chromel P–constantan and the Bi–Sb couples (about 1 percent).

### Cadmium-Antimony Alloys

The Cd–Sb series of alloys form an unstable intermetallic compound. This condition influences greatly the electrical properties, as reported in the literature.[30, 31] Efficiency tests failed to produce favorable results.

### Silicon and Silicon Alloys

The thermoelectric power and the resistivity of silicon is very markedly influenced by impurities. Relatively small changes in the amount of the impurities may result in a reversal of the sign of the thermoelectric power.[32–34] The specific heat conductivity of impure silicon is comparable to that of nickel, while the specific resistance of silicon is at least 1000 times greater. The Wiedemann-Franz-Lorenz relation, therefore, is very unfavorable and a high efficiency could not be expected.

### Sulfides, Oxides, Semi-Conductors

The sulfides and oxides as thermoelectric materials may be classified according to the nature of their electrical conductivity.

*Metallic conductors* of high conductivity, which decreases at increasing temperatures. Their temperature coefficient of resistivity is negative, as it is in most metals and alloys.

*Semi-conductors* of comparatively low electrical conductivity, which increases considerably at higher temperatures; the temperature coefficient of resistivity is negative. The thermoelectric power of semi-conductors is generally in the range of 100- to 1000-microvolt/°C.

A large group of semi-conductors show pure electronic conductivity, and only these are considered. Their electrical properties are usually

influenced by the presence of small amounts of impurities. With the exception of the elements Te, Se, Si, and Ge the semi-conductors are chemical compounds or intermetallic compounds. In their pure and stochiometrically exact form their electrical conductivity shows a minimum, approaching that of insulators.

Semi-conductors of the oxide and sulfide group are usually prepared by compressing and sintering. This procedure generally does not furnish solid compacts, a certain porosity remains, which decreases the conductivity, although it does not influence the thermoelectric power. With suitable treatment the semi-conductors can be prepared in a non-stochiometric form, with the electropositive or the electronegative element in excess as impurity (homogeneous or intrinsic impurity). Added foreign atoms in a similar way can act as heterogenous (extrinsic) impurities. The impurities may supply free conduction electrons or may combine with free electrons, altering the conductivity of the pure stochiometric compound. In some cases the conductivity may increase $10^3$- to $10^6$-fold. The thermoelectric power is generally not affected in a similar manner; in some cases it is hardly influenced at all.

The semi-conductors are classified as:

a. excess electron conductors containing a stochiometric excess of a metallic element; they generally show a negative thermoelectric power. The excess metal may be obtained through a reducing heat treatment.

b. defect or hole conductors containing a stochiometric excess of a non-metallic element; they generally show a positive thermoelectric power. The excess non-metal may be obtained by heat treatment in a suitable gas.

The theoretical treatment of the electrical conductivity and the thermoelectric power of semi-conductors[35–40] results in the following correlation:

The electrical conductivity

$$\sigma = A\exp(-\Delta\epsilon/2k_0T),$$

where

$$A = 0.024 l_0 n_b^{\frac{1}{2}} T^{\frac{3}{4}} (\text{ohm}^{-1}\,\text{cm}^{-1}).$$

The thermoelectric power

$$\theta = \pm[(\Delta\epsilon/2Te_0)+\text{const.}].$$

The value of the constant is $5k/4e_0 = 108\times10^{-6}$ volt for extrinsic conductors and $2k/e_0 = 172\times10^{-6}$ volt for intrinsic conductors.

The above equations may be verified experimentally by measuring the electrical conductivity ($\sigma$) as a function of the temperature ($1/T$) and deriving the values of $A$ and $\Delta\epsilon$. The experimental determination of $\theta$ as a function of the temperature ($1/T$) should result in the same $\Delta\epsilon$ value.

Several attempts have been made to correlate the theoretical calculations with the experimental evidence. Hochberg[41] found a reasonable agreement in the case of $V_2O_5$ and $WO_3$, but only a qualitative agreement with $MoS_2$, CuO and a mixture of cobalt oxides. Borelius[42, 43] found satisfactory agreement for Se.

The equations for $\sigma$ and $\theta$ are now examined from the point of view of the efficiency of the thermoelectric process. The requirement for a high thermoelectric power $\theta$ implies that $\Delta\epsilon$ must

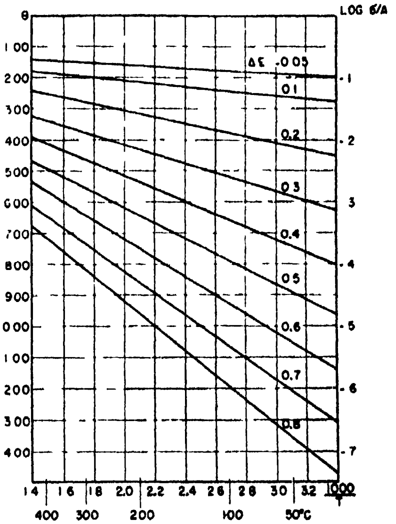

Fig. 3. Thermoelectric power $\theta$ and electric conductivity $\sigma$ of semi-conductors as a function of the temperature $T$ and the energy-level difference $\Delta\epsilon$; $\theta$ in microvolt/°C.

be high. With increasing temperature the thermoelectric power decreases, therefore higher temperatures are less advantageous. The electrical conductivity is subject to the opposite condition, it increases considerably at higher temperatures and decreases at higher values of $\Delta\epsilon$. The value of $A$ should be large, as the electrical conductivity is directly proportional to it. It should be noted that the porosity of pressed and sintered compacts should alter the value of $A$, but should not influence $\Delta\epsilon$.

Using various values of $\Delta\epsilon$, the conductivity in the form of $\log\sigma/A$ and the thermoelectric power $\theta$ can be plotted as a function of the temperature $1/T$. This is shown in Fig. 3. If the values of $\Delta\epsilon$ and $A$ are known for any semi-conductor, its conductivity as a function of the temperature can be obtained from Fig. 3, by inserting $A$ into the corresponding $\sigma/A$ values found on the particular $\Delta\epsilon$ line.

The efficiency calculations indicated that higher efficiencies can be expected only with thermoelectric powers in excess of 300-microvolt/°C, with a low heat conductivity of the order of magnitude $k=0.01$ with low specific resistance of the order of $\rho=0.001$ to $0.03$ (conductivity $\sigma=1000$ to $33$).

Figure 3 shows that near room temperature $\Delta\epsilon=0.2$ would correspond to a thermoelectric power of 440-microvolt/°C, with a corresponding $\log\sigma/A=-1.7$ or $\sigma/A\cong 0.02$. For higher efficiency $\sigma$ should be 33 to 1000 and therefore $A$ should be at least 1500 or greater. At a temperature of 200°C $\Delta\epsilon=0.2$ would correspond to a thermoelectric power of 310-microvolt/°C, with $\sigma/A\cong 0.1$ requiring an $A$ value$>1000$.

The application of the efficiency calculations indicates that higher efficiencies may be obtained only from those semi-conductors, which show $\Delta\epsilon$ of the order of 0.2, with corresponding $A>1000$.

Table VIII shows the properties of some oxides and sulfides with relatively higher thermoelectric power values. The thermoelectric power of some other oxides or sulfides is rather high, but as their conductivity is excessive they were not included in this table.

Mixtures of oxides have been investigated by F. Fischer.[51, 52] The electrical conductivity of certain mixtures is much higher than the conductivity of the components; the thermoelectric power of the highly conducting mixtures is somewhat lower than that of the components.

## Lead Sulfide Thermoelement

Inspecting Table VIII the material of highest conductivity is PbS with excess lead. This mixture shows metallic conduction, the conductivity decreasing at increasing temperatures. PbS thermoelements containing a slight excess of lead may be prepared by hot pressing and sintering. A thermocouple made of PbS and the ZnSb alloys of Table VII shows a thermoelectric power of 330 to 390 microvolt/°C. The specific heat conductivity of PbS was found to be

$k = 0.015$. The calculated efficiency of this couple, operating at a temperature difference of $\Delta t = 400°C$, is approximately 10 percent. The experimentally observed efficiency was 7 percent because of difficulties in attaching suitable end contacts to the PbS, which should be free of any contact resistance.

Efficiency tests made with $Cu_2S$ failed to produce any noteworthy results.

## CONCLUSIONS

The efficiency calculations establish a definite relationship between the thermoelectric power ($e$ or $\theta$), the specific electric resistance ($\rho$) or conductivity ($\sigma$), and the specific heat conductivity.

Higher efficiencies may be expected only with materials which show a constant Wiedemann-Franz-Lorenz relationship or a relatively small deviation from it. This criterion requires that the average specific resistance ($\rho$) should not be greater than 0.002 ohm cm ($\sigma = 500$) for materials of medium thermoelectric power (around 200-microvolt/°C). For high thermoelectric power values (around 500- to 1000-microvolt/°C, the maximum permissible average specific resistance ($\rho$) is about 0.03 ohm cm ($\sigma = 33$).

The thermoelectric power of most normal metals and alloys is less than 100-microvolt/°C, therefore their calculated efficiencies cannot exceed two to three percent even when operating at a temperature difference of 500 to 900°C. The observed efficiency of the best commercially available thermocouple (Chromel P-constantan) was only 0.9 percent, operating at the highest allowable temperature difference (500°C).

In the medium thermoelectric power range (200- to 300-microvolt/°C) some of the recently developed zinc-antimony alloys (containing small amounts of added metals) forming a thermocouple with constantan, produced an efficiency of 4.8 to 5.7 percent, at the highest allowable temperature difference (400°C). The same zinc-antimony alloy forming a thermocouple with a bismuth-antimony alloy, produced an efficiency of 4.2 percent at a much lower temperature difference (230°C). For these thermocouples the calculated and observed efficiencies showed very good agreement.

A survey of various alloys failed to produce any thermoelectric materials of higher calculated efficiency, with the exception of the tellurium-bismuth alloys and tellurium, with small amounts of some other metals.

Materials of higher thermoelectric power were found to contain Si, Sb, Bi, O, S, Se, Te (groups IV*B*, V*B*, VI*B* of the periodic table). Some of these materials are semi-conductors. The theoretical correlation of the electric conductivity ($\sigma$) and the thermoelectric power ($\theta$) were applied to derive the criteria of high efficiency for this group of materials. A survey of published data failed to reveal suitable materials of high efficiency, with the exception of PbS containing excess lead, which in this form is actually a metallic conductor. Thermocouples made with PbS (with excess lead) and some of the zinc-antimony alloys mentioned above, produced an efficiency of 7 percent, with a possible expectation of 10 percent indicated by the calculation. The discrepancy is due to a junction-resistance.

Some of the semi-conductor material showing high thermoelectric powers are greatly affected by relatively small amounts of impurities. The presence of impurities may increase the conductivity very considerably, while the thermoelectric power is changed only slightly, the heat conductivity remaining practically uninfluenced. Further study of the effects of impurities may improve the properties of some materials showing high thermoelectric power values.

The theoretical calculations indicate that the problem of producing thermoelectric generators of higher efficiency can be solved only by continued search for materials of high thermoelectric power, low specific electric resistance (high electric conductivity) and low specific heat conductivity.

# Cesium Chromate Photo-Tube Pellets

H. A. Liebhafsky and A. F. Winslow
*Research Laboratory, General Electric Company, Schenectady, New York*

(Received September 10, 1947)

The following results have been obtained in an exploratory investigation of the cesium chromate pellets used in the manufacture of photo-tubes: (1) hydrogen evolution or titration can be used to measure the yield of cesium with reasonable precision. Each method has limitations. (2) The theoretical yield could be obtained from cesium chromate-silicon pellets. (3) Within limits, the actual yield increases with the rate of heating; the maximum yield is not highly sensitive to composition in the range investigated. (4) No marked advantage was observed when titanium or zirconium was substituted for silicon as reducing agent. (5) An excess of hydrogen above the theoretical was consistently observed with nickel pellet holders, which points to a reaction of water vapor with reactive nickel formed during the heating and flashing of the pellet. The substitution of the less volatile molybdenum for nickel eliminated this difficulty. An excess of hydrogen was formed also when the reducing agent in the pellets was titanium.

It was suggested for purposes of further study that the complex process occurring when such pellets are induction heated be subdivided into two reactions of elementary silicon: (1) a preliminary exothermic reduction of hexavalent chromium, which initiates (2) a rapid reduction of monovalent cesium. The two reactions may proceed concurrently. This picture explains several observations made in the laboratory or in the factory.

THE function of the photo-tube pellet is to supply the alkali metal required for the light-sensitive surface. Such a pellet is usually made by compressing an intimately mixed powder containing a reducing agent and a compound of the metal, the metal being liberated in the tube by induction heating. Cesium chromate is a good compound for this purpose, and silicon is a good reducing agent; but little is known about the reaction between them.

Manufacturing processes could be considerably simplified if the pellets gave a reproducible yield. At the present time the only way of providing for enough metal is to make sure of an excess, though an excess is objectionable and must be removed in a subsequent bake-out. This investigation was undertaken in order (1) to find a reliable method of measuring the alkali metal produced when a pellet is "flashed," (2) discover under what conditions cesium chromate-silicon pellets give their maximum yield, and what this maximum is, (3) see how other reducing agents compared with silicon in effectiveness. The results given below were obtained before the war forced the work to be suspended.

## EXPERIMENTAL DETAILS

### Materials

Purified cesium chloride from the laboratory stock, made from pollucite ore by Dr. R. W. Moore, was the starting material for the preparation of cesium chromate. The sparingly soluble dichromate was precipitated out of a chloride solution and redissolved in cesium hydroxide electrolytically prepared, acetone finally being added to obtain the finely divided chromate. Chloride, which is objectionable in a chromate photo-tube pellet, was virtually absent from the product, the principal impurity present being sodium in small amount.

The silicon, titanium, and zirconium were commercial materials of good quality. The titanium was a "hydride;" that is, a product of indefinite composition which liberates hydrogen when heated to a low temperature (*ca.* 200°C) in vacuum. The hydrogen thus liberated did not falsify the experimental results since the system was always pumped out very carefully after the flashing of all pellets (see below).

Since all materials were powders, the particle size is an important variable. The silicon, titanium, and cesium chromate passed a 325-mesh sieve. The zirconium passed 100-, but was caught on 200-mesh. The thoroughly mixed pellet mixture containing silicon or titanium was put through 200-mesh; the zirconium mixture passed 100-mesh.

All pellets were prepared by subjecting about 25 mg of mixture to high pressure in a die. Before being used each pellet was weighed to 0.1 mg on an analytical balance.

## Apparatus

The apparatus in Fig. 1 is designed to produce a mirror of alkali metal in high vacuum when a pellet is heated at a pre-determined rate, to make possible the reaction of this mirror with water vapor, and to permit measurement of the hydrogen thus liberated and titration of the alkali hydroxide formed. The operation of the apparatus is obvious and need not be described in detail. The weight of alkali metal and the pressure of hydrogen will be of the order of 10 mg and 100 microns, respectively; all manipulations were planned to give a precision near 1 percent of these quantities.

The rate of heating the pellet determines the "heating interval," which is the time, measured on a stop watch, that elapses between the closing of the induction-heating circuit and the explosive liberation of metal from the pellet to form a mirror on the enclosing bulb. (The metal escapes around the periphery of the pellet holder, which is held together by 3 or 4 spot welds.) The relationship between the setting of the induction heater and the heating interval had to be established in advance of the actual investigation; since this relationship, which will differ for each experimental arrangement, is sensitive to the relative position of induction coil and pellet, care was taken that this position did not vary from one run to the next. This position was so chosen that the periphery of the pellet holder was heated uniformly in the field. Consistent heating intervals were obtained only when the pellet was held in close contact with the metal, which ensured satisfactory heat transfer.

Pellet holders made of nickel had to be discarded because yields greater than 100 percent cesium were consistently obtained from silicon pellets by the hydrogen method (see below) when they were used; presumably the action of water vapor on active nickel formed during the heating period was responsible. This difficulty disappeared when molybdenum was substituted for nickel.

## Evaluation of Yields

Cesium yields were always calculated according to the gas laws from the hydrogen liberated. To corroborate results thus obtained, the cesium hydroxide was occasionally titrated as follows. 5 cc of standardized 0.02 *N* perchloric acid was pipetted into the reaction bulb *H* (Fig. 1) at the end of the run, and the sides of the bulb were washed down with a little distilled water. After carbon dioxide had been expelled from the acid solution by boiling, the titration was carried out with 0.02 *N* sodium hydroxide containing methyl red. The acid was added to the bulb as soon as possible in order to minimize attack of the glass by cesium hydroxide.

Results from the hydrogen and from the titration method were calculated as percent yield for the pellet, whose weight and initial composition were known. A summary of all pairs of results obtained is given by Fig. 2, those in which the heating intervals were below 4 sec. being distinguished from the others. Inspection of Fig. 2 shows (1) that, three erratic points excepted, the agreement with the 45° line is generally satisfactory, (2) that for the low heating intervals the yield by the hydrogen method tends to exceed that obtained by titration. This tendency probably has the following cause. As the heating interval is decreased, the liberation of cesium becomes more and more explosive, with the result that some metal escapes the reaction bulb.

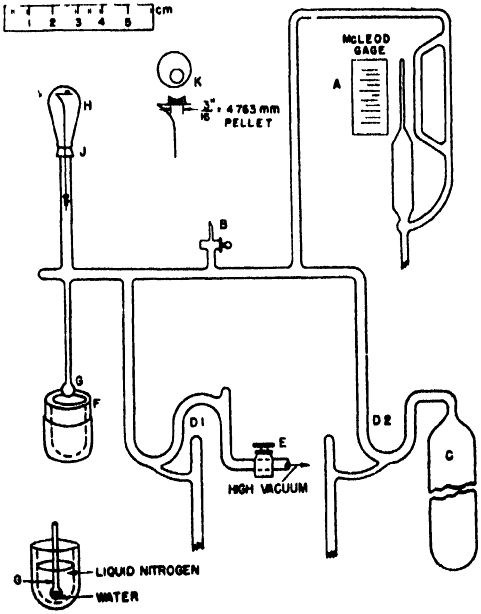

Fig. 1. Apparatus for studying activity of photo-tube pellets.

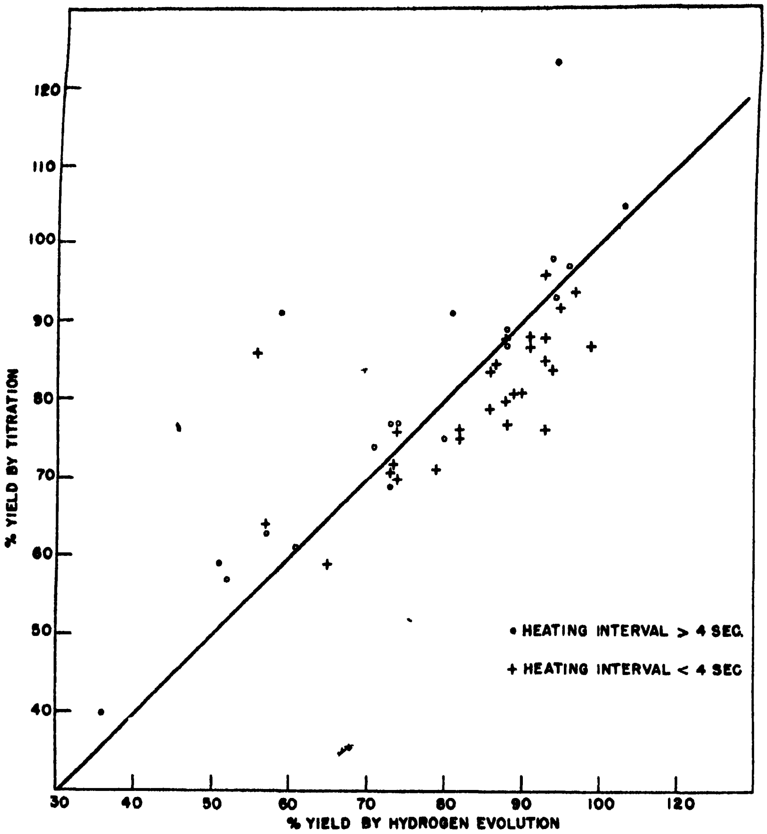

FIG. 2. Comparison of cesium yields as measured by hydrogen evolution and by titration.

Such metal would liberate hydrogen, but the corresponding cesium hydroxide would not be titrated. (Redesigning the apparatus might minimize this difficulty.) On this basis, we consider the hydrogen method to be the more reliable, provided there is no complicating liberation of excess hydrogen.

## EXPERIMENTAL RESULTS

### Silicon

The yields obtained by the hydrogen method on silicon-cesium chromate pellets of five compositions are shown in Fig. 3. The lowest abscissa plotted is 2 sec., because that is the heating interval corresponding to the maximum heating rate of which our experimental arrangement was capable. (In one instance a pellet flashed at 1 sec. and gave a 57 percent yield, as is recorded in Fig. 3. This result could not be duplicated.) It is noteworthy that the shortest heating interval becomes longer as the ratio $Si/Cs_2CrO_4$ increases; this is clear in spite of the scattering of the results, for the shortest interval at each composition was obtained with the maximum heating rate.

Figure 3 supports the following conclusions: (1) The yields fluctuate appreciably so that many measurements (more than in Fig. 3) are needed to establish all the characteristics of these pellets. (2) The theoretical yield, 100 percent, can be realized or very closely approached. (3) The yields tend to increase as the heating interval decreases. (4) The maximum yield is not highly sensitive to pellet composition in the range investigated. (If the heating rate could be increased, the yield for compositions such as $Si/Cs_2CrO_4 = 4$ would probably increase also.)

### Titanium

The striking feature of the titanium results is how frequently the calculated yields exceed 100 percent. This excess of hydrogen cannot be derived from titanium hydride, for, as has already been mentioned, the system was always thoroughly pumped out after each pellet was flashed. The most likely source of this hydrogen is the reaction of water vapor with highly reactive material, either titanium or one of its compounds, produced during the heating interval

It will be remembered that a similar evolution of excess hydrogen was observed when nickel pellet holders were used. There the reacting material was probably evaporated or sputtered metal, since the pellet holder is not likely to be involved in a chemical reaction. With titanium, however, the possibility of a lower valent compound that is a powerful reducing agent must be considered, especially since titanium is more likely to form such compounds than is silicon or zirconium.

Because of the formation of this excess hydrogen, which may have occurred no matter what the yield, there is little point in discussing the titanium results. They appear to be more erratic than those obtained with silicon, but that seems to be the principal difference. Titration ought to supplement the hydrogen method in further work with titanium; in any case, there seems to be no reason for replacing silicon by titanium in photo-tube pellets.

## Zirconium

Five experiments with $Zr/Cs_2CrO_4 = 1$ gave the following results: 82 percent at 5.0 sec., 81 per-

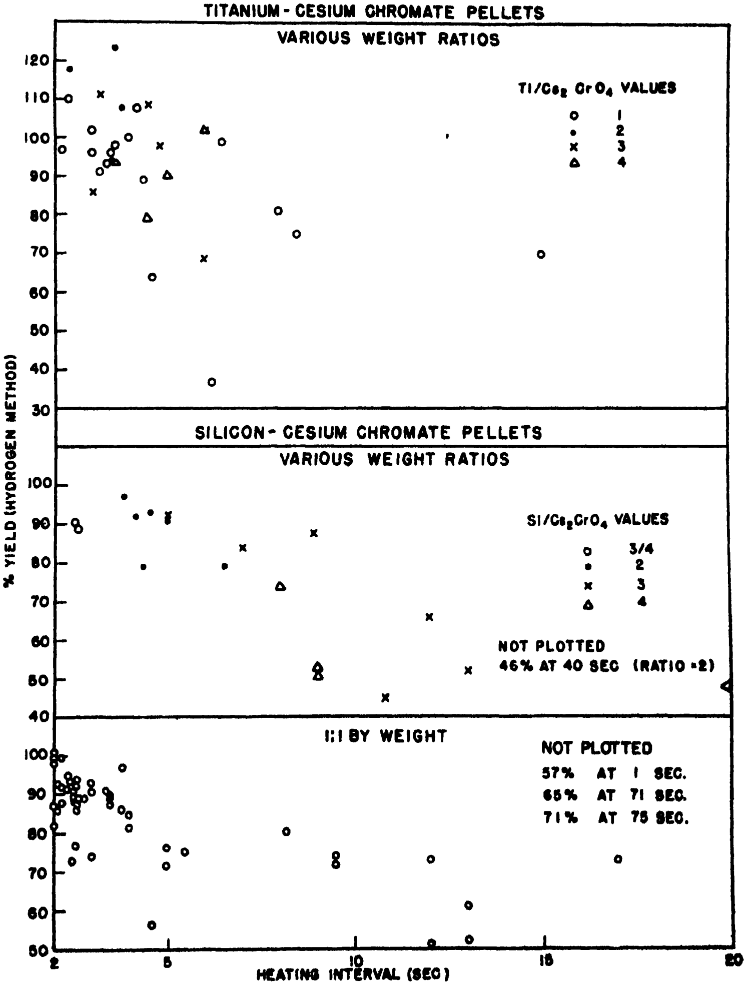

FIG. 3. Cesium yields for various compositions and various heating intervals as measured by hydrogen evolution.[1]

cent at 4.6 sec., 75 percent at 4.2 sec., 68 percent at 4.8 sec. Under our conditions, zirconium probably is a less effective reducing agent than silicon.[1]

## DISCUSSION

The present investigation is only an approach to the problem of cesium chromate photo-tube pellets, but it has shown how their yields can be measured and revealed several of their more important characteristics. The stoichiometry involved needs to be established by examining pellet residues; meanwhile, however, the equation

$$4Cs_2CrO_4+5Si=2Cr_2O_3+8Cs+5SiO_2 \quad (1)$$

may serve as a basis for a brief discussion intended primarily to point the way to future work. In reaction 1, 1 gram of silicon is equivalent to 11 grams of cesium chromate; hence, every silicon pellet investigated contained the reducing agent in large stoichiometric excess.

The heating interval may be subdivided into a relatively long initial heating period, and a short final period in which the cesium is liberated almost explosively. With the heating rate at its maximum, the heating interval lengthens as the proportion of the chromate decreases (Fig. 3). This indicates that the induction heating is being supplemented by an exothermic reaction, limited by the chromate present but evolving no cesium. For this reaction, we shall naively write

$$4Cs_2CrO_4+3Si=2Cr_2O_3+3SiO_2+4Cs_2O. \quad (2)$$

Cesium oxide would, of course, never exist free in contact with the two other oxides. But reaction 2 does emphasize that the action of hexavalent chromium on silicon supplies the heat that facilitates cesium liberation; this point of view is logical also because monovalent cesium, the other oxidizing agent present, is bound to be far the less reactive toward silicon.

For the cesium liberation we then write

$$4Cs_2O+2Si=2SiO_2+8Cs. \quad (3)$$

Actually, each silicon grain probably becomes covered, during the initial heating period, by a matrix containing the three resultants of reaction 2; cesium liberation occurs when the temperature is high enough to make possible the reaction of this matrix with silicon.

Reaction 2, if it proceeds too slowly, can give a matrix that blocks reaction 3. At least, this seems the best explanation for these observations: (1) Cesium yields tend to decrease as the heating interval increases (Fig. 3). (2) It has been observed in the factory that pellets stored near 100°C for long periods tend to give erratic yields. (3) Pellets containing dichromate, which would form more matrix since it contains more hexavalent chromium than does chromate, are more erratic than those made with chromate.

---

## Remarks on Some Recently Developed Devices for Summing Fourier Series for Crystal Structure Analysis

C. L. CHRIST
*Stamford Research Laboratories, American Cyanamid Company, Stamford, Connecticut*
August 6, 1947

THERE appeared in a recent issue of this journal a paper entitled, "An electronic computer for x-ray crystal structure analysis," by R. Pepinsky.[1] The author states that the method is based upon Huggins' modification[2,3] of Bragg's earlier method[4] for photographically summing Fourier series. In the Huggins method the necessary sinusoidal distribution of bands for each Fourier term is referred to a square cell in order that the masks prepared may be used for the study of any crystal. Thus the Huggins method differs from the Bragg method in that a set of masks once prepared may be used repeatedly. With the present electronic computer the bands representing each term are oriented and spaced according to the dictates of the actual shape of the unit cell of the crystal under study.[1] This method seems, therefore, to be more closely related to the original Bragg method than to the Huggins modification.

In the electronic computer paper it is further stated[1] that the sand deposition method of McLachlan and Champaygne for summing Fourier series[5] does not permit the computation of projections having various axial ratios and angles. The fact that the "sand machine" gives projections having the same shape as that of the unit cell being studied, with regard to both the ratios of the edges of the cell and the inter-edge angle, is explicitly stated in the abstract preceeding the body of the publication cited[5] and is, of course, implicit in the detailed description of the theory of the method. In this connection it is interesting to compare the electron density projection of hexamethyl benzene given in the paper of Brockway and Robertson[6] with that obtained using the same data, with the McLachlan-Champaygne method,[5] and with the Huggins method.[3] Such a comparison shows that the use of the square lattice necessary to the Huggins method introduces distortion of the projected molecule over and above that introduced by the non-parallelness of the plane of the molecule and the plane of projection, as was pointed out by Huggins.[3] In contrast, the sand deposition method gives a projected molecule essentially the same as that obtained by Brockway and Robertson.

All three of the summation devices discussed above are based upon an equation of the type:[4]

$$\rho(x, y)' = |F_{hko}| + \sum_{h=-\infty}^{\infty} \sum_{k=-\infty}^{\infty} |F_{hko}| \cos[2\pi(hx+ky) - \alpha_{hko}]. \quad (1)$$

Any term $(S_{xy})_{hko}$ of this series, involving the phase angle $\alpha_{hko}$, may be represented by the sinusoidial band distribution

$$(S_{xy})_{hko} = |F_{hko}| + |F_{hko}| \cos 2\pi(hx+ky) \quad (2)$$

displaced in the positive direction along the normal to the wave crests by the linear amount $\delta_{hko}$, which may be represented by the equation

$$\delta_{hko} = \frac{\alpha_{hko}\lambda_{hko}}{360}. \quad (3)$$

Here $\lambda_{hko}$ is the distance between wave crests, and $\alpha_{hko}$ is expressed in degrees. The electronic computer, at present, is confined to projections having a center of symmetry at the origin,[1] i.e., $\alpha_{hko}$ has the value 0 or 180°. In the case of the sand deposition method $\alpha_{hko}$ may have any value whatsoever,[5] and since the true unit cell is projected, $\lambda_{hko}$ is precisely the interplanar spacing $d_{hko}$. There seems to be no reason why the Huggins method cannot also be used for non-centrosymmetric projections, since the use of Eq. (3) is compatible with the method. The desired result may be obtained, for example, in the case of non-centrosymmetric projections, by shifting the photographic film or paper on which successive exposures for each term $(S_{xy})_{hko}$ are being made[3] before each exposure by the amount $\delta_{hko}$, according to the value of $\alpha_{hko}$. It follows that for centrosymmetric cases, if this method of shift is used, only positive masks are necessary since their negative counterparts are obtained, in projection, by a shift of $\delta_{hko} = \lambda_{hko}/2$. In the case of the Huggins method it is necessary to remember that $\lambda_{hko}$ is not, in general, equal to $d_{hko}$.

# New Books

## When the Earth Quakes

By James B. Macelwane, S.J., Pp. 283, Figs. 251, 15½×23 cm. The Bruce Publishing Company, Milwaukee, 1947. Price $5.00.

This book presents in non-technical language an introduction to seismology in all its phases. This is a popular treatment of an extensive field. Neverthless the book can command the interest of the technically trained reader.

Eleven chapters are devoted to natural earthquakes. Among the subjects discussed are: kinds of earthquakes, mechanisms of earthquakes, immediate and ultimate causes of earthquakes, isostasy, earthquake prediction, field studies, instrumental studies of earthquakes, location of epicenters, sea quakes, seismic sea waves, and the principles of seismographs. Twenty modern earthquakes are described in considerable detail. Each description is accompanied by a map of the epicentral region and there are many good reproductions of photographs showing the effects of earthquakes. There is reproduced also an excellent collection of photographs of seismographs. Older types as well as the most recently developed instruments are represented.

The remaining six chapters present several less-publicized branches of seismology.

Two chapters outline the purpose, methods, and instruments of engineering seismology which is the study of buildings and structures from the point of view of resistance to damage by earthquakes. There are excellent descriptions and illustrations of accelerographs, strong motion seismographs, and vibration meters. Also explained and illustrated are the shaking machines used to generate vibrations in the ground and in buildings or other structures.

One chapter deals with seismological engineering—a term used to cover the study of industrial problems arising from man-made disturbances, such as quarry blasts or machinery vibrations, and the laboratory study of those rock properties involved in natural or artificial earthquakes.

The author describes rock bursts which constitute a serious safety problem in underground workings in some areas. He explains the rock properties which make bursts possible and shows how the seismological attack on the problem has achieved at least partial success.

In another chapter is presented an easily understood explanation of the seismic refraction and reflection methods of mapping buried structures. The machanism of petroleum accumulation is outlined and several illustrations of instruments and equipment as well as good reproductions of commercial field records.

The final chapter, entitled "Microseisms and storms at sea", is based upon recent work. The nature of the relation between large microseisms and storms at sea has been established for only a few years. The author decribes the first application of this newly acquired knowledge. During the latter part of World War II special seismograph stations were set up in the Carribean area to aid in the detection and location of storm centers at sea.

Appendix A discusses briefly the geological forces at work on the earth and explains many geological terms. There is an extensive bibliography to which references are made in the text and a glossary of terms which may be new to the average reader.

This well written book by a famous authority in seismology gives an interesting informative account of earthquake study. In addition, it does a good service for the literature by introducing aspects of modern seismology which are less familiar to workers in other fields.

The author is Dean of the Institute of Geophysical Technology of St. Louis University.

## Mechanism of Reactions at Carbon-Carbon Double Bonds

By Charles C. Price. Pp. 120, 16×23 cm. Interscience Publishers, Inc., New York., 1946. Price $2.50.

This book is based on a series of lectures presented by the author at the Polytechnic Institute of Brooklyn, and is the first volume of a series of *Lectures on Progress in Chemistry* edited by H. Mark. It is clearly pointed out in the introduction and preface that the book is not intended to be a complete detailed review of all published work on the subject, but rather a brief treatment of the pertinent information together with the author's personal interpretation of the material.

The book deals ultimately with the subject of polymerization and the various mechanisms involved. However, more than half of the book is devoted to background material on structure and reactions of unsaturated compounds in general. Modern concepts of electronic structure are presented in the first chapter together with their relation to reactivity, orientation, and reaction mechanisms. The concept of a pulsating resonant mesomerism is compared to the fixed hybrid theory of resonance, and it is apparent that the author is somewhat skeptical of certain aspects of the resonance concept as applied to organic molecules. Evidence is presented to show that an electrostatic approach may be more fundamental than the resonance hypothesis in explaining many reactions such as the orientation of substitution in benzene derivatives in which the substituent already present is one of those which do not appear to be capable of mesomeric interaction with the unsaturation of an aromatic ring or a double bond.

The second and third chapters deal with the mechanisms of ionic and free radical reactions, respectively, at double bonds. Aromatic as well as olefinic reactions are included in both chapters.

The last four chapters deal with the mechanisms involved in the various types of polymerization. The free radical mechanism of addition polymerization is discussed in Chapter 4; and the various factors involved in copolymerization are presented in Chapter 5. The author's theory that the polarity of the double bond is an important determining factor in copolymerization, is of particular interest.

Polymerization in emulsion and in suspension are treated in Chapter 6, with the function and fate of the emulsifying agent receiving particular attention. Chapter 7 concludes the book with a discussion of the polar mechanism of polymerization, and the catalysts which promote this type of reaction.

The book is well written and fully illustrated throughout with specific formulae and reactions. There are a few minor errors in the printing such as the apparent omission of certain substituent groups in formulae on pages 86 and 102. The personal manner of presentation lends interest to the book, and the author's frank appraisal of various theories and mechanisms contributes much to its value. However, the reader should keep in mind that other authorities may not be in complete accord with all of the author's interpretations. The book should be of great interest to all who are concerned with the modern concepts of organic chemistry in general, and will be of particular value to those who are concerned either with high polymer chemistry or with the general question of reaction mechanisms involving unsaturation in both aliphatic and aromatic compounds.

## Cosmic Radiation

Edited by W. Heisenberg. English translation by T. H. Johnson. Pp. 192, 16×24½ cm. Dover Publications, New York., 1946. Price $3.50.

We may welcome the advent of any opus edited by and contributed to by so competent a physicist as Heisenberg. Because the subject of the cosmic radiation has so few adequate, modern treatises, this one is doubly welcome. The book has come at a time to help meet the fast-growing need for good compendia in this field.

The book represents the views of a number of authors, and is a condensation of a series of lectures by these persons. Each chapter is written by a different author, the majority of whom are well-known investigators in this field. Hence the book is certainly authoritative.

The book starts with a review of the present state of cosmic-ray knowledge by Heisenberg. Next, the soft component is considered, with chapters on cascade theory by Heisenberg and on large showers by Moliere. Turning to the hard component, the bulk of the book is devoted to various phases of mesotron studies. Klemm discusses the production of mesotrons, Klemm and Heisenberg the showers with penetrating particles, Voltz the absorption of mesotrons, and Weiszacker the excitation of bursts by mesotrons. The decay is next treated by Heisenberg, the decay electrons by Bopp, and the theory of mesotrons by Weiszacker. Next follow chapters on the mesotron theory of deuterons by Flugge and the theory of explosive showers by Heisenberg. The final three chapters deal with nuclear disruptions as discussed by Bagge, the production and distribution of neutrons as treated by Flugge, and the geomagnetic effects which are summarized by Meixner. At the end a rather extensive bibliography is appended.

As would be inevitable in a work of this sort, the chapters vary somewhat in the degree of sophistication expected of the reader. Naturally, each author writes of his own specialty from his own point of view, and with varying mathematical complexity, the theoretical chapters being the most complex. The style of each author varies, but the skillful editing of the volume is evident.

The book is clearly not intended as a text, and is written primarily for the specialist in the field. It is not suitable for beginners. However, every graduate student contemplating a thesis in the subject should be thoroughly familiar with the contents. Further, since it is precisely cosmic rays themselves which provide us with our only source particles of energies higher than can be produced in man-made accelerators, the entire subject of ultra high energy physics is based on a study of cosmic-ray phenomena. Hence the book will be of value to all those interested in this rapidly expanding field. The subject is presented on the level of articles in the Reviews of Modern Physics. It will be of value to those in allied fields who wish to inform themselves about current ideas on the subject. The publication will constitute a desirable addition to any physicist's bookshelf.

*New York University*

## Modern Development of Chemotherapy

By E. Havinga, H. W. Julius, H. Veldstra, and K. C. Winkler. Pp. 175+xi, Figs. 31. Elsevier Publishing Company, Inc., Amsterdam, 1946. Price $3.50.

This volume is number four in a series of more than twenty monographs intended to record the advances made in various branches of scientific work in Holland during World War II. We cannot but be amazed at the nobility of spirit which showed itself by the perseverance in difficult activities in occupied countries during the war. This nobility is now shown again in the unique mixture of pride and generosity with which those activities are revealed to the rest of the world.

This little book summarizes the work of several Dutch laboratories up to about May 1945. In it are detailed numerous researches having to do primarily with sulfonamides, and to a very small extent with antibiotic chemotherapeutic agents. It is regrettable that this brave record can hardly be assured a permanent place in the scientific literature. Such a monograph is inevitably occupied with details too near the uncertain boundaries of knowledge to have a timeless factual value. This one is on the other hand, so limited in geographical coverage and (understandably enough) was long enough delayed in preparation that it is hardly a review of modern trends or recent advances. Especially is this true in the case of a field such as chemotherapy which is developing so rapidly all over the world.

The first and longest section deals with bacteriological investigations by Julius and Winkler on the mode of action of sulfonamides. This work is a well-conceived straightforward approach which has certainly foreshadowed many features of the theory that our more recent knowledge (particularly of the folic acids) has made more secure. Much of this approach is based upon bacterial growth curves which were probably determined more reliably than in almost any similar study. Modifying the environments of the bacteria gave the opportunity to study the intimate effects of various inhibitors and activators. Wood's *para*-aminobenzoic acid displacement theory is re-examined with an admirable detachment. The authors insist that an antagonistic displacement of *para*-aminobenzoic acid by sulfonamide has never been demonstrated, only the reverse antagonism being known. The net result is that sulfonamides are viewed as interfering with a mechanism (involving in some way *para*-aminobenzoic acid) which leads to the synthesis of a peptone-like substance.

Here and elsewhere in the book, the authors discuss certain of the findings of workers elsewhere that were available to them through abstracts or otherwise. This is true even though in the preface it is stated that "foreign work will be referred to only in so far as it has a direct bearing on Dutch research work."

A section describing physico-chemical investigations on the sulfonamides by Havinga and Veldstra does not materially increase our knowledge of the mode of action of these substances. Certain studies were made of the titration curves, light absorption spectra, polarographic behavior, and the properties of surface films. The impression is given that these approaches were chiefly exploratory, based upon plausible but casual hypotheses. An interesting part of this section is the attempt to estimate the collision frequency of *para*-aminobenzoic acid or sulfonamide molecules with receptor spots upon a bacterial cell. If it is assumed that the former substance is required only at certain moments of the division cycle for normal growth to occur, then it may be easier to understand why the antagonists must be present in much higher concentration if they are to prevent growth.

The results of the testing of approximately seventy-five synthetic compounds related to sulfanilamide are given. There is a brief summary of clinical and animal testing of a few of these substances. Finally, the mold antibiotic "expansine" is described, a substance that appears to be identical with clavacin (and patulin) discovered elsewhere at about the same time.

This volume makes available in very satisfactory English translation a summary of brave and independent investigations.

Rollin D. Hotchkiss
*Rockefeller Institute*

## High Vacuum Technique

By J. Yarwood. Second Edition. 15½×24 cm. John Wiley and Sons, Inc., New York, 1945. Price $2.75.

From the authors intention, which, as stated in the preface, is "to describe important industrial processes hitherto discussed only in scientific periodicals," it is difficult to discern to whom he addresses this addition to the "know-how" literature.

The author's intention "to introduce the latest developments . . . with special emphasis on the most recent work," is unfulfilled—the author does not, for example, discuss the palladium-window ion gauge for leak hunting, the silicone-diffusion pump oils, or Vycore.

There are instances where the author contributes but little to the subject he treats—for example, on page 82, after stating that silver oxidation can be followed by surface color changes the exposition concludes with: "The degree of oxidation is found only by experience based on previous experimental work . . . ."

The judgment of your reviewer does not always concur with that of the author on the value of the apparatus or of the procedures described and evaluated. It would be helpful to know which procedures the author knows first hand and intimately, and which he is merely re-writing, or reporting.

The author occasionally lets himself speak in the vernacular as: "The gun must be vacuum-stoved before mounting in the tube." In a book such as this the use of the vernacular seldom enlightens those who understand it and is unintelligible to those one would teach.

The chapter on the properties of materials does contribute to the author's stated intention, "to bring together in one volume the diverse facts regarding the relevant properties and uses of materials encountered in all types of vacuum work." However, his treatment of some materials, like copper, is certainly not up-to-date from the high vacuum point of view.

It is to be expected that engineers and experimental physicists will get substantial help and provocative suggestions from Yarwood's work. The references to the literature will be of value to some; several procedures are described which will be novel to others; and the subject matter is more modern than the "classics", to which the author refers.

John D. Strong

## Electrical Transmission in Steady State

By Paul J. Selgin. Pp. 427, Figs. 100, 14½×22 cm. McGraw-Hill Book Company, Inc., New York, 1946. Price $5.00.

This book, like many others recently published, is the outgrowth of notes developed in connection with courses taught for war-training purposes. For this reason the manner of presentation of the subject matter, as well as its selection, is not entirely what one would desire for ordinary undergraduate instruction in an electrical communications curriculum on a peacetime basis. The book is essentially one on the subject of transmission lines for use at high and ultra high frequencies, the first 332 pages out of a total of 416 being devoted to this topic. Following this material there is a chapter on inductively coupled circuits, a ten-page chapter on capacitive coupling, and two chapters, totalling 34 pages, on high frequency vacuum-tube amplifiers.

The first two chapters comprise a condensed review of some basic lumped-constant circuit principles, including such topics as matching and optimizing conditions for power transfer at junctions, transmission and insertion loss, reciprocity, Thévenin's and Norton's theorems, image parameters, etc. The steady-state behavior of transmission lines is then dealt with through considering the limit approached by an increasing number of smaller and smaller lumped networks in cascade, and a detailed (rather involved) discussion is given of the frequency behavior of the attenuation and phase functions. At this point and throughout the remainder of the book, one has a very definite conviction that a student having no previous acquaintance with this subject would find the going very rugged indeed, unless considerable additional guidance were available from an experienced instructor.

The input impedance of the line is dealt with through a discussion of the mapping properties of the hyperbolic tangent function, followed by a consideration of the impedance transformations of analogous lumped networks based upon the circle properties of simple inversion. The bi-polar line chart is then introduced and applied to various conventional impedance-transformation problems, including the quarter-wave line as an impedance transformer. This discussion is generalized to a consideration of cascades of quarter-wave lines used to secure a more frequency insensitive impedance transformation, and an "optimum" design of such a transformer is given which, after several pages of involved algebra, finishes with the statement of an end result, the proof of which "although not particularly difficult, is beyond the scope of the present discussion" (footnote, page 203 . Single and double stub tuners are discussed with the help of the Smith Chart (not so called), and detailed treatment is given of the frequency sensitivity of such tuners, taking into account the effect of incidental dissipation and expressing these effects in terms of the "$Q$" of the system.

Chapter XI then turns to a consideration of a review of static field theory, a discussion that in the next chapter is extended to dynamic fields and Maxwell's equations. This material admittedly is too condensed to be helpful to the beginner, while for the reader with sufficient background to follow the argument, it fails to provide a picture that is compact and effective in presenting the essential relationships clearly and completely. While a reasonably good job is done here for readers who at this stage do not expect to acquire a proficient knowledge of these tools, there is left much room for improvement.

After some discussion concerning the relationship of lumped circuit theory to field theory, the author considers the propagation of plane waves and derives the uniform line equations from the field equations, extending this discussion to the consideration of the exponential tapered line and the exponential stub line.

The subject of inductively coupled, lumped tuned circuits given in the following chapter (XIV), and introduced through a consideration of self- and mutual inductances and the simple transformer, is dealt with in a manner as involved as any that this reviewer has seen to date (the average student must surely despair at this point). The succeeding short chapter on capacitive coupling is given primarily as a means for dealing with the inter-electrode capacitances of vacuum tubes, of which some basic principles are discussed in the concluding brief pages of this book.

A feature on which the author is to be complimented is the inclusion throughout the book of illustrative numerical examples fully worked out.

In view of some of the above rather harshly critical comments it is only fair to state in conclusion that for the purpose for which this material was originally intended, the accomplishment of the author ranks on the whole with the better text material of a similar nature. Now that war-training programs are over, however, it is to be hoped that more attention in textbook writing will be given to the needs of students following a more orderly and progressively stimulating program of education in basic circuit theory and closely related subjects.

# New Booklets

Fischer and Porter Company, Hatboro, Pennsylvania, has issued a 32-page booklet entitled *A New Era in Liquid and Gas Flow Measurement*, which describes the advantages of the flowrator meter for flow rate measurement. Address request to Department 6F-F of the company.

Burrell Technical Supply Company, 1936 Fifth Avenue, Pittsburgh 19, Pennsylvania, has published a bulletin on its *Junior Spectrophotometer--The Successor to Colorimeters*. 8 pages, free on request.

The Daven Company, 191 Central Avenue, Newark 4, New Jersey, announces the publication of a new bulletin of technical data, presenting information widely used in the design of sound equipment. 4 pages. Free on request. Write on company letterhead.

Tin Research Institute, Fraser Road, Greenford, Middlesex, England, issues at regular intervals (because of present conditions) a review entitled *Tin and Its Uses*. The issue of July 1947 contains 16 pages and has numerous photographs in color. Interested readers are invited to address a request to the Publications Department of the Institute, stating that they wish to receive, free of charge, any publications of the Tin Research Institute dealing with given subjects or products (naming them), and mentioning their own business connections and titles. The July 1947 issue may be obtained directly from the Battelle Memorial Institute, 505 King Avenue, Columbus, Ohio.

The Gaertner Scientific Corporation, 1201 Wrightwood Avenue, Chicago 14, Illinois, announces two new bulletins: 140-74, entitled *Dilatation Interferometer*, and an unnumbered booklet entitled *Survey of Precision Instruments*, which is intended to serve as a guide to the company's products. Both bulletins are eight pages in length and are free on request.

*Interchemical Review* for Summer 1947, published by the Interchemical Corporation, 432 West 45th Street, New York 19, New York, features "Acids, bases, salts—pH," by C. Ross Bloomquist, and "Printing inks for postage stamps," by Milton Zucker. 30 pages.

Eberbach and Son Company, Ann Arbor, Michigan, has published the fall issue of its house magazine, the *Announcer of Scientific Equipment*. The feature article is entitled "Functional design of laboratory glassware". Free on request.

The National Bureau of Standards has announced the publication of the following bulletins in the physics field. All are available at 10 cents per copy from the Superintendent of Documents, Government Printing Office, Washington 25, D. C.

RP 1807—*Solution of Problem of Producing Uniform Abrasion and Its Application to the Testing of Textiles*" by Herbert F. Schiefer.
RP 1808—*Chromaticities of Lovibond Glasses* by Geraldine W. Haupt and Florence L. Douglas.
RP 1813—*Resistance-Temperature Relation and Thermoelectric Properties of Uranium* by Andrew I. Dahl and Milton S. Van Dusen.
RP 1814—*Infared Absorption Spectrum of Carbon Disulfide* by Earle K. Plyler and Curtis J. Humphreys.

North American Philips Company, Inc., 100 East 42nd Street, New York 17, New York, has issued a 4-page folder entitled *X-Ray Diffraction Camera for Microtechniques.* The company states that it should be of value to those actively engaged in fiber research. Free on request.

The *RCA Review* Department of RCA Laboratories Division, Princeton, New Jersey, has published the first volume of its new *Engineering Book Series*, entitled *Patent Notes for Engineers.* Copies may be obtained from *RCA Review* at $2.50 per copy for the permanent clothbound edition (plus 20 cents per copy postage if mailing address is outside the United States). The book was written by the director of the company's patent department.

# Here and There

### New Appointments

Bruce S. Old has been appointed consultant to the Atomic Energy Commission, Division of Research, in the capacity of chief metallurgist. He will continue his present work with Arthur D. Little, Inc., on a part-time basis. Dr. Old will assist in organizing the work of the Commission in the metallurgical field.

Irving A. Denison has been named Chief of the Underground Corrosion Section of the National Bureau of Standards.

Bowen C. Dees (until recently an Assistant Professor of Physics at Rensselaer Polytechnic Institute) has accepted a position as physicist with the Economic and Scientific Section, under the Supreme Commander for the Allied Powers in Tokyo. He will survey and advise concerning the physical research being conducted in the university and commercial laboratories in Japan.

Ernest R. Hanson has joined the staff of Foster D. Snell, Inc., to direct research and development in the field of plastics and rubber.

### Necrology

Dr. Selig Hecht, Professor of Biophysics at Columbia University, died in New York on September 18. A distinguished authority in the field of vision, Dr. Hecht had been an Associate Editor of the Journal of Applied Physics since 1943.

### Awards

Warren A. Marrison, a member of the technical staff of Bell Telephone Laboratories, has been awarded the British Horological Institute's gold medal for 1947 in recognition of pioneer researches in the development of the quartz crystal clock, which has become the most accurate timekeeper in the world.

A. A. Knowlton, veteran physics professor at Reed College, Portland, Oregon, was recently voted a special award of $1,000 for distinguished teaching by directors of Research Corporation. The award is unique in that Dr. Knowlton, now in his thirty-third year at Reed, may spend it in any way he wishes. It was based on the extraordinary achievement of Dr. Knowlton's graduates. Specifically, the award stems from a recent study in the American Journal of Physics which showed that of all physicists granted Ph.D. degrees by American universities between 1936 and 1945, a disproportionate number had done their undergraduate work at one of two small colleges—Reed, and North Central College, Naperville, Illinois. (A similar award has been voted to Dr. Clifford N. Wall, formerly of North Central.)

### Lincoln Arc Welding Foundation Award and Scholarship Program

The James F. Lincoln Arc Welding Foundation, Cleveland 1, Ohio, has issued a brochure outlining the continuing features of its ten-year award and scholarship program designed to help develop the arc welding industry. Under the award plan, engineering students of various colleges will submit papers on arc welded design. Under the scholarship plan, scholarships will be allocated to the schools in which the three highest award winners under the award program are registered. Awards will total $5,000 and scholarships, $1,750. Rules for the 1947-1948 competition may be obtained by addressing the Secretary of the Foundation at Cleveland 1, Ohio.

### Research Corporation Reports on Grants

Research Corporation, which in late 1945 established the Frederick Gardner Cottrell Fund for grants in aid of postwar science, has announced that in the following year more than 100 grants were approved, totaling about $430,000. The grantee institutions are located in about thirty states, Alaska, and the District of Columbia. The awards were made largely to aid younger men just returned to academic research from wartime occupations.

### Conference on the Administration of Research

A conference on the administration of research was held at The Pennsylvania State College October 6 and 7, 1947. It was sponsored by the School of Engineering of the College. Two hundred people registered, representing laboratories, both large and small, managed by industry, educational institutions, and governmental agencies. Proceedings of the conference will be published as soon as possible, at a price of $3. Persons who wish to have a copy and who did not have an opportunity to ask for it at the conference may order from Professor Kenneth L. Holderman, The Pennsylvania State College, State College, Pennsylvania.

### Pittsburgh Physical Society Officers

The Physical Society of Pittsburgh has elected the following officers for the year 1947–1948: *President*, Dr. Frank Morgan, Gulf Research and Development Corporation; *Vice President*, Dr. E. Stickley, Pittsburgh Plate Glass Company; *Secretary-Treasurer*, Dr. F. A. Schwertz, Mellon Institute.

### Bureau of Standards Establishes Atomic Physics Division

The National Bureau of Standards has formed a Division of Atomic Physics in which the main Bureau activities relating to atomic and molecular physics have been grouped together. The functions of the new division are the promotion of fundamental fact finding research and the precise determination of important fundamental standards in the field of atomic physics. Six sections make up the new division: spectroscopy, electronics, mass spectrometry, radioactivity, x-rays, and atomic physics. Dr. E. U. Condon, Director of the Bureau of Standards, has assumed charge of the new division, and Dr. Robert D. Huntoon has been named assistant chief.

### Conference on the Use of Radioactive Isotopes in Agricultural Research

The Alabama Polytechnic Institute, in cooperation with the Oak Ridge Institute of Nuclear Studies, sponsored a three-day conference on the Use of Radioactive Isotopes in Agricultural Research at Auburn, Alabama, December 18–20, 1947. The attendance, through special invitations, consisted of representative scientists largely from the southeastern States.

### Lalor Foundation Fellowship Program

The Lalor Foundation fellowship program at the Marine Biological Laboratory, inaugurated in 1947, will continue in 1948. Postdoctoral summer fellowships in the fields of biophysics, biochemistry, and physiological chemistry will be available. The fellowships are designed primarily to aid promising young investigators who can make maximum use of the facilities and opportunities provided at the Marine Biological Laboratory. In addition to laboratory facilities, the grants are intended to cover approximately the living expenses of the investigators at Woods Hole and necessary traveling expenses to and from Woods Hole. The committee administering the fellowships consists of Drs. Eric Ball, Kenneth Cole, Charles Packard, A. K. Parpart, and C. W. Metz (Chairman). Inquiries and applications should be addressed to the Director of the Marine Biological Laboratory, Woods Hole, Massachusetts. The applications should be received by December 31, 1947, but will be considered after this date.

### Calendar of Meetings

**December, 1947**

29–31 American Physical Society (and its Division of High-Polymer Physics), American Association of Physics Teachers, *and* the American Association for the Advancement of Science, Chicago, Illinois

**January, 1948**

2– 3 American Physical Society Los Angeles, California
21–23 American Society of Civil Engineers, New York, New York
29–31 American Physical Society, New York, New York

**March**

1– 5 American Society for Testing Materials (Spring Meeting), Washington, D. C.
22–25 Institute of Radio Engineers, New York, New York

**April**

19–23 American Chemical Society, Chicago, Illinois
22–24 Acoustical Society of America, Washington, D. C.
